Attention deficit hyperactivity disorder

Diagnosis and management of ADHD in children, young people and adults

National Clinical Practice Guideline Number X

National Collaborating Centre for Mental Health Commissioned by the National Institute for Health and Clinical Excellence
Guideline Development Group members

Professor Eric Taylor (Chair, Guideline Development Group)
Head of Department of Child and Adolescent Psychiatry, Institute of Psychiatry, London

Dr Tim Kendall (Facilitator, Guideline Development Group)
Joint Director, The National Collaborating Centre for Mental Health; Deputy Director, Royal College of Psychiatrists Research and Training Unit; Consultant Psychiatrist and Medical Director, Sheffield Care Trust

Professor Philip Asherson
Professor of Molecular Psychiatry and Honorary Consultant Psychiatrist, MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, London

Mr Simon Bailey (2006-2007)
Service User Representative

Dr Karen Bretherton
Consultant Psychiatrist for Children with Learning Disabilities, Child and Adolescent Mental Health Services, Leicestershire Partnership NHS Trust

Ms Amy Brown
Research Assistant, The National Collaborating Centre for Mental Health (2006-2007)

Ms Liz Costigan
Project Manager, The National Collaborating Centre for Mental Health (2006-2007)

Mr Alan Duncan
Systematic Reviewer, The National Collaborating Centre for Mental Health

Dr Val Harpin
Consultant Paediatrician (Neurodisability), Ryegate Children’s Centre, Sheffield Children’s NHS Foundation Trust

Professor Chris Hollis
Professor of Child & Adolescent Psychiatry, Division of Psychiatry, University of Nottingham, Queens Medical Centre, Nottingham

Dr Daphne Keen
Consultant Developmental Paediatrician, Developmental Paediatrics, St George’s Hospital, London
Ms Angela Lewis
Research Assistant, The National Collaborating Centre for Mental Health
(2007-2008)

Dr Ifigeneia Mavranezouli
Senior Health Economist, The National Collaborating Centre for Mental Health

Dr Christine Merrell
Education Specialist, Curriculum, Evaluation and Management Centre, Durham University, Durham

Ms Diane Mulligan
Carer Representative

Dr Alejandra Perez
Systematic Reviewer, The National Collaborating Centre for Mental Health

Dr Catherine Pettinari
Centre Manager, The National Collaborating Centre for Mental Health (2007-2008)

Ms Noreen Ryan
Nurse Consultant, Child and Adolescent Mental Health Services, Royal Bolton NHS Hospital Trust, Bolton

Dr Nicola Salt
General Practitioner, Thurleigh Road Surgery, London

Dr Kapil Sayal
Senior Lecturer in Child & Adolescent Psychiatry, Institute of Mental Health and University of Nottingham, Nottingham

Ms Linda Sheppard (2006-2007)
Carer Representative

Ms Sarah Stockton
Information Scientist, The National Collaborating Centre for Mental Health

Dr Clare Taylor
Editor, The National Collaborating Centre for Mental Health

Dr Geoff Thorley
Head Clinical Child and Adolescent Psychologist, Child and Adolescent Mental Health Service, Leicestershire Partnership NHS Trust, Leicester

Ms Jenny Turner
DRAFT FOR CONSULTATION

1 Research Assistant, The National Collaborating Centre for Mental Health
2 (2006-2007)

3 Professor Peter Tymms
4 Professor of Education and Director of the Curriculum, Evaluation and
5 Management Centre, Durham University

6 Dr Miranda Wolpert (2006-2007)
7 Director, CAMHS Evidence Based Practice Unit, University College London
8 and Anna Freud Centre, London

9 Professor Ian Wong
10 Professor of Paediatric Medicine Research, Centre for Paediatric Pharmacy
11 Research, The School of Pharmacy, London

12 Dr Susan Young
13 Senior Lecturer in Forensic Clinical Psychology, Institute of Psychiatry, Kings’
14 College London, Honorary Consultant Clinical and Forensic Psychologist,
15 Broadmoor Hospital, West London Mental Health Trust
Acknowledgements

The Attention Deficit Hyperactivity Disorder Guideline Development Group and the National Collaborating Centre for Mental Health Review team would like to thank those who acted as advisors on specialist topics or have contributed to the development of the guideline by meeting with the Guideline Development Group:

Ms Mary Sainsbury
Practice Development Manager, Social Care Institute for Excellence

Dr Ilina Singh
Wellcome Trust University Lecturer in Bioethics and Society, London School of Economics

Dr Miranda Wolpert (2007-2008)
Director, CAMHS Evidence Based Practice Unit, University College London and Anna Freud Centre, London

1 Preface

This guideline has been developed to advise on the treatment and management of attention deficit hyperactivity disorder (ADHD). The guideline recommendations have been developed by a multidisciplinary team of healthcare professionals, a carer and service user, and guideline methodologists after careful consideration of the best available evidence. It is intended that the guideline will be useful to clinicians and service commissioners in providing and planning high-quality care for people with ADHD while also emphasising the importance of the experience of care for them and their carers (see Appendix 1 for more details on the scope of the guideline).

Although the evidence base is rapidly expanding, there are a number of major gaps, and future revisions of this guideline will incorporate new scientific evidence as it develops. The guideline makes a number of research recommendations specifically to address gaps in the evidence base. In the meantime, it is hoped that the guideline will assist clinicians, people with ADHD and their carers by identifying the merits of particular treatment approaches where the evidence from research and clinical experience exists.

1.1 National guidelines

1.1.1 What are clinical practice guidelines?

Clinical practice guidelines are ‘systematically developed statements that assist clinicians and patients in making decisions about appropriate treatment for specific conditions’ (Mann, 1996). They are derived from the best available research evidence, using predetermined and systematic methods to identify and evaluate the evidence relating to the specific condition in question. Where evidence is lacking, the guidelines incorporate statements and recommendations based upon the consensus statements developed by the Guideline Development Group (GDG).

Clinical guidelines are intended to improve the process and outcomes of healthcare in a number of different ways. They can:

- provide up-to-date evidence-based recommendations for the management of conditions and disorders by healthcare professionals
- be used as the basis to set standards to assess the practice of healthcare professionals
- form the basis for education and training of healthcare professionals
- assist patients and carers in making informed decisions about their treatment and care
- improve communication between healthcare professionals, patients and carers
• help identify priority areas for further research.

In addition, when the condition has an impact on another topic area, as in this guideline with education, guidelines are increasingly joint efforts informed by research in those areas and they make recommendations for practice in those areas.

1.1.2 Uses and limitations of clinical guidelines

Guidelines are not a substitute for professional knowledge and clinical judgement. They can be limited in their usefulness and applicability by a number of different factors: the availability of high-quality research evidence, the quality of the methodology used in the development of the guideline, the generalisability of research findings and the uniqueness of individuals with ADHD.

Although the quality of research in this field is variable, the methodology used here reflects current international understanding on the appropriate practice for guideline development (AGREE: Appraisal of Guidelines for Research and Evaluation Instrument; www.agreecollaboration.org), ensuring the collection and selection of the best research evidence available and the systematic generation of treatment recommendations applicable to the majority of people with these disorders and situations. However, there will always be some people and situations for which clinical guideline recommendations are not readily applicable. This guideline does not, therefore, override the individual responsibility of healthcare professionals to make appropriate decisions in the circumstances of the individual, in consultation with the person who misuses drugs or carer.

In addition to the clinical evidence, cost-effectiveness information, where available, is taken into account in the generation of statements and recommendations of the clinical guidelines. While national guidelines are concerned with clinical and cost effectiveness, issues of affordability and implementation costs are to be determined by the National Health Service (NHS).

In using guidelines, it is important to remember that the absence of empirical evidence for the effectiveness of a particular intervention is not the same as evidence for ineffectiveness. In addition, of particular relevance in mental health, evidence-based treatments are often delivered as part of an overall treatment programme including a range of activities, the purpose of which may be to help engage the person and to provide an appropriate context for providing specific interventions. It is important to maintain and enhance the service context in which these interventions are delivered; otherwise the specific benefits of effective interventions will be lost. Indeed, the importance of organising care in order to support and encourage a good therapeutic relationship is at times as important as the specific treatments offered.
1.1.3 Why develop national guidelines?

The National Institute for Health and Clinical Excellence (NICE) was established as a Special Health Authority for England and Wales in 1999, with a remit to provide a single source of authoritative and reliable guidance for patients, professionals and the public. NICE guidance aims to improve standards of care, to diminish unacceptable variations in the provision and quality of care across the NHS and to ensure that the health service is patient centred. All guidance is developed in a transparent and collaborative manner using the best available evidence and involving all relevant stakeholders.

NICE generates guidance in a number of different ways, three of which are relevant here. First, national guidance is produced by the NICE Centre for Health Technology Evaluation to give robust advice about a particular treatment, intervention, procedure or other health technology. Second, the NICE Centre for Public Health Excellence commissions public health guidance focused on both interventions and broader health promotion activities that help to reduce people’s risk of developing a disease or condition or help to promote or maintain a healthy lifestyle. Third, the NICE Centre for Clinical Practice commissions the production of national clinical practice guidelines focused upon the overall treatment and management of specific conditions. To enable this latter development, NICE has established seven National Collaborating Centres in conjunction with a range of professional organisations involved in healthcare.

1.1.4 The National Collaborating Centre for Mental Health

This guideline has been commissioned by NICE and developed within the National Collaborating Centre for Mental Health (NCCMH). The NCCMH is a collaboration of the professional organisations involved in the field of mental health, national patient and carer organisations, a number of academic institutions and NICE. The NCCMH is funded by NICE and is led by a partnership between the Royal College of Psychiatrists’ research unit (College Research and Training Unit) and the British Psychological Society’s equivalent unit (Centre for Outcomes Research and Effectiveness).

1.1.5 From national guidelines to local protocols

Once a national guideline has been published and disseminated, local healthcare groups will be expected to produce a plan and identify resources for implementation, along with appropriate timetables. Subsequently, a multidisciplinary group involving commissioners of healthcare, primary care and specialist mental health professionals, patients and carers should undertake the translation of the implementation plan into local protocols taking into account both the recommendations set out in this guideline and the priorities set in the National Service Framework for Mental Health and related documentation. The nature and pace of the local plan will reflect local healthcare needs and the nature of existing services; full implementation may take a considerable time, especially where substantial training needs are
identified. When the guideline is informed by another discipline, such as education, joint efforts to inform implementation of the recommendations are undertaken wherever possible.

1.1.6 Auditing the implementation of guidelines

This guideline identifies key areas of clinical practice and service delivery for local and national audit in the NHS. Although the generation of audit standards is an important and necessary step in the implementation of this guidance, a more broadly based implementation strategy will be developed. Nevertheless, it should be noted that the Healthcare Commission will monitor the extent to which Primary Care Trusts, trusts responsible for mental health and social care and Health Authorities have implemented these guidelines. Although formal national audit for education is outside the remit for this guideline, the recommendations relevant to education in this guideline would be consistent with a national audit programme or equivalent quality improvement methods.

1.2 The national ADHD guideline

1.2.1 Who has developed this guideline?

The GDG was convened by the NCCMH and supported by funding from NICE. The GDG included a carer, service user, and professionals from psychiatry, paediatrics, clinical psychology, education, general practice, nursing, and Child and Adolescent Mental Health Services.

Staff from the NCCMH provided leadership and support throughout the process of guideline development, undertaking systematic searches, information retrieval, appraisal and systematic review of the evidence. Members of the GDG received training in the process of guideline development from NCCMH staff, and the service user and carer received training and support from the NICE Patient and Public Involvement Programme. The NICE Guidelines Technical Advisers provided advice and assistance regarding aspects of the guideline development process.

All GDG members made formal declarations of interest at the outset, which were updated at every GDG meeting. The GDG met a total of 20 times throughout the process of guideline development. It met as a whole, but key topics were led by a national expert in the relevant topics. The GDG was supported by the NCCMH technical team, with additional expert advice from special advisers where needed. The group oversaw the production and synthesis of research evidence before presentation. All statements and recommendations in this guideline have been generated and agreed by the whole GDG.

1.2.2 For whom is this guideline intended?

This guideline will be relevant for people with ADHD.
The guideline covers the care provided by primary, community, and secondary healthcare professionals and educational services who have direct contact with, and make decisions concerning the care of children, young people, and adults with ADHD with ADHD.

The guideline will comment on the interface with other services with other services such as social services, the voluntary sector and young offender institutions, but it will not include recommendations relating to the services exclusively provided by these agencies.

The experience of ADHD can affect the whole family and often the community. The guideline recognises the role of both in the treatment and support of people with ADHD.

1.2.3 Specific aims of this guideline

The guideline makes recommendations for the treatment and management of ADHD. It aims to:

- Examine the validity of the diagnostic construct of ADHD
- Evaluate the role of specific pharmacological agents, non-pharmacological, psychological, psychosocial interventions in the treatment and management of ADHD
- Evaluate the role of specific services and systems for providing those services in the treatment and management of ADHD
- Integrate the above to provide best-practice advice on the care of people with a diagnosis of ADHD through the different phases of illness, including the initiation of treatment, the treatment of acute episodes and the promotion of well-being
- Consider economic aspects of various interventions for ADHD.

The guideline does not cover treatments that are not normally available on the NHS.

1.2.4 How this guideline is organised

The guideline is divided into chapters, each covering a set of related topics. The first three chapters provide a general introduction to the guideline, to the ADHD condition, and to the methods used to develop the guideline. Chapters 4 to 10 provide the evidence that underpins the recommendations.

Each evidence chapter begins with a general introduction to the topic that sets the recommendations in context. Depending on the nature of the evidence, narrative reviews or meta-analyses were conducted, and the structure of the chapters varies accordingly. Where appropriate, details about current practice, the evidence base and any research limitations are provided. Where
meta-analyses were conducted, information is given about both the interventions included and the studies considered for review. Clinical summaries are then used to summarise the evidence presented. Finally, recommendations related to each topic are presented at the end of each chapter. On the CD-ROM, full details about the included studies can be found in Appendix 17. Where meta-analyses were conducted, the data are presented using forest plots in Appendix 18 (see Text Box 1 for details).

2 Attention deficit hyperactivity disorder

2.1 The disorder

This guideline is concerned with the management of attention deficit hyperactivity disorder (ADHD) (including hyperkinetic disorder [HKD]), as defined in the International Classification of Diseases (ICD-10) and the Diagnostic and Statistical Manual for Mental Disorder (DSM-IV–TR), in primary, community and secondary care.

2.1.1 The concept and its history

The definitions of ADHD and HKD are based on maladaptively high levels of impulsivity, hyperactivity and inattention. They are all based on observations about how children behave: ‘impulsivity’ signifies premature and thoughtless actions; ‘hyperactivity’ a restless and shifting excess of movement; and ‘inattention’ is a disorganised style preventing sustained effort. All are shown by individual children to different extents, and are influenced by context as well as by the constitution of the person.

Historically, the origins of the concept were in the idea that some disturbances of behaviour were the result of brain damage or ‘minimal brain dysfunction’, such as were seen in the pandemic of encephalitis in the 1920s or after traumatic birth. These neurological formulations, however, were called into question when epidemiological science examined systematically the causes of behaviour problems in childhood.

In the place of unsubstantiated brain damage theories, the classification of mental disorders emerging in the 1980s in the American Psychiatric Association’s (APA) diagnostic scheme, DSM-III (later DSM-IV) and the World Health Organization’s (WHO) classification of disease ICD-9 (now ICD-10), put to one side the aetiological theories and concentrated on the reliable description of problems at a behavioural level. Clinical and statistical studies indicated that impulsivity, hyperactivity and inattention were often associated and were disproportionately common in children referred for psychiatric help. North American and European practice diverged: in North America moderate to severe levels were recognised and termed ‘attention deficit hyperactivity disorder’; in most of Europe, only extreme levels were seen as an illness and called ‘hyperkinetic disorder’.

More recently, extensive biological investigations of both ADHD and HKD have yielded some neuroimaging and molecular genetic associations; neurocognitive theories have emerged; and there is a better understanding of
the natural history and the risks that hyperactive behaviour imposes.
Nevertheless, the disorder remains one that is defined at a behavioural level, and its presence does not imply a neurological disease.

There has also been a large increase in recognition of the problem and a corresponding rise in the numbers treated: from an estimate of 0.5 per 1,000 children diagnosed in the UK 30 years ago, to more than 3 per 1,000 receiving anti-ADHD medication in the late 1990s. The rates in the US have risen too, but from a much higher base; from about 12 per 1,000 30 years ago to about 35 per 1,000 in the late 1990s, with the increase continuing (Olfson et al., 2003). The terminology in Europe has also changed, and ‘ADHD’ has become the diagnostic phrase most commonly used in practice, even when more restrictive criteria are being used.

2.1.2 Common problems associated with ADHD
It is very common for the core problems of ADHD to present together with other developmental impairments and/or mental health problems. There are many rather non-specific problems that are very common in ADHD, and can even be used – incorrectly – as grounds for the diagnosis (see Table 1):

<table>
<thead>
<tr>
<th>Table 1. Common problems associated with ADHD</th>
</tr>
</thead>
<tbody>
<tr>
<td>Non-compliant behaviour</td>
</tr>
<tr>
<td>Sleep disturbance</td>
</tr>
<tr>
<td>Aggression</td>
</tr>
<tr>
<td>Temper tantrums</td>
</tr>
<tr>
<td>Literacy and other learning problems</td>
</tr>
</tbody>
</table>

These will need recognising, and sometimes intervention, but they are not in themselves grounds for the diagnosis, because they can be the results of many different causes.

2.1.3 Changes with age
The problems associated with ADHD appear in different ways at different ages, as the individual matures and as the environmental requirements for sustained self-control increase (Taylor & Sonuga-Barke, in press).

Hyperactivity in a preschool child may involve incessant and demanding extremes of activity; during the school years an affected child may be showing excess movements during situations where calm is expected rather than on every occasion; during adolescence hyperactivity may present as excessive fidgetiness rather than whole body movement; in adult life it may be a sustained inner sense of restlessness. Inattention too may diminish in absolute terms, and attention span will usually increase with age; but it tends still to lag behind that of unaffected people, and behind the level that is expected and needed for everyday attainments.
2.1.4 Course of the disorder

Onset

The core behaviours of ADHD are typically present from before the age of 7, and often the first 2 years of life, but presentation as a problem is very variable. Mild forms need not be impairing at all. Extreme forms are considered to be harmful to the individual’s development in most cultures, but there are cultural differences in the level of activity and inattention that is regarded as a problem. Furthermore, both teachers and parents can find it very hard to live with a hyperactive child, and their tolerance and ability to cope may determine whether it is presented as a problem. Children with hyperactivity rarely ask for help themselves. Inattentive children, without hyperactivity, are often not presented as a problem even though they may have a marked cognitive impairment. The presentation to the clinician is therefore a complex blend of the skills and tolerance of adults surrounding the child and the qualities of the children themselves.

Course and impairment

The core problems of ADHD and the associated features can persist over time and impair development in children. Several studies have followed diagnosed schoolchildren over periods of 4 to 14 years; all have found that they tend to show, by comparison with people of the same age who have not had mental health problems, persistence of hyperactivity and inattention, poor school achievement and a higher rate of disruptive behaviour disorders.

The risk of later maladjustment also affects children not referred to clinics. Longitudinal population studies have shown that hyperactive-impulsive behaviour is a risk for several kinds of adolescent maladjustment. Lack of friends, work and constructive leisure activities are prominent and affect the quality of life. Severe levels of hyperactivity and impulsivity also make children more likely to develop an antisocial adjustment and more likely to show personality dysfunction or substance misuse in later adolescence and adult life.

Nevertheless, it is important to remember that many young people with ADHD will make a good adult adjustment and be free of mental health problems. A good outcome may be more likely when the main problem is inattention rather than hyperactivity-impulsivity, when antisocial conduct does not develop, and when relationships with family members and other children remain warm.

2.2 Diagnosis and assessment

2.2.1 Diagnostic systems and criteria

The most commonly used criteria for the diagnosis of both children and adults are those provided in DSM-IV-TR and in ICD-10.
The DSM criteria break down symptoms into two groups: inattentive and hyperactive-impulsive. Six of the nine symptoms in each section must be present for a ‘combined type’ diagnosis of ADHD. If there are insufficient symptoms for a combined diagnosis then predominantly inattentive (ADHD-I) and hyperactive (ADHD-H) diagnoses are available. Additionally, symptoms must be: chronic (present for 6 months), maladaptive, functionally impairing across two or more contexts, inconsistent with developmental level, and differentiated from other mental disorders (see Table 2).

The ICD uses a different nomenclature; the same symptoms are described as part of a group of hyperkinetic disorders of childhood, and inattention, hyperactivity and impulsivity must all be present; so only ‘combined-type’ ADHD qualifies. In addition, the research diagnostic criteria of the ICD provide an even more restricted set of requirements: the symptom counts must all be met in more than one context. Furthermore, there are quite strict exclusion criteria: whereas co-existent psychiatric disorders are allowed under DSM-IV, the diagnosis of HKD is not made when criteria for certain other disorders, including anxiety states, are met – unless it is plain that HKD is additional to the other disorder (see Table 3).

Hyperkinetic disorder (ICD-10) therefore describes a group that forms a severe sub-group of the DSM-IV combined subtype of ADHD. HKD is further divided into HKD without conduct disorder and HKD with conduct disorder.
Table 2. DSM-IV criteria for attention deficit hyperactivity disorder

</table>

4. Onset of the disorder is no later than the age of 7 years.

5. Pervasiveness - The criteria should be met for more than a single situation, e.g., the combination of inattention and hyperactivity should be present both at home and at school, or at both school and another setting where children are observed, such as a clinic. (Evidence for cross-situationality will ordinarily require information from more than one source; parental reports about classroom behaviour, for instance, are unlikely to be sufficient.)

6. The symptoms in 1 and 3 cause clinically significant distress or impairment in social, academic, or occupational functioning.

Adapted from *ICD10: Classification of Mental and Behavioural Disorders* (1992) with permission from the World Health Organisation.

With regards to adults, strict usage of the full diagnostic criteria may be inappropriate, because the criteria focus on childhood problems and do not take full account of the developmental changes mentioned above.

Recommendations for identification in adult life have therefore included lowering of diagnostic thresholds and providing age-appropriate adjustment of the symptoms. Issues such as self-awareness and motivation in adult patients reinforce the importance of taking a thorough developmental and psychiatric history and mental state – though this should be a key feature of any diagnostic process. DSM-IV allows a category of ‘ADHD in partial...
remission’ for individuals who no longer meet the full criteria; this criterion is particularly relevant for adults where some of the symptoms may have declined with age but where significant impairments related to the symptoms remain.

In this guideline, we will use ADHD as an umbrella term when discussing the disorder more broadly. Some of the earlier literature used the term ‘hyperactivity’ for the cluster of hyperactive, impulsive and inattentive symptoms. In this guideline the term ‘hyperactivity’ will be restricted to mean the combination of symptoms that define overactive behaviour and the term ‘ADHD symptoms’ used to refer to the combination of hyperactive, impulsive and inattentive symptoms.

Oppositional defiant disorder (ODD) and conduct disorder (CD) are also diagnoses in the ICD and DSM schemes and need to be differentiated from ADHD. ODD refers to persistent and frequent disobedience and opposition to authority figures (such as parents, teachers or other adults), characterised by negative, hostile or defiant behaviour. The diagnosis should not be made unless these behaviours persist for more than 6 months and are considerably more frequent than normal for a person of the same developmental age. Conduct disorder represents more severe behavioural problems: a persistent pattern of behaviour that violates the societal rules and the rights of others. This includes aggression that can take the form of bullying or cruelty to animals, destruction of property, stealing and persistent lying (other than to avoid harm). All these oppositional and conduct disorder problems can be seen in some children with ADHD, but they are not essential features and should not be used as grounds for making the diagnosis of ADHD.

2.2.2 Differential diagnosis

ADHD features often coexist with other problems of mental health; and these other conditions may be both differential diagnoses (because they may produce behaviours superficially similar to those of ADHD) and comorbid disorders that need to be recognised in their own right.

DSM-IV and ICD-10 treat coexistent disorders in different ways. In DSM, symptoms must not exist ‘exclusively during the course of’ autism spectrum disorders, schizophrenia or other psychotic disorders, and furthermore must not be ‘better accounted for’ by another mental disorder, such as affective disorders, anxiety disorders, dissociative and personality disorders. ICD-10 research diagnostic criteria go further and make such conditions exclusionary criteria without the need for judgement about whether they account for ADHD features. There is a potential danger in a strict application of these exclusionary criteria: it may lead to the overlooking of ADHD when it coexists with another problem, as described in Chapter 5, Diagnosis.
What is clear is that the confounding effect of comorbid conditions needs to be evaluated for each individual, considering especially: global and specific learning disorders, neurological disorder, conduct and oppositional disorders, Tourette syndrome, bipolar illnesses, other affective disorders including anxiety and depression, attachment and post-traumatic disorders, autistic spectrum disorders and borderline and antisocial personality disorders.

The confounding effects of stress, parent/carer/institutional/social intolerance or pressure, and individual or familial drug and alcohol misuse should also be taken into account.

2.2.3 Controversies with diagnosis

The diagnosis of ADHD has attracted criticisms from many who challenge several assumptions associated with the process, as described in Chapter 5, Diagnosis. Broadly these issues can be summarised into three categories:

- **Technical critiques** focus on the difficulties of diagnosis as a practical accomplishment. These include: the language and specificity of the criteria, accurate differentiation from co-occurring conditions, and the lack of criteria and guidance for adult diagnosis in particular.

- **Sociological critiques** cover a broad range of issues, including the present gender, class and ethnicity skew in diagnosis, the ideological bases of the practice of psychiatry and the allegedly hegemonic practices of the APA, and the existence and effects of social pressures, media hype, and stereotyping.

- **Validity critiques** question the very existence of the disorder and emphasise the institutional and social conditions upon which they claim the diagnosis is contingent.

2.2.4 Assessment - the influence of key clinical characteristics

The assessment of ADHD is best understood when related to the key characteristics of ADHD (including HKD), as set out in diagnostic schemes. These key features are:-

- the presence of the core problems of inattention, hyperactivity and impulsivity
- the inappropriateness of these features in comparison with the qualities of people at a similar developmental level
- long symptom duration
- difficulties evident in more than one setting, such as the home, school or workplace and other social settings
- adverse impact on current and/or general development and psychosocial adjustment
• the need to distinguish from neurodevelopmental disorders associated with learning disabilities and cognitive problems, and other mental health disorders or problems—neither using those other problems as evidence for ADHD nor neglecting the presence of ADHD when it coexists with them
• the need to consider whether impairment is attributable solely to ADHD or is caused or exacerbated by other disorders (mental and physical) as well as personal and social circumstances.

2.2.5 Key assessment features
There is no single definitive psychological or biological test for ADHD. Diagnosis is the outcome of several strands of investigation that are directed to establishing:

• the extent and severity of the core symptoms and any associated problems
• the characteristics of the symptoms in different situations
• the origins and developmental course of the symptoms
• how any symptoms compare with those seen in other people at the same developmental level
• the presence of other physical, mental health and/or learning disorders.

The complexity of assessment requires cooperation among a number of professionals employed by different agencies and using a wide variety of techniques—in other words, a multi-modal, multi-professional and multi-agency approach.

2.2.6 Key approaches
Essential components of a full assessment process include a clinical interview, a medical examination, and administration of rating scales to parents and teachers (for example, self-report). Other components such as direct observation in educational settings, cognitive, neuropsychological, developmental and literacy skills assessments may or may not be indicated.

Clinical interview
A clinical interview is usually carried out by a paediatrician, psychiatrist, clinical psychologist or specialist nurse; and usually in a semi-structured format so that key issues can be systematically investigated. Although fully structured interview instruments, such as the Diagnostic Interview Schedule for Children (DISC) (Costello et al., 1982), the Diagnostic Interview Scale (DIS) for adults (Robins et al., 1981) and the Conners ADHD Adult Diagnostic Interview for DSM-IV (Epstein et al., 2001), are often used in research, the
length and inflexibility of such instruments has, however, meant that they are
seldom employed in clinical practice.

The chief aim of the interview is to detail the full range of problems and their
history, together with family, health, social, educational and demographic
information. It is also helpful to find out how patients and their families have
tried to deal with any problems over the years. The interview is also designed
to highlight any further, more specialist assessments that might be required to
facilitate diagnosis and intervention planning.

A detailed clinical interview in child mental health practice will typically take
between 2 and 3 hours, often arranged over two sessions. Frequently, persons
other than the child are involved in the interview to provide additional
information and perspectives. Time is also set aside to see young people
individually with a similar opportunity for parents.

**Standardised rating scales**

These help in the evaluation of mental health, social and behavioural
problems and possess normative data to enable comparisons with the general
population, specific clinical groups or both. There are three main types:

1. Broad-band instruments that evaluate general behavioural and
   psychosocial functioning: The Strengths and Difficulties Questionnaire
   (Goodman, 2001) is a widely available and used example. A longer
   example is the Achenbach scales (Achenbach, 2003; Achenbach &
   Rescorla, 2001), which cover the age range 18 months to 59 years with
   adult, parent, teacher and adolescent self-report versions. Another
   example is the long version of the Conners Rating Scales (Conners,
   1997) for young people, which have versions for parents and teachers.

2. Narrow-band scales that are specific to ADHD symptomatology:
   Examples include the Conners scales for young people (Conners et al.,
   1997), the Brown Attention Deficit Disorder Scale (Brown, 2001; 1996)
   with versions for adults and young people; ADHD Rating Scale IV
   (DuPaul et al., 1997); the Child Attention Profile (Dulcan & Popper,
   1991; Barkley, 1990) and the Home Situations Questionnaire (Barkley &
   Murphy, 1998).

3. Other rating scales are used to evaluate other types of mental health
   symptomatology that are comorbid, or associated, with ADHD such as
   anxiety, self-esteem, depression and conduct problems.

The limitations of rating scales include an inter-rater reliability that is at best
moderate (Verhulst & Van der Ende 2002) and less than complete sensitivity
and specificity for the diagnosis compared with a full diagnostic assessment.
Many scales describe symptoms only and not their developmental
appropriateness or the level of impairment. When developmental appropriateness is included, then it is by asking the rater to judge according to what is considered normal for a child of that age, which may be a difficult task for a non-expert rater and prone to errors of interpretation.

**Educational and occupational adjustment**

An understanding of a child or young person’s adjustment at school or an adult’s functioning in the workplace is an important component of the assessment process. Teachers, in addition to questionnaire information, may be asked to provide specific information on social and academic functioning. If functioning at school is particularly problematic, direct observation by the assessing clinicians of behaviour in the classroom and in other, less structured situations is undertaken.

**Medical assessment**

People referred for assessment for ADHD receive a specialist clinical assessment by a psychiatrist or paediatrician. One aim is to rule out undiagnosed disorders with symptoms that in rare instances may mimic or cause some aspects of ADHD, such as hearing impairment, epilepsy, thyroid disorder and iron deficiency anaemia. The possible contribution of prenatal and perinatal factors known to increase the risk of development of ADHD symptoms is noted (and parental questions about risk factors are responded to) and the assessment identifies physical signs of certain genetic conditions that have increased risk of ADHD. There may also be other co-existing physical, neurological and developmental disorders that need to be identified (including developmental coordination disorder, also known as dyspraxia, chronic tic disorders or Tourette syndrome, and sleep disorders) which will then shape later management. After diagnosis, if ADHD is confirmed, and if drug therapy is being considered, examination involves baseline measurements of height and weight, blood pressure, with continued monitoring of these being an ongoing feature.

**Psychological and psychometric assessment**

Educational and clinical psychologists may undertake further assessments if learning difficulties involving literacy skills, dyslexia, or other problems are suspected. These may help to explain the presence of attentional problems; and even if ADHD is present as well, they will need addressing as part of the management plan.

Global learning disabilities may also be present, particularly with Hyperkinetic Disorder; intellectual status needs to be understood so that therapy can be designed to be developmentally appropriate. Cognitive impairments involving memory, attention, or others are very likely to be present and ideally should be investigated further by clinical or educational psychologists. There are many such tests; of particular interest are specific ones to measure attention. One of the best known is the Test of
Everyday Attention (Robertson et al., 1994) for adults and the Test of Everyday Attention for Children (Manly et al., 1998). There are also visual and auditory attentional subtests in neuropsychological batteries such as the NEPSY (Korkman et al., 1998) for children. Auditory attention is also a feature of the Auditory Continuous Performance Test for children (Keith, 1994). There are also a number of versions of the Continuous Performance Test (Rosvold et al., 1956) available and helpfully discussed by Barkley (1998).

2.3 Epidemiology

ADHD (as defined in DSM-IV) is a common disorder. In the UK, a survey of 10,438 children between the ages of 5 and 15 found that 3.62% of boys and 0.85% of girls had ADHD (Ford et al., 2003). This survey was founded on careful assessment and included impairment in the diagnosis.

The more restricted diagnosis of HKD ICD-10, representing a severe sub-group of DSM-IV combined type ADHD, is naturally less common; prevalence estimates are around 1.5% for boys in the primary school years.

In the international scientific literature, prevalence estimates vary widely across studies. At one extreme, in Columbia, the prevalence rates were estimated to be 19.8% and 12.3% for boys and girls respectively (Pineda et al., 2003). Such a wide range in prevalence estimates is unlikely to reflect true differences in the numbers of individuals with ADHD in various populations. Polanczyk and colleagues (2007) made a systematic review of prevalence studies and concluded that the great majority of variability derived from the methods used, such as the way symptoms were measured and the exact definitions used. There were relatively minor differences in different parts of the world and the review’s summary of rates was around 5.3%.

This highlights the difficulties in making direct comparisons between studies and occurs for several reasons. ADHD symptoms are continuously distributed throughout the population with no natural threshold between affected and unaffected individuals (Taylor et al., 1991). This particular problem can be successfully resolved by the application of strictly applied operational diagnostic criteria such as the DSM-IV definition for ADHD or the research ICD-10 criteria for HKD. However, even where the same diagnostic definitions are applied, there may still be differences in the thresholds applied for individual symptoms, which are rarely operationalised. For example, how severe should avoidance of tasks requiring sustained attention or levels of fidgetiness be before they are considered to be clinically significant?

A key criterion when defining ADHD is not only the presence of sufficient numbers of ADHD symptoms but also, importantly, their association with clinical and social impairments at home, school and in other settings. Surveys that include strict definitions of impairment alongside the symptom count find that prevalence of the syndrome (without evidence of impairment) is
around twice the prevalence of the disorder when the syndrome is associated with impairment (Canino et al., 2004). In the UK, a survey in Newcastle found that prevalence was 11% for the syndrome with no impairment, 6.7% when associated with moderately low impairment, 4.2% for moderate impairment and 1.4% for severe pervasive impairment (McArdle et al., 2004).

Taking into account the differences in investigator training and measures used across studies it is not possible to draw firm conclusions from the large variation in prevalence rates cited in the literature. However, small differences are likely to exist. One study from the US using the same diagnostic procedures reported small but significant differences in prevalence rates between African-Americans (5.65%), Hispanics (3.06%) and whites (4.33%) (Cuffe et al., 2005); however such differences might also be explained by different cultural tolerances for the symptoms of ADHD.

**Adult ADHD**

Prevalence for strictly applied operational definitions of ADHD decline with age. A recent review of longitudinal follow-up studies of individuals diagnosed with ADHD as children found that by age 25 only 15% retained the full ADHD diagnosis. However, a much larger proportion (65%) fulfilled the DSM criteria for ADHD in partial remission, indicating the persistence of some symptoms associated with significant clinical impairments (Faraone et al., 2006). Applying these figures to the prevalence range commonly seen in children of 4-8% we would expect to find 0.6-1.2% of adults retaining the full diagnosis by age 25 years and a larger percentage (2-4%) with ADHD in partial remission. This is consistent with population surveys in adult populations that estimate prevalence of ADHD in adults to be between 3-4% (Faraone & Biederman, 2005; Kessler et al., 2006).

These data suggest that ADHD in adults will be under-identified if the same clinical criteria applied to children is applied to adults. ADHD symptoms follow a developmental decline that parallels the normal change in levels of inattentive, hyperactive and impulsive behaviours seen in the general population. Estimation of prevalence rates will vary unless age-adjusted criteria are applied in a similar way across studies.

### 2.4 Aetiology

The diagnosis of ADHD does not imply a medical or neurological cause. Equally, the presence of psychosocial adversity or risk factors should not exclude the diagnosis of ADHD. The aetiology of ADHD involves the interplay of multiple genetic and environmental factors. ADHD is viewed as a heterogeneous disorder with different sub-types resulting from different combinations of risk factors acting together.
2.4.1 Genetic influences

ADHD symptoms show quite strong genetic influences. Twin studies suggest that around 75% of the variation in ADHD symptoms in the population are due to genetic factors (heritability estimate of 0.7 to 0.8) (Faraone et al., 2005). The genetic influences appear to affect the distribution of ADHD symptoms across the whole population and not just in a clinically defined sub-group. No single gene of large effect has been identified in ADHD; rather several DNA variants of small effect – each increasing the susceptibility of ADHD by a small amount – have been associated. These findings have fuelled a controversy over whether ADHD should be considered as part of normal variation or as a categorically defined medical disorder (see diagnosis chapter). Testing for susceptibility genes is currently not justified in clinical practice given the small predictive value of the associated genes, which therefore lack direct clinical relevance.

2.4.2 Environmental influences

Biological factors

A range of factors that adversely affect brain development during perinatal life and early childhood are associated with an increase in the risk of ADHD or ADD-W/O (attention deficit disorder without hyperactivity). These include maternal smoking (Markussen-Linnet et al., 2003), alcohol consumption (Mick et al., 2002) and heroin during pregnancy (Ornoy et al., 2001), very low birth weight (Botting et al., 1997) and fetal hypoxia, brain injury and exposure to toxins such as lead or zinc (Toren et al., 1996). Risk factors do not act in isolation, but interact with one another. For example, the risk of ADHD associated with maternal alcohol consumption in pregnancy may be stronger in those children with a dopamine transporter susceptibility gene (Brookes et al., 2006). Further research is required to confirm whether these act as direct risks for ADHD.

There is increased risk of ADHD symptoms in epilepsy and of ADHD in genetic conditions such as neurofibromatosis type 1 (see Mautner et al., 2002), and syndromes such as Angelman, Prader-Willi, Smith Magenis, velocardo facial and fragile X (see Hagerman 1999). Secondary ADHD may follow traumatic brain injury (see Gerring et al., 1998).

Dietary factors

The influence of dietary factors in ADHD has attracted much public attention: food additives, sugar, colourings and ‘E’ numbers are often regarded as causes of ADHD, and elimination and supplementation diets are widely used, often without professional advice.

Nevertheless, epidemiological research indicates a link between additives and preservatives in the diet and levels of hyperactivity (McCann et al., 2007); and at least a small proportion of children with ADHD demonstrate idiosyncratic
reactions to some natural foods and/or artificial additives, and may be helped by a carefully applied exclusion diet (see Chapter 8 on diet).

Richardson (2004) reviewed the evidence on associations between ADHD and long-chain polyunsaturated fatty acids (PUFA) and commented on the brain’s need throughout life for adequate supplies, a relative lack of omega-3 PUFA, and a possibility that males may be more vulnerable because testosterone may impair PUFA synthesis. Scientific uncertainties remain, however, concerning the physiological significance of different measures of PUFA metabolism and they are not used in practice.

Psychosocial factors

ADHD has been associated with severe early psychosocial adversity, for instance, in children surviving depriving institutional care (Roy et al., 2000). The mechanisms are not known but may include a failure to acquire cognitive and emotional control.

Disrupted and discordant relationships are more common in the families of young people with ADHD (Biederman et al., 2002). However, discordant family relationships may be as much a consequence of living with a child with ADHD as a risk for the disorder itself. In established ADHD, discordant relationships with a harsh parenting style are a risk factor for developing oppositional and conduct problems. Parental hostility and criticism can be reduced in children where ADHD symptoms are been successfully treated with stimulants. Parents themselves may also have unrecognised and untreated ADHD, which may adversely affect their ability to manage a child with the disorder.

2.5 Current care and treatment of ADHD for children in the NHS

2.5.1 Recognition and treatment strategies

The provision of treatments and interventions for children, young people and their families who have ADHD is varied. The ability to recognise and diagnose the disorder and the way in which services are provided and organised for this identified group are inconsistent as services move towards providing comprehensive child and adolescent mental health services (CAMHS) (Department of Health, 2004). The identification of affected people is unsystematic and driven largely by the extent to which parents are knowledgeable about the condition or recognise that their child might have hyperactive behaviour (Sayal et al., 2002; 2006). Historically, services for affected children and young people have mostly been provided by CAMHS, psychiatrists with a specialism in learning disability, or paediatricians based in child development centres or in community child health departments.
The willingness of children, young people and their families to seek help has sometimes been compromised by stigma associated with mental health services. Referral pathways can be complicated, and are subject to considerable variation in the local organisation of mental health services for children and young people. There can be difficulties with awareness and recognition of the symptoms by healthcare professionals in schools, primary and secondary care and by the other professionals who come into contact with this group (Schacher & Tannock, 2002).

Treatments and interventions for ADHD are varied and provided in a variety of settings, usually including specialist CAMHS or paediatric clinics:

**Psychological therapies and parent training**

Psychological therapies include psychoeducational input, behavioural therapy, cognitive behavioural therapy (CBT) in individual and group formats, interpersonal psychotherapy (IPT), family therapy, school-based interventions, social skills training, and parent management training to encourage the development of coping strategies for managing the behavioural disturbance of ADHD (Taylor et al., 2004 and Fonagay et al., 2002). Advice is sometimes given to schools and residential institutions. Remedial disciplines such as occupational therapy and speech and language therapy are sometimes involved in helping the development of individual children.

**Social intervention**

Families of children and young people who have ADHD may require social support for example, child care relief, help in the home and family support workers.

**Dietary measures**

Dietary supplements or restrictions are not commonly provided by health services as interventions for ADHD, but they are nevertheless used by many families, sometimes with advice from voluntary or private sectors. Paediatric dietitians are occasionally involved, especially when potentially hazardous regimes, such as exclusion diets, are contemplated.

**Medication**

In the UK, atomoxetine, dexamfetamine and methylphenidate are licensed for the management of ADHD in children and adolescents. The NICE technology appraisal (NICE, 2006) has concluded that these medications are effective in controlling the symptoms of ADHD relative to no treatment.

Methylphenidate is a central nervous system (CNS) stimulant. Its action has been linked to inhibition of the dopamine transporter, with consequent increases in dopamine available for synaptic transmission (Volkow et al., 1998). It is a Schedule 2 controlled drug (CD) and is currently licensed for use in children over 6 years old (Summaries of Product Characteristics for Ritalin, Equasym, Concerta XL, Equasym XL, Medikinet XL,
Both immediate-release and modified-release formulations are available in the UK. Common adverse effects include insomnia, nervousness, headache, decreased appetite, abdominal pain and other gastrointestinal symptoms, cardiovascular effects such as tachycardia, palpitations and minor increases in blood pressure. Growth can be affected, at least in the short term, so height and weight are monitored regularly and plotted on growth charts (BNF, 2005).

Dexamfetamine is a sympathomimetic amine with a central stimulant and anorectic activity and is licensed as an adjunct in the management of refractory hyperkinetic states in children from 3 years old (Summary of Product Characteristics for Dexedrine, http://emc.medicines.org.uk/ (accessed 19/01/2008). Dexamfetamine is also a Schedule 2 CD. The common adverse effects are similar to those of methylphenidate. Dexamfetamine is unlikely to be used as a first-line treatment for the majority of children or adolescents with ADHD because of a greater potential for diversion and misuse than the other medications (NICE, 2006).

Atomoxetine is a selective noradrenaline reuptake inhibitor. It is licensed for the treatment of ADHD in children 6 years and older and in adolescents (Summary of Product Characteristic for Strattera, http://emc.medicines.org.uk/ (accessed 18/08/2006). Common adverse effects are abdominal pain, decreased appetite, nausea and vomiting, early morning awakening, irritability and mood swings. Increased heart rate and small increases in blood pressure were observed in clinical trials. Cases of hepatic disorders associated with atomoxetine have been reported, and patients and parents should be advised of the risk and how to recognise the symptoms of hepatic disorders (BNF, 2005). Furthermore, reports of suicidal ideation in a small number of affected children have led to recommendations that clinicians and parents should be alerted to a possible risk of self-harm.

Other medications, including atypical antipsychotics, bupropion, nicotine, clonidine, modafinil, tricyclic and other antidepressants are occasionally prescribed off-label to patients who do not respond to licensed medications. These drugs were not included in the NICE Technology Appraisal 98 (NICE, 2006).

Medications should only be initiated by an appropriately qualified healthcare professional with expertise in ADHD after a comprehensive assessment. Continued prescribing and monitoring of medications may be performed by GPs, under shared care arrangements (NICE, 2006).

2.5.2 Multi-agency working

Multi-agency working in relation to ADHD currently appears to present a number of challenges. There appears to be potential for issues to arise
regarding how paediatricians and psychiatrists work together. Both groups of
professionals have individuals with ADHD on their caseload, but often there
is only an informal arrangement in place regarding who takes which case.
This informal approach may lead to disagreements regarding diagnosis and a
lack of parity regarding the service provided and treatment options. In
addition, while services do report including representatives from education as
part of their team or steering group, and a few include representatives from
the youth justice service and the voluntary sector, very few report inclusion of
representatives from social services. It may be that collaborative working in
this area is hampered at times by different models of disability and how to
respond to it held by different agencies.

A number of successful multi-professional teams for ADHD are emerging
with protocols for multi-professional working, including the role of GPs in
monitoring aspects of care. There remain, however, difficulties regarding
transitional arrangements between CAMHS and adult mental health services
(AHMS), and a general lack of support for adults with ADHD due to the
difficulties associated with getting a diagnosis and treatment. Furthermore,
the parents of young people with ADHD often have mental health problems
themselves, and find it difficult to get support from AMHS.

2.5.3 Child and adolescent mental health services and ADHD
Children and young people with mental health problems should have access
to local CAMHS. Services nationally remain highly variable regarding the
number and range of professionals providing the service, models of service
provision, the age of transition into adult provision, waiting times for first
appointments and whether the needs of children with a learning disability are
met by the service.

Children identified as requiring assessment for ADHD are generally seen by
tier 1 services and then referred to more specialist services for full assessment
or treatment. Referrals into health services may be made to primary mental
health workers, nurses, child psychiatrists, psychologists or paediatricians
depending on local protocols and services. Children may therefore be
assessed and treated by a range of professionals and there does appear to be a
lack of consistent assessment and treatment protocols. In some services there
is also a lack of availability of psychosocial approaches.

The age of transition into AMHS continues to vary between the age of 16 and
19 with services working towards age 18 as recommended in the National
Service Framework (NSF) for Children (Department of Health, 2004). The
transition between services remains a challenge in some areas due to different
thresholds for referral into AMHS and models of service provision.
Unfortunately there continue to be gaps in provision for some young people
once they have left CAMHS with GPs continuing to monitor and prescribe medication for ADHD without specialist advice or support.

### 2.6 ADHD from an educational perspective

Many studies (for example, Barkley et al., 1990) have noted that children with ADHD achieve lower grades in academic subjects than their peers. More recently this trend has been found for children with teacher-identified ADHD characteristics (Merrell & Tymms, 2001; McGee et al., 2002; Merrell & Tymms, 2005). Such children, identified at the end of their first year at school, have significantly lower reading and mathematics attainment at that point than children with no observed behavioural problems. By the end of primary school they have fallen even further behind, in particular those children with symptoms of inattention. Wolraich and colleagues also suggest that inattention is a key ingredient of poor academic achievement (Wolraich et al., 2003). Using rating scales based on the diagnostic criteria published in DSM-IV, the proportion of children observed by their class teachers to be inattentive, hyperactive and/or impulsive in the classroom has been estimated to be between 8.1 and 17% (Wolraich et al., 1996; Gaub & Carlson, 1997; Merrell & Tymms, 2001; Wolraich et al., 2003). A later study by Wolraich and colleagues (2004) found that teachers’ screening of elementary pupils gave a higher estimate of 25% of their pupils having a high risk of ADHD.

When children start school, aged 4 or 5 years, their teachers could be very well placed to identify ADHD characteristics. The challenges of the school setting are likely to make those difficulties more obvious and may be picked up by teachers who are experienced in observing a wide range of children’s behaviour. However, Bailey (1996) warns that inattentive, hyperactive and impulsive behaviour could be a reaction to the expectations and constraints of the school environment, and it is important to bear in mind this might be the case for some children.

Theoretically once children with ADHD symptoms have been identified, further assessment can be done and interventions can be put in place at an early stage although Tymms and Merrell’s (2006) research did not support screening. Early interventions can be successful in reducing behavioural problems and negative outcomes and the earlier they are implemented, the better (Farrington, 1994). O’Shaughnessy and colleagues (2003) have suggested that co-ordinated school-wide identification and interventions for children with behavioural problems increase the likelihood of improving their outcomes. Even though many studies have found that classroom-based interventions have a positive impact on the behaviour of children with ADHD and to a lesser extent on their academic progress (Purdie et al. 2002), at the present time teachers in England are not systematically trained to use these classroom management and teaching strategies.
All children and young people, including those with ADHD, have the right to a school experience that provides a broad, balanced and relevant curriculum, including the National Curriculum, which is appropriately differentiated according to their needs. This has implications for the provision of initial teacher training and in-service professional development. Further, a whole school approach to promoting positive behaviour outside as well as inside the classroom is desirable and so training should extend to non-teaching members of staff (Philbrick et al., 2004). Several studies have shown that teachers’ and student teachers’ perceived competence in the management of children with ADHD in the classroom is variable and is correlated with their professional knowledge and experience (Avramidis, 2000; Bekle, 2004; Sciutto et al., 2000). At the present time training is lacking, as illustrated by the report from the Education and Skills Select Committee’s Inquiry into Special Educational Needs (July 2006), which recommended that ‘the Government needs to radically increase investment in training its workforce so that all staff, including teaching staff, are fully equipped and resourced to improve outcomes for children with special educational needs (SEN) and disabilities’.

2.7 Adults with ADHD

2.7.1 Treatment strategies for adults

The treatment strategies for ADHD adults are essentially similar to those used in childhood, however there are some key differences that need to be taken into account. Identification has been uncommon in the UK, and there are currently very few specialist services in the NHS and only a few that offer diagnostic or treatment services within generic AMHS. Psychological treatment is not routinely offered to adults with ADHD and there have been few attempts to quantify the benefits of such interventions.

Medication

The number of drug trials in adults is far less than that for childhood but these consistently demonstrate the effectiveness of stimulants to reduce the level of ADHD symptoms in adults fulfilling diagnostic criteria for ADHD. Treatment regimes in adults are similar to those used in children, although in a few cases higher doses are used. Although stimulants are the most studied and most effective treatment for ADHD in children and adults, their use in adults remains controversial across Europe. In the UK, treatment of ADHD has dramatically changed in the last decade with a marked increase in the diagnosis of ADHD and a doubling of stimulant prescriptions between 1998 and 2004. However this change in perspective is only slowly filtering through to those engaged in treating the adult population. It remains an anomaly that many drugs that are considered to be safe and effective in children and adolescents are not licensed for use in adults.

Stimulants are usually the first-choice pharmacological treatment for ADHD in both children and adults. In the UK, both methylphenidate and
dexamfetamine are available, although as of yet remain unlicensed for use in adults. There is a great deal of evidence regarding the safety and effectiveness of stimulants in children, and an increasing amount of evidence for efficacy in adults. The effects of stimulants on ADHD symptoms are different from many other psychiatric treatments, as there is an immediate effect, starting within 30 minutes of an initial dose and continuing for 3-4 hours. These preparations have to be taken several times throughout the day. Long-acting preparations, which last approximately 8-12 hours and are usually taken only once a day, are particularly useful for those who are forgetful or disorganised once the effects of medication begin to wear off.

The second-line choice medication for ADHD in adults is usually atomoxetine. Third line choices include bupropion, modafinil, and antidepressants with noradrenergic effects such as imipramine, venlafaxine and Reboxetine; although there is less consistent evidence for these medications in the reduction of ADHD symptoms in adults. Trial evidence is described in Chapter 9. Atomoxetine is licensed in the USA for the treatment of ADHD in both children and adults, although in the UK it is only licensed for treatment of adults who started atomoxetine in childhood or adolescence.

**Psychological treatments**

Psychotherapeutic interventions that have been used to treat adults with ADHD include psychoeducation, use of support groups, skills training, CBT, coaching and counselling.

Psychological interventions applying a cognitive paradigm have been applied to adults with ADHD (Stevenson *et al*., 2003; Stevenson *et al*., 2002; Wilens *et al*., 1999) usually as a complementary treatment to the use of stimulant medication although it may be sufficient for adults where considerable moderation of symptoms has occurred with age. Qualitative research has suggested that psychological support begins at the time of diagnosis following which ADHD adults go through a process of adjustment in coming to terms with their diagnosis and the impact of the disorder on their lives (Young *et al*., submitted). Psychological treatment can then shift to focus on the treatment of comorbid psychiatric problems, psychological problems and skills deficits (Young, 1999; 2002; Young & Bramham, 2007). The aim is to help people develop methods to structure daily living and improve interpersonal skills so they may function more successfully and achieve their potential. Indeed there is a strong evidence base for psychological treatment of many psychiatric problems that are associated with ADHD.

Other forms of psychotherapy such as counselling or client-based psychotherapies have had a role in helping some individuals come to terms with and better understand the way ADHD has influenced their personal and emotional lives. Coaching interventions parallel a mentoring paradigm by supporting people with ADHD to rehearse newly learned skills on a daily
basis and these have been used as an adjunct to cognitive group programmes for ADHD adults (Stevenson et al., 2002; 2003). Formal studies of the effectiveness of psychotherapy and coaching have not yet been carried out, but many adults with ADHD report they gain benefit from these approaches.

2.7.2 Special issues for adults diagnosed with ADHD

Educational and occupational disadvantage

Adults with ADHD commonly report a history of erratic academic performance and underachievement. These problems begin in primary school years and continue often into adolescence and young adulthood. This is a time when young people have important decisions to make regarding their future, yet, compared with their peers, young people with ADHD are less likely to make future plans (Young et al., 2005). Academic difficulties are most likely strongly associated with ADHD symptoms and individual or small group tuition and additional time in examinations may help reduce their impact.

With increasing age, in further education and/or the workplace, young people are expected to take greater personal responsibility for structuring and organising their time, prioritising tasks and meeting deadlines. This may explain why adults with ADHD often underachieve academically compared with the expectations and achievements of their family members. They often deviate from family expectations of job status by being employed in significantly lower-ranking jobs than those of their siblings. While some individuals with ADHD find work that is compatible with their symptoms, many report higher rates of employment problems, including a higher turnover of jobs and periods of unemployment. They also try out many different types of occupations as opposed to developing a career (Young et al., 2003).

Substance misuse

The reason for the increased level of substance use disorders among individuals with ADHD is complex. ADHD is a risk factor for substance use disorders through three potential mechanisms: (1) increased levels of reward-seeking (risk-taking) behaviours; (2) increased level of psychosocial impairments (ODD and CD in childhood that are themselves associated with substance misuse); and (3) self-medication for ADHD symptoms.

In most cases severe substance use disorders should be treated first because of the known risks and impairments associated with such behavior. Ongoing substance misuse will interfere with evaluation of ADHD treatment response — interactions will emerge and side effects can be intensified. While all substance use should be minimised before the start of pharmacological treatment, it should be recognised that the persistence of ADHD symptoms may maintain substance misuse in order to supplement medication to treat symptoms. Self-treatment with stimulants is however infrequent, while use of
alcohol and cannabis to dampen down symptoms associated with adult ADHD is far more common.

The concerns of some professionals that the use of stimulants in ADHD may lead to drug misuse either by sensitisation or as gateway to other drugs is not supported by available evidence. Although there may be a risk that some individuals with drug misuse problems may sell stimulants, it is important to note that when stimulants are used appropriately by adults they are not habit forming or addictive, and they do not cause euphoria.

Assessment with crime

Early onset and persistent antisocial behaviour is commonly associated with ADHD. Longitudinal studies have shown that ADHD independently predicts the development of antisocial behaviour, a developmental trajectory thought to be mediated by familial environmental influences (Bambinski et al., 1999; Taylor et al., 1996).

The association between ADHD and crime is becoming increasingly recognised and regarded with concern. Studies conducted in the US, Canada, Sweden, Germany, Finland and Norway suggest that around two-thirds of youth offending institutions and up to half of the adult prison population screened positively for ADHD in childhood and many continued to be symptomatic (for review see Young, in press). A sizeable number of individuals may have mild symptoms, and are in partial remission from their ADHD symptoms. All these studies have limitations in their methodologies, nevertheless it seems that the rate of young people and adults with ADHD in the prison population far exceeds that reported in the general population (that is, 3-4% of children and 1% of adults).

ADHD has been associated with early onset of criminal behaviour, even prior to age 11, and high rates of recidivism have been found in studies of young people detained in institutions. Young people are likely to have more severe and pervasive symptoms than older offenders detained in adult prisons, and this most likely accounts for the much higher prevalence of ADHD reported in youth offending institutions. For such youngsters the revolving door between prison, probation and the community is most likely strongly associated with the severity of their ADHD symptoms.

A meta-analysis of 20 ADHD studies reported a strong association between measures of ADHD and criminal/delinquent behaviour (Pratt et al., 2002) and concludes that effect size deserves theoretical explanation and that ADHD is a factor that should be considered in the delivery of treatment services, starting with early intervention programmes and going on to rehabilitation and supervision of adult offenders.
Differential diagnosis and mistaken diagnosis

In adulthood, comorbid problems include personality disorder (particularly antisocial and borderline), bipolar disorder, obsessive-compulsive disorder and, to a lesser extent, psychotic disorders. Adults with severe mental illness, such as schizophrenia, or severe learning disability often have problems with attention and activity levels yet these disorders do not occur any more frequently in people with ADHD than in the normal population (Mannuzza et al., 1998).

However, a difficulty is that attentional problems are common to many psychiatric disorders; thus adults with other psychiatric problems may appear to have symptoms of ADHD. On the other hand this also means that there is a pool of adult psychiatric patients in whom the diagnosis of ADHD has been unidentified and where ineffective treatments have been put in place for alternative diagnoses such as anxiety, depression, cyclothymia and personality disorder. This may account for the high rates of contact reported with mental health services for adults with ADHD (Dalsgaard et al., 2003), which in turn has associated cost implications.

ADHD in adults is frequently misdiagnosed because there are potential ‘traps’ for the inexperienced ADHD diagnostician. ADHD in adulthood does not present in the same way as ADHD in children who, for example, have more symptoms of hyperactivity. The age criterion is crucial to distinguish ADHD from later onset conditions and, unless care is taken to rule out the existence of the other conditions, there may be a high rate of falsely identified cases.

Psychopathology overlaps with other psychiatric conditions in two main ways. First, the chronic trait-like characteristics of ADHD symptoms that start in early childhood and persist into adulthood are frequently mistaken for traits of a personality disorder. This occurs, in particular, for cluster B personality disorders (that is, antisocial, borderline and emotionally unstable personality disorders) as these include symptoms that are commonly associated with adult ADHD such as mood instability, impulsivity and anger outbursts. Second, the volatile and irritable mood frequently reported by adults with ADHD is a symptom that overlaps with that seen in major affective disorders. Both bipolar disorder and ADHD are characterised by hyperactivity, distractibility, inattentiveness and mood changes. The distinction, however, is that the mood state of ADHD is irritable and volatile, rather than containing elements of euphoria and grandiosity. More recently, it has been argued that ‘juvenile mania’ of very early onset is characterised by a mood of irritability rather than euphoria, and by chronicity rather than fluctuation. If this change of definition is accepted, then this distinction from ADHD in young people will become highly problematic.
2.8 The economic cost of ADHD

The current estimated prevalence of children and adolescents with ADHD in the UK is 3.62% in boys and 0.85% in girls (Ford et al., 2003). Based on these figures and national population statistics (Office for National Statistics, 2007) it can be estimated that about 210,000 children aged 5-18 years are affected by ADHD in England and Wales, although only a minority of them will seek or receive medical treatment (Sayal et al. 2002; 2006). It has been estimated that in England and Wales, children with ADHD place a significant cost on health, social and education services, reaching £23 million for initial specialist assessment, and £14 million annually for follow-up care, excluding medication (King et al., 2006). These figures do not include costs incurred by adults with ADHD to health and social services.

In 2006, the total annual cost of prescribed stimulants and other drugs for ADHD in England was roughly £29 million, an increase of almost £5 million from the previous year (Prescription Cost Analysis, 2006). This increase in cost is attributed in part to the increased numbers of individuals being treated, and in part to a shift in prescribing towards more expensive extended-release formulations. Schlander (2007) estimated that, in 2012, the ADHD pharmacotherapy expenditures for children and adolescents may exceed £78 million in England, owing to an increase in the number of diagnosed cases, growing acceptance and intensity of pharmacotherapy, and higher unit costs of novel medications.

UK data on the economic burden of ADHD are limited, and figures from the US relate to a very different pattern of service provision and therefore they cannot be generalised to this country. Costs in the US have increased over the years due to a constantly increasing rate of identification by clinicians, with identification by paediatricians from 1.4% of children in 1979 to 9.2% in 1996 (Kelleher et al., 2000). Birnbaum and colleagues (2005) estimated that the total cost of ADHD in the US was $31.6 billion in 2000 prices, using a prevalence of 8% for boys, 4% for girls, 5% for male adults, and 3.5% for female adults. Of this cost, only 5% ($1.6 billion) related directly to treatment of the condition; the rest constituted other healthcare costs of children and adults with ADHD ($12.1 billion or 38%), healthcare costs of family members of individuals with ADHD (a striking $14.2 billion or 45%), and productivity losses of adults with ADHD and adult family members of persons with ADHD ($3.7 billion or 12%). These figures express excess costs, that is, additional costs of people with ADHD and their families, over and above respective costs of comparable control individuals. Pelham and colleagues (2007) reported an estimated annual cost of ADHD in children and adolescents approximately $14,600 per individual in 2005 prices (range from $12,000 to $17,500), consisting of healthcare costs (18%), costs to the education system (34%), as well as costs associated with crime and delinquency (48%). Using a prevalence rate of 5%, the authors estimated a total cost of children and adolescents with ADHD in the US reaching $42.5 billion (range from $36 to $52.5 billion).
Children with ADHD have been found to incur similar healthcare costs to children with asthma (Chan et al., 2002; Kelleher et al., 2001) and significantly higher to those of children without ADHD (Chan et al., 2002; Burd et al., 2003a; DeBar et al., 2004; De Ridder & Graeve, 2006; Leisbon et al., 2001; Swensen et al., 2003; Hakkaart-van Roijen et al., 2007; Guevara et al., 2001). This difference in costs was found to be related to a higher frequency in contacts with general practitioners and outpatient mental health services, visits to emergency departments and hospitalisations (DeBar et al., 2004; De Ridder & Graeve, 2006; Leisbon et al., 2001; Guevara et al., 2001). Moreover, children with ADHD are more likely to have other psychiatric comorbidities such as conduct disorder, oppositional defiant disorder, depression etc, compared to children without ADHD (Burd et al., 2003b), which significantly increase use of healthcare services and associated costs (Burd et al., 2003b, Hakkaart-van Roijen et al., 2007; Guevara et al., 2001, DeBar et al., 2004). Children with ADHD are also much more likely to have learning difficulties and to incur higher educational costs than children without ADHD; these costs may include costs of special education and the cost of either a school nurse or office staff administering medication to children with ADHD (Guevara & Mandell, 2003).

Adults with ADHD also incur high healthcare costs relative to matched adults without ADHD (Secnik et al., 2005a), despite the relatively low treatment rates of ADHD in this age cohort, estimated roughly at 25% (Birnbaum et al., 2005). Adults with ADHD are more likely to have a comorbid diagnosis of asthma, depression, anxiety, bipolar disorder, antisocial personality disorder and alcohol or drug misuse, which contributes further to the magnitude of medical expenses (Secnik et al., 2005a). However, even after controlling for the impact of comorbidities, adults with ADHD have been found to have higher inpatient and outpatient costs, as well as prescription drug costs. The annual estimated cost of an adult with ADHD in the US was $5,600 in 2001 prices, versus $2,700 for a matched adult without ADHD (Secnik et al., 2005a). Further to the increase in healthcare costs, the presence of ADHD in adults is associated with increased productivity losses due to absenteeism (Kessler et al., 2005 and Secnik et al., 2005a) and decrements in work performance (Kessler et al., 2005).

Apart from affected individuals, ADHD also places a substantial financial burden on carers and family in terms of out-of-pocket-expenses as well as productivity losses related to reduced ability to work and absenteeism (De Ridder & Graeve, 2006; Hakkaart-van Roijen et al., 2007; Swensen et al., 2003). In addition, families of children with ADHD bear a significant emotional burden, comprising strained family relationships (parent-child or sibling interactions), parenting distress and worry, and marital discord (Hankin et al., 2001).
It is evident, from the above review, that ADHD is associated with a significant financial and emotional cost to the healthcare system, education services, carers and family, and society as a whole. Efficient use of healthcare resources is required, so as to maximise the health benefit for children and adults with ADHD, and, at the same time, reduce the financial and psychological burden to society.
3 Methods used to develop this guideline

3.1 Overview

The development of this guideline drew upon methods outlined by NICE (The Guidelines Manual\(^1\) [NICE, 2006]). A team of healthcare professionals, lay representatives and technical experts known as the Guideline Development Group (GDG), with support from the NCCMH staff, undertook the development of a patient centred, evidence-based guideline. There are six basic steps in the process of developing a guideline:

- Define the scope, which sets the parameters of the guideline and provides a focus and steer for the development work.

- Define clinical questions considered important for practitioners and service users.

- Develop criteria for evidence searching and search for evidence.

- Design validated protocols for systematic review and apply to evidence recovered by search.

- Synthesise and (meta-)analyse data retrieved, guided by the clinical questions, and produce evidence summaries and profiles.

- Answer clinical questions with evidence-based recommendations for clinical practice.

The clinical practice recommendations made by the GDG are therefore derived from the most up-to-date and robust evidence base for the clinical and cost effectiveness of the treatments and services used in the treatment and management of ADHD. In addition, to ensure a service user and carer focus, the concerns of service users and carers regarding health and social care have been highlighted and addressed by recommendations agreed by the whole GDG.

3.2 The scope

Guideline topics are selected by the Department of Health and the Welsh Assembly Government, which identify the main areas to be covered by the guideline in a specific remit (for further information see The Guidelines Manual\(^2\)). The remit for this guideline was translated into a scope document by staff at the NCCMH (see Appendix 1).

\(^1\) Available from: www.nice.org.uk

\(^2\) Available from: www.nice.org.uk
The purpose of the scope was to:

- provide an overview of what the guideline will include and exclude
- identify the key aspects of care that must be included
- set the boundaries of the development work and provide a clear framework to enable work to stay within the priorities agreed by NICE and the NCCMH and the remit from the Department of Health/Welsh Assembly Government
- inform the development of the clinical questions and search strategy
- inform professionals and the public about the expected content of the guideline
- keep the guideline to a reasonable size to ensure that its development can be carried out within the allocated period.

The draft scope was subject to consultation with registered stakeholders over a 4-week period. During the consultation period, the scope was posted on the NICE website (www.nice.org.uk). Comments were invited from stakeholder organisations and the Guideline Review Panel (GRP). Further information about the GRP can also be found on the NICE website. The NCCMH and NICE reviewed the scope in light of comments received, and the revised scope was signed off by the GRP.

3.3 The Guideline Development Group

The GDG consisted of: professionals in clinical child and adolescent psychiatry, clinical child and adolescent psychology (and neuropsychology), psychiatry for learning disorders, developmental paediatrics, paediatrics (neurodisability), general practice, and nursing; academic experts in child and adolescent psychiatry, paediatric medicine research, forensic clinical psychology, and education; carers and a service user. In order to ascertain the experiences of children and young people of stimulant medication for ADHD, the NCCMH commissioned a focus group study. The guideline development process was supported by staff from the NCCMH, who undertook the clinical and health economics literature searches, reviewed and presented the evidence to the GDG, managed the process, and contributed to drafting the guideline.

3.3.1 Guideline Development Group meetings

Twenty GDG meetings were held between March 2006 and May 2008. During each day-long GDG meeting, in a plenary session, clinical questions and clinical evidence were reviewed and assessed, and recommendations formulated and reviewed. At each meeting, all GDG members declared any
potential conflicts of interest, and service user and carer concerns were routinely discussed as part of a standing agenda.

3.3.2 Topic groups
The GDG divided its workload along clinically relevant lines to simplify the guideline development process, and GDG members formed smaller topic groups to undertake guideline work in that area of clinical practice. Topic group 1 covered questions relating to diagnosis and assessment; topic group 2 covered psychological interventions; topic group 3 covered pharmacological interventions; topic group 4 covered education interventions; and topic group 5 covered dietary interventions. These groups were designed to efficiently manage the large volume of evidence appraisal prior to presenting it to the GDG as a whole. Each topic group was chaired by a GDG member with expert knowledge of the topic area (one of the health care professionals). Topic groups refined the clinical definitions of treatment interventions, reviewed and prepared the evidence with the systematic reviewer before presenting it to the GDG as a whole, and helped the GDG to identify further expertise in the topic. Topic group leaders reported the status of the group’s work as part of the standing agenda. They also introduced and led the GDG discussion of the evidence review for that topic and assisted the GDG Chair in drafting that section of the guideline relevant to the work of each topic group.

3.3.3 Service users and carers
Individuals with direct experience of services gave an integral service-user focus to the GDG and the guideline. The GDG included carers and a service user. They contributed as full GDG members to writing the clinical questions, helping to ensure that the evidence addressed their views and preferences, highlighting sensitive issues and terminology associated with ADHD, and bringing service-user research to the attention of the GDG. In drafting the guideline, they contributed to the editing of the first draft of the guideline’s introduction and to the writing of Chapter 4, and identified recommendations from the service user and carer perspective.

3.3.4 Special advisors
Special advisors, who had specific expertise in one or more aspects of treatment and management relevant to the guideline, assisted the GDG, commenting on specific aspects of the developing guideline and making presentations to the GDG. Appendix 3 lists those who agreed to act as special advisors.

3.3.5 National and international experts
National and international experts in the area under review were identified through the literature search and through the experience of the GDG members. These experts were contacted to recommend unpublished or soon-to-be published studies in order to ensure up-to-date evidence was included in the development of the guideline. They informed the group about
completed trials at the pre-publication stage, systematic reviews in the
process of being published, studies relating to the cost effectiveness of
treatment, and trial data if the GDG could be provided with full access to the
complete trial report. Appendix 5 lists researchers who were contacted.

3.4 Clinical questions

Clinical questions were used to guide the identification and interrogation of
the evidence base relevant to the topic of the guideline. The questions were
developed using a modified nominal group technique. The process began by
asking each topic group of the GDG to submit as many questions as possible.
The questions were then collated and refined by the review team. The GDG
members were then asked to rate each question for importance. At a
subsequent meeting, the GDG Chair facilitated a discussion to further refine
the questions. The results of this process were then discussed and consensus
reached about which questions would be of primary importance and which
would be secondary. The GDG aimed to address all primary questions, while
secondary questions would only be covered time permitting. The PICO
(patient, intervention, comparison and outcome) framework was used to help
formulate questions about interventions. This structured approach divides
each question into four components: the patients (the population under
study); the interventions (what is being done; or test/ risk factor); the
comparisons (other main treatment options); and the outcomes (the measures
of how effective the interventions have been; or what is being predicted/
prevented). Appendix 6 lists the clinical questions.

To help facilitate the literature review, a note was made of the best study
design type to answer each question. There are four main types of clinical
question of relevance to NICE guidelines. These are listed in Text Box 2. For
each type of question the best primary study design varies, where ‘best’ is
interpreted as ‘least likely to give misleading answers to the question’.

However, in all cases, a well conducted systematic review of the appropriate
type of study is likely to always yield a better answer than a single study.

Deciding on the best design type to answer a specific clinical or public health
question does not mean that studies of different design types addressing the
same question were discarded.
### Text Box 2: Best study design to answer each type of question

<table>
<thead>
<tr>
<th>Type of question</th>
<th>Best primary study design</th>
</tr>
</thead>
<tbody>
<tr>
<td>Effectiveness or other impact of an intervention</td>
<td>Randomised controlled trial (RCT); other studies that may be considered in the absence of an RCT are the following: internally / externally controlled before and after trial, interrupted time-series</td>
</tr>
<tr>
<td>Accuracy of information (for example, risk factor, test, prediction rule)</td>
<td>Comparing the information against a valid gold standard in a randomised trial or inception cohort study</td>
</tr>
<tr>
<td>Rates (of disease, patient experience, rare side effects)</td>
<td>Cohort, registry, cross-sectional study</td>
</tr>
<tr>
<td>Costs</td>
<td>Naturalistic prospective cost study</td>
</tr>
</tbody>
</table>

### 3.5 Systematic clinical literature review

The aim of the clinical literature review was to systematically identify and synthesise relevant evidence from the literature in order to answer the specific clinical questions developed by the GDG. Thus, clinical practice recommendations are evidence-based, where possible, and if evidence was not available, informal consensus methods were used (see section 3.5.7) and the need for future research was specified.

#### 3.5.1 Methodology

A stepwise, hierarchical approach was taken to locating and presenting evidence to the GDG. The NCCMH developed this process based on methods set out in *The Guidelines Manual* (NICE, 2006) and after considering recommendations from a range of other sources. These included:

- Clinical Policy and Practice Program of the New South Wales Department of Health (Australia)
- Clinical Evidence Online
- The Cochrane Collaboration
- Grading of Recommendations: Assessment, Development, and Evaluation (GRADE) Working Group
- New Zealand Guidelines Group
- NHS Centre for Reviews and Dissemination
- Oxford Centre for Evidence-Based Medicine
- Oxford Systematic Review Development Programme
- Scottish Intercollegiate Guidelines Network (SIGN)

---

3 Available from: www.nice.org.uk
3.5.2 The review process

After the scope was finalised, a more extensive search for systematic reviews and published guidelines was undertaken. Existing NICE guidelines were updated where necessary.

At this point, the review team, in conjunction with the GDG, developed an evidence map that detailed all comparisons necessary to answer the clinical questions. The initial approach taken to locating primary-level studies depended on the type of clinical question and availability of evidence.

The GDG decided which questions were best addressed by good practice based on expert opinion, which questions were likely to have a good evidence base and which questions were likely to have little or no directly relevant evidence. Recommendations based on good practice were developed by informal consensus of the GDG. For questions with a good evidence base, the review process depended on the type of clinical question (see below). For questions that were unlikely to have a good evidence base, a brief descriptive review was initially undertaken by a member of the GDG (see section 3.5.7).

Searches for evidence were updated between 6 and 8 weeks before the stakeholder consultation. After this point, studies were included only if they were judged by the GDG to be exceptional (for example, the evidence was likely to change a recommendation).

The search process for questions concerning interventions

For questions related to interventions, the initial evidence base was formed from well-conducted randomised controlled trials (RCTs) that addressed at least one of the clinical questions (the review process is illustrated in Flowchart 1). Although there are a number of difficulties with the use of RCTs in the evaluation of interventions in mental health, the RCT remains the most important method for establishing treatment efficacy. For other clinical questions, searches were for the appropriate study design (see above).

All searches were based on the standard mental health related bibliographic databases (EMBASE, MEDLINE, PsycINFO, Cochrane Library, ERIC) for all trials potentially relevant to the guideline. If the number of citations generated from this search was large (>5000), existing systematic reviews and question-specific search filters were developed to restrict the search while minimising loss of sensitivity.

Where the evidence base was large, recent high-quality English-language systematic reviews were used primarily as a source of RCTs (see Appendix 10 for quality criteria used to assess systematic reviews). However, in some circumstances existing data sets were utilised. Where this was the case, data were cross-checked for accuracy before use. New RCTs meeting inclusion
criteria set by the GDG were incorporated into the existing reviews and fresh analyses performed.

After the initial search results were scanned liberally to exclude irrelevant papers, the review team used a purpose built ‘study information’ database to manage both the included and the excluded studies (eligibility criteria were developed after consultation with the GDG). For questions without good-quality evidence (after the initial search), a decision was made by the GDG about whether to (a) repeat the search using subject-specific databases (for example, CINAHL, AMED, SIGLE or PILOTS), (b) conduct a new search for lower levels of evidence, or (c) adopt a consensus process (see section 3.5.7). Future guidelines will be able to update and extend the usable evidence base starting from the evidence collected, synthesised and analysed for this guideline.
Flowchart 1: Guideline Review Process

1. **NCCMH Review team tasks**
   - Brief search for recent SRs to help inform the development of the scope
   - Conduct systematic search for relevant systematic reviews (initial 5 year limit)
   - Perform first scan; retrieve all eligible papers for more detailed evaluation
   - Apply eligibility/quality criteria to retrieved papers
   - Produce evidence map with all comparisons necessary to answer clinical questions
   - Consult GDG about appropriate level of evidence to begin searching for
   - Conduct systematic search for relevant level(s) of evidence
   - Scan titles and abstracts & apply eligibility criteria liberally; cross-check excluded
   - Check SRs for additional evidence
   - Set up Access database according to evidence map
   - Enter study info. into database & apply eligibility/quality criteria
   - Update evidence map - highlight areas without evidence
   - Consult GDG about likely-likelihood of lower levels of evidence
   - For questions likely to have lower levels of evidence, conduct new question specific search

2. **GDG tasks**
   - Draft clinical questions with help from GDG chairperson
   - No. of citations excluded; No. that could not be located
   - No. of citations excluded
   - Develop clinical question specific search filters:
     - Update existing high-quality SRs
     - Run new filters only where necessary
   - Finalise clinical questions
   - Help produce evidence map
   - Consider known RCT evidence
   - For questions unlikely to have lower levels of evidence, begin consensus process
   - For questions unlikely to have lower levels of evidence, begin consensus process

3. **Consider known available evidence for each question**
In addition, searches were made of the reference lists of all eligible systematic reviews and included studies, as well as the list of evidence submitted by stakeholders. Known experts in the field (see Appendix 5), based both on the references identified in early steps and on advice from GDG members, were sent letters requesting relevant studies that were in the process of being published. In addition, the tables of contents of appropriate journals were periodically checked for relevant studies.

The search process for questions of diagnosis and prognosis

For questions related to diagnosis and prognosis, the search process was the same as described above, except that the initial evidence base was formed from studies with the most appropriate and reliable design to answer the particular question. That is, for questions about diagnosis, the initial search was for systematic reviews and meta-analyses as well as cross-sectional, factor analytic, genetic and diagnostic studies; for questions about prognosis, it was for cohort studies of representative patients. In situations where it was not possible to identify a substantial body of appropriately designed studies that directly addressed each clinical question, a consensus process was adopted (see section 3.5.7).

Search filters

Search filters developed by the review team consisted of a combination of subject heading and free-text phrases. Specific filters were developed for the guideline topic, and where necessary, for each clinical question. In addition, the review team used filters developed for systematic reviews, RCTs and other appropriate research designs (see Appendix 8).

Study selection

All primary-level studies included after the first scan of citations were acquired in full and re-evaluated for eligibility at the time they were being entered into the study information database (see Appendix 9 for screen-shots of the database). Specific eligibility criteria were developed for each clinical question and are described in the relevant clinical evidence chapters. Eligible systematic reviews and primary-level studies were critically appraised for methodological quality (see Appendix 10 for the quality checklists). The eligibility of each study was confirmed by at least one member of the appropriate topic group.

For some clinical questions, it was necessary to prioritise the evidence with respect to the UK context (that is, external validity). To make this process explicit, the topic groups took into account the following factors when assessing the evidence:

- participant factors (for example, gender, age, ethnicity)

4 Unpublished full trial reports were also accepted where sufficient information was available to judge eligibility and quality (see section on unpublished evidence).
• provider factors (for example, model fidelity, the conditions under which
the intervention was performed and the availability of experienced staff to
undertake the procedure)

• cultural factors (for example, differences in standard care and differences
in the welfare system).

It was the responsibility of each topic group to decide which prioritisation
factors were relevant to each clinical question in light of the UK context and
then decide how they should modify their recommendations.

Unpublished evidence

The GDG used a number of criteria when deciding whether or not to accept
unpublished data. First, the evidence must have been accompanied by a trial
report containing sufficient detail to properly assess the quality of the data.
Second, the evidence must be submitted with the understanding that data
from the study and a summary of the study’s characteristics would be
published in the full guideline. Therefore, the GDG did not accept evidence
submitted as commercial in confidence. However, the GDG recognised that
unpublished evidence submitted by investigators might later be retracted by
those investigators if the inclusion of such data would jeopardise publication
of their research.

3.5.3 Data extraction

Outcome data were extracted from all eligible studies, which met the quality
criteria, into RevMan 4.2.10 (Review Manager, The Cochrane Centre, 2003) or
Word tables. Studies with factor analysis were quality assessed using a
checklist elaborated and agreed by the GDG members (see chapter 5).

For each outcome, a hierarchy of most suitable outcome measures was agreed
upon by the GDG members. If a study reported more than one relevant
outcome measure for a given outcome, only the measure with the highest
hierarchy was included in the meta-analysis.

For a given outcome (continuous and dichotomous), where more than 50% of
the number randomised to any group were not accounted for by trial
authors, the data were excluded from the review because of the risk of bias.
However, where possible, dichotomous efficacy outcomes were calculated on
an intention-to-treat basis (that is, a ‘once-randomised-always-analyse’ basis).
This assumes that those participants who ceased to engage in the study – from
whatever group – had an unfavourable outcome. This meant that the 50% rule
was not applied to dichotomous outcomes where there was good evidence
that those participants who ceased to engage in the study were likely to have
an unfavourable outcome (in this case, early withdrawals were included in

5 ‘Accounted for’ in this context means using an appropriate method for dealing with missing data (for
example, LOCF or a regression technique).
both the numerator and denominator). Adverse effects were entered into 1
Review Manager as reported by the study authors because it was usually not 2
possible to determine whether early withdrawals had an unfavourable 3
outcome. For the outcome ‘leaving the study early for any reason’, the 4
denominator was the number randomised.

Where some of the studies failed to report standard deviations (for a 5
continuous outcome), and where an estimate of the variance could not be 6
computed from other reported data or obtained from the study author, the 7
following approach was taken:

1. When the number of studies with missing standard deviations was 8
small and when the total number of studies was large, the pooled 9
standard deviation from all the other available studies in the same 10
meta-analysis was used. In this case, the appropriateness of the 11
imputation was made by comparing the standardised mean differences 12
(SMDs) of those trials that had reported standard deviations against 13
the hypothetical SMDs of the same trials based on the imputed 14
standard deviations. If they converged, the meta-analytical results 15
were considered to be reliable.

2. When the number of studies with missing standard deviations was 16
large or when the total number of studies was small, standard 17
deviations were taken from a previous systematic review (where 18
available), because the small sample size may allow unexpected 19
deviation due to chance. In this case, the results were considered to be 20
less reliable.

The meta-analysis of survival data, such as time to any mood episode, was 21
based on log hazard ratios and standard errors. Since individual patient data 22
were not available in included studies, hazard ratios and standard errors 23
calculated from a Cox proportional hazard model were extracted. Where 24
necessary, standard errors were calculated from confidence intervals or p- 25
value according to standard formulae (for example, Cochrane Reviewers’ 26
Handbook 4.2.2.). Data were summarised using the generic inverse variance 27
method using Review Manager.

Consultation was used to overcome difficulties with coding. Data from 28
studies included in existing systematic reviews were extracted independently 29
by one reviewer and cross-checked with the existing data set. Where possible, 30
two independent reviewers extracted data from new studies. Where double 31
data extraction was not possible, data extracted by one reviewer was checked 32
by the second reviewer. Disagreements were resolved with discussion. Where 33
consensus could not be reached, a third reviewer resolved the disagreement. 34
Masked assessment (that is, blind to the journal from which the article comes,

6 Based on the approach suggested by Furukawa et al. (2006)
the authors, the institution and the magnitude of the effect) was not used since it is unclear that doing so reduces bias (Jadad et al., 1996; Berlin, 2001).

3.5.4 Synthesising the evidence

Where possible, meta-analysis was used to synthesise the evidence using Review Manager. If necessary, reanalyses of the data or sub-analyses were used to answer clinical questions not addressed in the original studies or reviews.

Dichotomous outcomes were analysed as relative risks (RR) with the associated 95% CI (for an example, see Figure 1). A relative risk (also called a risk ratio) is the ratio of the treatment event rate to the control event rate. An RR of 1 indicates no difference between treatment and control. In Figure 1, the overall RR of 0.73 indicates that the event rate (that is, non-remission rate) associated with intervention A is about three quarters of that with the control intervention or, in other words, the relative risk reduction is 27%.

The CI shows with 95% certainty the range within which the true treatment effect should lie and can be used to determine statistical significance. If the CI does not cross the ‘line of no effect’, the effect is statistically significant.

Figure 1: Example of a forest plot displaying dichotomous data

Continuous outcomes were analysed as weighted mean differences (WMD), or as a standardised mean difference (SMD) when different measures were used in different studies to estimate the same underlying effect (for an example, see Figure 2). If provided, intention-to-treat data, using a method such as ‘last observation carried forward’, were preferred over data from completers.

Test for heterogeneity: Chi² = 6.13, df = 4 (P = 0.19), I² = 34.8%
Test for overall effect: Z = 4.98 (P < 0.00001)

To check for consistency between studies, both the I² test of heterogeneity and a visual inspection of the forest plots were used. The I² statistic describes the proportion of total variation in study estimates that is due to heterogeneity (Higgins & Thompson, 2002). The I² statistic was interpreted in the following way:

- > 50%: notable heterogeneity (an attempt was made to explain the variation, for example outliers were removed from the analysis or sub-analyses were conducted to examine the possibility of moderators. If studies with heterogeneous results were found to be comparable, a random-effects model was used to summarise the results (DerSimonian & Laird, 1986). In the random-effects analysis, heterogeneity is accounted for both in the width of CIs and in the estimate of the treatment effect. With decreasing heterogeneity the random-effects approach moves asymptotically towards a fixed-effects model).

- 30 to 50%: moderate heterogeneity (both the chi-squared test of heterogeneity and a visual inspection of the forest plot were used to decide between a fixed and random-effects model)

- < 30%: mild heterogeneity (a fixed-effects model was used to synthesise the results).

To explore the possibility that the results entered into each meta-analysis suffered from publication bias, data from included studies were entered, where there was sufficient data, into a funnel plot. Asymmetry of the plot was taken to indicate possible publication bias and investigated further.

An estimate of the proportion of eligible data that were missing (because some studies did not include all relevant outcomes) was calculated for each analysis.

The Number Needed to Treat - Benefit (NNTB) or the Number Needed to Treat - Harm (NNTH) was reported for each outcome where the baseline risk (i.e. control group event rate) was similar across studies. In addition, NNTs calculated at follow-up were only reported where the length of follow-up was similar across studies. When the length of follow-up or baseline risk varies
(especially with low risk), the NNT is a poor summary of the treatment effect (Deeks, 2002).

Study characteristics tables, generated automatically from the study database, were used to summarise general information about each study (see Appendix 17). Where meta-analysis was not appropriate and/or possible, the reported results from each primary-level study were also presented in the included studies table (and included, where appropriate, in a narrative review).

3.5.5 Presenting the data to the GDG

Study characteristics tables and, where appropriate, forest plots generated with Review Manager were presented to the GDG in order to prepare a GRADE evidence profile table for each review and to develop recommendations.

GRADE evidence profile tables

A GRADE evidence profile was used to summarise both the quality of the evidence and the results of the evidence synthesis (see Table 4 for an example of an evidence profile). For each outcome, quality may be reduced depending on the study design, limitations (based on the quality of individual studies; see Appendix 10 for the quality checklists), inconsistency (see section 3.5.4 for how consistency was measured), indirectness (that is, how closely the outcome measures, interventions and participants match those of interest), and imprecision (based on the confidence interval around the effect size). For observational studies, the quality may be increased if there is a large effect, plausible confounding would have changed the effect, or there is evidence of a dose-response gradient (details would be provided under the other considerations column). Each evidence profile also included a summary of the findings: number of patients included in each group, an estimate of the magnitude of the effect, and the overall quality of the evidence for each outcome. The quality of the evidence was based on the quality assessment components (study design, limitations to study quality, consistency, directness and any other considerations) and graded using the following definitions:

- **High** = Further research is very unlikely to change our confidence in the estimate of the effect
- **Moderate** = Further research is likely to have an important impact on our confidence in the estimate of the effect and may change the estimate
- **Low** = Further research is very likely to have an important impact on our confidence in the estimate of the effect and is likely to change the estimate
- **Very low** = Any estimate of effect is very uncertain.

</table>

¹ The upper confidence limit includes an effect that, if it were real, would represent a benefit that, given the downsides, would still be worth it.
² The lower confidence limit crosses a threshold below which, given the downsides of the intervention, one would not recommend the intervention.
³ Random-effects model.
⁴ 95% CI crosses the minimal importance difference threshold.
For further information about the process and the rationale of producing an evidence profile table, see GRADE (2004).

**Forest plots**

Each forest plot displayed the effect size and CI for each study as well as the overall summary statistic. The graphs were organised so that the display of data in the area to the left of the 'line of no effect' indicated a 'favourable' outcome for the treatment in question.

### 3.5.6 Forming the clinical summaries and recommendations

Once the GRADE profile tables relating to a particular clinical question were completed, summary tables incorporating important information from the GRADE profiles were developed (these tables are presented in the evidence chapters). Finally, the systematic reviewer in conjunction with the topic group lead produced a clinical evidence summary.

Once the GRADE profiles and clinical summaries were finalised and agreed by the GDG, the associated recommendations were drafted, taking into account the trade-off between the benefits and downsides of treatment as well as other important factors. These included economic considerations, values of the development group and society, and the group’s awareness of practical issues (Eccles et al., 1998).

### 3.5.7 Method used to answer a clinical question in the absence of appropriately designed, high-quality research

In the absence of level-I evidence (or a level that is appropriate to the question), or where the GDG were of the opinion (on the basis of previous searches or their knowledge of the literature) that there were unlikely to be such evidence, either an informal or formal consensus process was adopted. This process focused on those questions that the GDG considered a priority.

**Informal consensus**

The starting point for this process of informal consensus was that a member of the topic group identified, with help from the systematic reviewer, a narrative review that most directly addressed the clinical question. Where this was not possible, a brief review of the recent literature was initiated.

This existing narrative review or new review was used as a basis for beginning an iterative process to identify lower levels of evidence relevant to the clinical question and to lead to written statements for the guideline. The process involved a number of steps:

1. A description of what is known about the issues concerning the clinical question was written by one of the topic group members.
2. Evidence from the existing review or new review was then presented in narrative form to the GDG and further comments were sought about the evidence and its perceived relevance to the clinical question.

3. Based on the feedback from the GDG, additional information was sought and added to the information collected. This may include studies that did not directly address the clinical question but were thought to contain relevant data.

4. If, during the course of preparing the report, a significant body of primary-level studies (of appropriate design to answer the question) were identified, a full systematic review was conducted.

5. At this time, subject possibly to further reviews of the evidence, a series of statements that directly addressed the clinical question were developed.

6. Following this, on occasions and as deemed appropriate by the GDG, the report was then sent to appointed experts outside the GDG for peer review and comment. The information from this process was then fed back to the GDG for further discussion of the statements.

7. Recommendations were then developed and could also be sent for further external peer review.

8. After this final stage of comment, the statements and recommendations were again reviewed and agreed upon by the GDG.

3.6 Health economics methods

The aim of the health economics was to contribute to the guideline’s development by providing evidence on the cost effectiveness of interventions for children, young people and adults with ADHD covered in the guideline, in areas with likely major resource implications. This was achieved by:

- systematic literature review of existing economic evidence
- economic modelling, in areas where economic evidence was lacking or was considered inadequate to inform decisions.

3.6.1 Key economic issues

The following economic issues relating to diagnosis and management of children, young people and adults with ADHD were identified by the GDG in collaboration with the health economist as primary key issues that should be considered in the guideline:

- the cost effectiveness of parent training for preschool-age children and cognitive behavioural therapy (CBT) for older children and adolescents
• the cost effectiveness of CBT for adults with ADHD
• the relative cost effectiveness between different pharmacological interventions for children and adults with ADHD
• the cost effectiveness of intensive medication management for children
• the relative cost effectiveness of psychological, pharmacological and combination therapies for children.

In addition, literature on health-related quality of life of children with ADHD was systematically searched to identify studies reporting appropriate utility weights that could be utilised in a cost-utility analysis.

The rest of this section describes the methods adopted in the systematic literature review of economic studies. Methods employed in economic modelling are described in the respective sections of the guideline.

3.6.2 Search strategy

For the systematic review of economic evidence on treatments for ADHD the standard mental-health-related bibliographic databases (EMBASE, MEDLINE, CINAHL and PsycINFO) were searched. For these databases, a health economics search filter adapted from the Centre for Reviews and Dissemination at the University of York was used in combination with a general filter for ADHD. Additional searches were performed in specific health economics databases (NHS EED, OHE HEED), as well as in the HTA database. For the HTA and NHS EED databases, the general filter for ADHD was used. OHE HEED was searched using a shorter, database-specific strategy. Initial searches were performed in June 2006. The searches were updated regularly, with the final search between 4 and 6 weeks before the final submission to NICE.

In parallel to searches of electronic databases, reference lists of eligible studies and relevant reviews were searched by hand. Studies included in the clinical evidence review were also screened for economic evidence.

The systematic search for economic evidence resulted in 47 potentially relevant studies. Full texts of all potentially eligible studies (including those for which relevance/eligibility was not clear from the abstract) were obtained. These publications were then assessed against a set of standard inclusion criteria by the health economists, and papers eligible for inclusion were subsequently assessed for internal validity. The quality assessment was based on the checklists used by the British Medical Journal to assist referees in appraising full and partial economic analyses (Drummond & Jefferson, 1996) (see Appendix 12).
3.6.3 Selection criteria

The following inclusion criteria were applied to select studies identified by the economic searches for further analysis:

- No restriction was placed on language or publication status of the papers.
- Studies published from 1990 onwards were included. This date restriction was imposed in order to obtain data relevant to current healthcare settings and costs.
- Only studies from Organisation for Economic Co-operation and Development countries were included, as the aim of the review was to identify economic and health-related quality of life information transferable to the UK context.
- Selection criteria based on types of clinical conditions and patients were identical to the clinical literature review.
- Studies were included provided that sufficient details regarding methods and results were available to enable the methodological quality of the study to be assessed, and provided that the study’s data and results were extractable. Poster presentations or abstracts were in principle excluded; however, they were included if they reported additional data from studies which had already been published elsewhere and met the inclusion criteria, or if they contained appropriate input data required for economic modelling that were not otherwise available.
- Full economic evaluations that compared two or more relevant options and considered both costs and consequences (that is, cost-effectiveness analysis, cost-utility analysis, cost-consequences analysis or cost-benefit analysis) were included in the review. Health-related quality of life studies were included if they reported utility weights appropriate to use in a cost-utility analysis.

3.6.4 Data extraction

Data were extracted by the health economist using a standard economic data extraction form (see Appendix 13).

3.6.5 Presentation of economic evidence

The economic evidence identified by the health economics systematic review is summarised in the respective chapters of the guideline, following presentation of the clinical evidence. The characteristics and results of all economic studies included in the review are provided in the form of evidence tables in Appendix 14. Results of additional economic modelling undertaken alongside the guideline development process are also presented in the relevant chapters.
3.7 Focus group methodology

Besides making recommendations based on the clinical and cost effectiveness of interventions for ADHD, an important function of developing this guideline is capturing the voice of the service user; this is particularly pertinent where the service user is a young person.

In order to provide sufficient breadth of context and depth of understanding of children’s views on taking stimulant medicine, the NCCMH commissioned the London School of Economics to undertake a qualitative focus group study with children and young people on their perceptions of their use of stimulant medication, together with a review of the available literature on young people’s experiences. The full version of this report, including the extensive bibliography, can be found in Appendix 15, and a summary of the findings in Chapter 4.

Besides being reviewed by the GDG, the focus group proposal was also reviewed by a nationally sanctioned ethics committee and local R&D committees. The research team undertaking the focus group interviews and analyses were experienced both in qualitative methodologies and working with young people. Prior to data collection, they carefully researched the issues on the extra care required both in the design and execution of data collection methods in order to ensure that the information gathered was robust and useable, and that all ethical considerations relating to the vulnerable participant group were met.

3.7.1 Focus group participants

Participants in the study had all been diagnosed with ADHD and all were taking stimulant medication. They were recruited from clinics at three hospitals: Richmond Royal Hospital, London; the Maudsley Hospital, London; and Queen’s Medical Centre, Nottingham.

The sample consisted of 16 children (14 boys and two girls) ranging in age from nine to 15 years old. All were attending state schools and all were white, with the exception of one child who was of mixed race. Fifty percent of the children were living in two-parent homes, and 37% lived in single-mother homes. Two children lived with their fathers; and one child lived with his grandmother. Educational achievement and type of employment were used as indicators of socioeconomic status (CITE). A majority of parents had completed O-levels; one parent had attended university. Seventy-two percent of parents’ job types ranged from semi-skilled to skilled work. A majority of mothers did not report having employment.

---

7 Data was only available on mothers. Fathers’ educational achievement and job types would be more reliable indicators of socioeconomic status.
3.7.2 Data collection

Semi-structured focus groups were used to collect data about how children and adolescents experience stimulant medication. Allowing children to describe their experiences through qualitative interviews has been found to be both reliable and valid (Deatrick & Faux, 1991; Sorensen, 1992), and there is compelling evidence to suggest that children are competent research participants (Singh, 2007). Children’s competence as research participants is supported by the literature on children’s capacity and competence as patients. Children have been found to be capable of understanding the complexities of their condition; they have the capacity to give informed consent to invasive treatments, to contribute to deliberations over treatment strategies, and, in the case of diabetic children, to take responsibility for administering their own treatment (Alderson et al., 2006; Bluebond-Langner et al., 2005).

Thirteen children were interviewed as part of a series of focus groups. Three children were interviewed one-to-one, either because they were unable to attend the focus groups or because they preferred to be interviewed individually. The interviews took place in a room based at the hospital clinic and lasted approximately 1 hour. Written informed consent was obtained from one parent and also from the participant. Parents were also asked to complete a basic demographic questionnaire.

3.7.3 Focus group methodology

Focus groups are a widely used method in qualitative health research, and are often used when the research aim is to gather information in a little-understood or under-researched area. Focus groups elicit a range of experiences, opinions and feelings about a topic (Krueger & Casey, 2000), and the interaction in focus groups can result in enhanced disclosure, as participants challenge each other’s perceptions and opinions.

The collective nature of focus group discussion is often said to provide ‘more than the sum of its parts’ (Wilkinson, 1998). Interactive data result in enhanced disclosure, better understanding of participants’ own agendas, the production of more elaborated accounts, and the opportunity to observe the co-construction of meaning in action. Focus groups are, then, an ideal method for exploring people’s own meanings and understandings of health and illness.

Although focus groups with children are less commonly used in social science health research, market research with children, including market research around health and well being, more commonly uses a focus group approach (for example, Caruana & Vassallo, 2003). Focus groups with children provide access to children’s own language and concepts, and encourage elaboration of children’s own concerns and agendas.
3.7.4 Interviews

Interviews were conducted in a conversational style and included a standard set of open-ended questions (see Appendix 15 for the complete topic guide).

The first half of the interview involved posing broad questions that were followed by more specific probe questions. Principle areas of investigation included children’s understanding of ADHD diagnosis and behaviours, perceptions of how tablets helped them (or not), experiences of stigma, experiences of non-drug interventions for ADHD behaviours, impact of tablets on children’s perceptions of personal agency, and experiences of psychiatric services.

The second half of the interview involved a set of games and a vignette which provided children with the opportunity to elaborate their experiences and perceptions of medication in more creative and imaginative ways. The primary aims in this section of the interview were to contextualise children’s perceptions of tablets within their perceptions, understandings and/or experiences of other means of improving behaviour, and to elicit their ideas about resources that could help them have more positive experiences of an ADHD diagnosis and of medication.

The following methods were used in the second half of the interview (see Appendix 15 for further elaboration):

a. Children were asked to compare how the experience of taking tablets was similar to, or different from, doing other things that were commonly considered good for them.

b. Children were asked to respond to a vignette that elicited their ideas about what sorts to things can help a child’s behaviour (figure 3)

c. Children were asked to think up and discuss an invention that could help children with ADHD.

d. Children were asked to rank order a list of items that described common concerns voiced by school-age children. Each item was written on a separate card, and children were asked to put the cards in order of what they worried about most, to what they worried about least. The list included global warming, having ADHD, taking tablets, exams, homework, friendships. Global warming and exams were included on the list because these concerns were found to be significant sources of anxiety in a recent large cohort study of UK school-age children (Alexander & Hargreaves, 2007)
3.7.5 Data analysis

All interviews were digitally recorded, transcribed, and analysed using rigorous qualitative coding practices that meet established criteria of validity and relevance to qualitative health research (Mays & Pope 2000). Focus groups were coded using content analysis. The coding process captured the data on two analytic levels: individual concepts were coded first, and then these concepts were grouped together under higher order themes. Systematic coding meant that it was possible to code at both the individual level and at the group level. Group level data were represented in the frequency with which concepts and themes were expressed by group members. Transcript excerpts elucidated the meaning of codes.

A coding frame was drawn up by the lead author of the study, Ilina Singh, and validated within a coding team. The coding team applied the same codes to a transcript in order to discuss their definition and validity. This discussion resulted in refinements to the structure of categories and sub-categories, as well as refinements to individual codes. The coding team was able to reach agreement on the validity of a majority of codes.

3.8 Stakeholder contributions

Professionals, service users, and companies have contributed to and commented on the guideline at key stages in its development. Stakeholders for this guideline include:

- service user/carer stakeholders: the national service user and carer organisations that represent people whose care is described in this guideline
- professional stakeholders: the national organisations that represent healthcare professionals who are providing services to service users
- commercial stakeholders: the companies that manufacture medicines used in the treatment of ADHD.
- Primary Care Trusts
- Department of Health and Welsh Assembly Government.

Stakeholders have been involved in the guideline’s development at the following points:

- commenting on the initial scope of the guideline and attended a briefing meeting held by NICE
- Commenting on the draft of the guideline.
3.9 Validation of this guideline

Registered stakeholders had an opportunity to comment on the draft guideline, which was posted on the NICE website during the consultation period. The GRP also reviewed the guideline and checked that stakeholders' comments had been addressed.

Following the consultation period, the GDG finalised the recommendations and the NCCMH produced the final documents. These were then submitted to NICE. NICE then formally approved the guideline and issued its guidance to the NHS in England and Wales.
4 The experience of treatment and care for ADHD

4.1 Introduction
This chapter aims to provide a service user and carer context for the chapters on interventions and services for ADHD. The first part contains personal accounts from people with ADHD and their families/carers, while the second part summarises the results of a qualitative focus group study with children and young people, which set out to ascertain how they felt about the diagnosis and having treatment (particularly taking stimulant medication for ADHD). There is also a review of the available literature on people’s experiences of ADHD and its treatment.

4.2 The experience of ADHD

4.2.1 Introduction
This section presents personal accounts from people with ADHD and their families/carers. The views represented here are illustrative only and are not intended to be representative of the experience of people with ADHD and their families and carers.

The writers of the accounts were contacted primarily through the service user and carer representatives on the GDG. The people who were approached to write the accounts were asked to consider a number of questions when composing their narratives. These included:

- What is the nature of your experience of living with ADHD?
- When were you diagnosed and how old were you; how did you feel about the diagnosis or ‘label’?
- Do you think that any life experiences led to the onset of the condition? If so, please describe if you feel able to do so.
- When did you seek help from the NHS and whom did you contact? (Please describe this first contact.)
- What possible treatments were discussed with you?
- What treatment(s) did you receive?
- Was the treatment(s) helpful? (Please describe what worked for you and what didn’t work for you.)
- How would you describe your relationship with your practitioner(s)? (GP/community psychiatric nurse/psychiatrist, etc.)
- Did you attend a support group and was this helpful? Did any people close to you help and support you?
• How has the nature of the condition changed over time?
• How do you feel now?
• If your condition has improved, do you use any strategies to help you to stay well? If so, please describe these strategies.
• In what ways has ADHD affected your everyday life (such as schooling, employment and making relationships) and the lives of those close to you?

The questions for carers were based on the above.

The first two accounts from people with ADHD (A and B) are written by adults reflecting on their experience. The third account (C) is by a young person (male) still at school. In the accounts from parents, one is written by the mother (parent E) of the child in personal account C. Two of the accounts (B and D) are written by the same person; account D was written from the perspective of a mother of a child with ADHD and account B was written with hindsight, reflecting on how her son’s behaviour mirrored her own behaviour as a child and adolescent.

4.2.2 Personal accounts from people with ADHD

Personal account (A)

My mother comments that she immediately saw many differences between me as a baby and my three older sisters; however she ascribed this to me being a boy. As a baby I used to bite my mum so much that she had bruises all down her arm. I was obsessed with things involving movement, especially cars. Apparently I used to look at the main road watching the cars for hours at a time, murmuring my first words – ‘car’ or ‘bus’. When I first went to nursery I refused to interact or even share a room with the other children, instead playing with cars in another room, and reacting aggressively to anyone who tried to interfere. I frequently had tantrums and made no friends. My mother, who is a paediatrician, feared I may have obsessive-compulsive disorder, but at this time did not follow it up. My main other problem was sleep; as a child it would regularly take me a long time to switch off and get to sleep, and this has stayed with me my whole life. (I now find I can function well on only about 5 hours a night, possibly due to my hyperactivity, and I regularly use a herbal mix to help me get to sleep.)

Starting at my first primary school was a mixed experience. I did not make friends easily and although I was fairly bright I did not apply myself to my work with any commitment or enthusiasm. The older I got the more trouble I got into: answering back to teachers, lying to other children and performing stupid pranks to try and gain credibility. When my parents moved away from the area and I started a new school I had even more problems. I did not like the school or my teachers. I was rude, lazy and aggressive and I lied constantly; as a result I was very lonely. I struggled to make any friends in the
new village and it was left up to my mum to try and fulfil my constant
demands outside school.

When I was 7 years old and had only been in the new school for less than two
terms, my parents took me to see an educational psychologist. I completed a
few tests and had a short interview with him. He concluded that I had some
obsessive tendencies, anxiety and esteem problems. He recommended to my
parents that I move to a smaller school with smaller classes. This meant going
to a private school, where I was relatively happy for 2 years; I enjoyed
boarding and found myself able to build good relationships with other
children. I also really enjoyed sport, and eventually captained the cricket and
rugby teams. I still got into trouble a fair amount, but the headmaster was
very patient and not punitive.

My fortunes changed when a new headmaster came to the school. He and I
did not see eye to eye from the start. He was a military-styled bully who
suspended me on the second day he was there for getting into a fight with his
son (who received no punishment). From then on he assumed that I was an
idle, lying bully, and in time this is what I became. Driving him mad became a
source of great enjoyment to me; I was suspended on numerous occasions,
though he never carried through the expulsion which he constantly
threatened. His punishments were severe and eventually he took away any
self-respect I had left when he forced a confession out of me for something I
hadn’t done, in the process helping me to lose a good friend. At the age of 12
my behaviour had become enough of a concern for a visit to a private
paediatrician, which my mum arranged. She had been fairly sure for some
time that I had ADHD and contacted a paediatrician in London. He
immediately diagnosed me with ADHD, and wanted to prescribe me
methylphenidate, however my family history of epilepsy was thought at this
time to be a risk, so I was not given it. I was not offered any other treatment
either medical or behavioural, and my mum, who by this time ran a
paediatric ADHD clinic, didn’t feel like she needed any support at home.

My senior year was perhaps one of my best. We were a very small group
(only ten in the class), and my teacher made a huge difference to my
experience of school when he realised that a lot of the time I did not ignore
people but in fact did not hear them. I had small plastic drainage tubes (to
treat glue ear) inserted into my ears, and this had an immediate and positive
impact. When I got to the end of my senior year I passed my exams and went
off to public school.

My headmaster, who described me as his ‘hair shirt’, had one last punishment
in store for me however, ensuring that an absolutely terrible reference would
got to my new school before I did. The effect was so obvious it was as if
everyone had been told that I was someone to watch out for. I made no
friends, did not apply myself to either study or sport, and hated the other
activities we had to do. The place was like a prison and the routine
suffocating. After 6 weeks I walked out of school and into a local shop where I
shoplifted an item in obvious view of the camera. When I was called before
the headmaster the following day I hoped I was going to be expelled.
However I got put on ‘headmaster’s jankers’ instead, a dehumanising
experience involving complete and highly visible exclusion from normal
school activities and about 4 hours of manual labour per day. After half-term I
refused to go back.

I then went to the local comprehensive, where I started with quite high hopes
(I knew some people from my time in the two local primary schools).
However, I was teased relentlessly as a ‘poof’ or ‘posh boy’ for my time at
private school, and my teachers thought that my ADHD was an excuse for
needless bad behaviour and laziness, and as such I wasn’t offered any
treatment or intervention for it. Once again this became a mould I fitted into: I
ignored my studies completely, was often in trouble, bullied other children,
stopped participating in the sport I had previously enjoyed, and on several
occasions I took flasks of alcohol into school and would drink during lessons.
I still lied compulsively, and stole frequently from other children and from
my parents. I had also started smoking when I was 11 and this became
heavier; I regularly skived off school to smoke, drink or get high. I quickly put
on weight, and the bigger I became the more I ate and drank, until at 16,
despite being below average height, I was almost 16 stone. I barely passed my
GCSE exams, and though I was admitted onto an A-level course, I stuck it for
less than a term before I decided to leave school.

When I left home and got my own place, there were many times when I felt
much more content. I started to make some good friends, with whom I still
remain very close today. However, drugs and alcohol were still an increasing
problem. I worked in pubs and clubs and would get drunk most days; I
experimented with many drugs—mostly pills and LCD. I frequently drove
while in a dangerous state, and although I had many friends, lying was still a
problem. I got bored with the jobs I did very quickly—one lasted only a single
day, and the most I managed was 6 months. Eventually things fell apart
completely following a disastrous relationship. I returned home depressed
and feeling like I had failed. My father and I did not really see eye to eye at
this point; he could not understand that I had no interest in going to
university, we argued and I ended up leaving again.

For the next 3 or 4 months I lived a nomadic existence; I wandered round the
town with a friend who was in a similar position, and we stopped at various
places to buy, sell or take drugs, and slept on sofas or in the park. Though this
experience was cathartic in some ways, and I built some very strong
relationships, after some time it became clear that I would have to do
something with my life. My mum, who had stayed in regular contact with me,
told me that my dad had managed to get an interview for me in London. I

ADHD: full guideline DRAFT (January 2008)
was afraid of leaving the life I had created for myself, and London seemed like a very frightening prospect; however, a close friend managed to talk me round and I went for the interview and got the job. My sister in London offered me a room in her house.

I had not thought about my ADHD for a long time, and I had not made the connection between it and dropping out of school, not committing to a job and my extensive drug and alcohol abuse. (Only later did I discover that the disorder was also associated with my frequent trips to casualty: I have broken both my funny bones, have cracked ribs and have fractured my skull, as well as having many injuries from cycling accidents. I also had five car accidents in my first 2 years of driving.) However, signs of my ADHD came back to me in my new job, which was very repetitive laboratory work. After about 2 months my careless mistakes – due to inattention – were causing a problem, and I moved departments and left a month later. I fell back on my pub and club experience, which left me short of money and exhausted. I started drinking and using drugs heavily again.

Eventually I went to see a psychiatrist in London, a very compassionate and patient man, who I spoke to for about an hour, and who I really opened up to. He described me as an underachiever and said he thought I was depressed, for which he offered me drugs, but I refused them. Instead I made the decision to go back to college to try and complete my A-levels. I had a fantastic experience on the course and excelled in my studies, managing to get into a top university. I found disciplining myself at university very difficult due to the lack of structure and availability of drugs and alcohol. In my first year, after another painful relationship ended, I found myself drinking alone most days and neglecting my studies. I barely passed the end of year exams, and this was sufficient to scare me into working harder. Towards the end of my second year I met my current girlfriend, who helped me cut down on my drinking and knuckle down to my studies. We are now considering marriage—she has made a massive difference to my life and I have great faith in our future.

My educational re-birth has taken me through a degree and masters and I am now in the final year of a PhD. This most recent experience has been a great challenge requiring long-term commitment, organisation, concentration, and a huge amount of reading, research and analysis. However, since giving up alcohol over 2 months ago, I have a renewed enthusiasm for the project and am confident of a successful conclusion.

I have never taken drugs for my ADHD, though I have no doubt they would help me. At times the symptoms have impaired me greatly, and they remain a challenge, as does my depression. However I have managed to overcome these challenges through other means. There are many things that I do which help greatly: regular exercise is a must, and without it I get restless and
depressed. I also ensure that I reserve plenty of time for creative activities—I
have played the guitar for many years and love composing, performing and
recording music. I also love writing, something my current work lends itself
very well to, and I have already had three papers published. I had a very
difficult experience at school and there are many things I would do differently
if I could. However, I am currently happier than I have ever been and
enjoying a very demanding new world of work, in which I use my difficult
experiences at school to try and effect change in the systems and structures of
our institutions, particularly with those children who are marked out as
difficult and suffer as a consequence.

It is only in the last 5 years, since I have been working on ADHD
academically as part of my graduate studies, that I have started to consider
the role it may have played in my life. Previously I had never acknowledged
that there was a causal or explanatory role for the disorder. I did not use it as
a means to explain my behaviour at school, and I felt as indifferent to my
diagnosis as I did to the demands of teachers. My perspective now, which is a
combination of personal experience and research, is that ADHD represents a
complex bio-cultural construct, which is contingent on the influence of
medicine and genetics in explaining life problems, on the examination of
individuals in terms of deficit and dysfunction, on limiting and competitive
academic environments, and, in my case, on my mum’s knowledge of the
disorder. Although it offends my sense of personal agency to do so, I can
acknowledge that the symptoms associated with ADHD can be very
impairing; even harder to acknowledge is that the effects frequently bypass
my conscious control. I still take offence when anyone uses the disorder to
explain any of my actions; even though I am limited by the symptoms, I do
not think they explain my behaviour, and my academic work now can be read
partly as an attempt to push the boundaries of what ‘someone with ADHD’
may or may not be capable of. As such, I have, whether passively or actively,
always resisted the label. I do recognise, however, that the principal factor
that has kept me from some of the more extreme outcomes of the disorder has
been good fortune, which many people with ADHD will not share with me.

I am very fortunate in having a supportive family and friends. As well as my
girlfriend, I have a very loving family around me – my mum, in particular,
worked tirelessly to make me happy as a child, and I would love to be able to
give her back her sleepless nights and tears of concern. I was fortunate in my
parents both being doctors, because they could afford to send me to fee-
paying schools, and could help me out when I was working crappy jobs; and
if it hadn’t been for my sister putting a roof over my head when I moved back
to London then I may never have gone, and may never have started the ball
rolling back to a happy and fulfilling life.
Personal account (B)

I realised that I was different from other kids when I was at primary school. I remember having both the desire to do really bad things and then acting them out, like poking my mum in the eye with a pencil or ripping up the book she was reading. I really struggled at school with reading and used to steal money from my parents to pay other children to read the books I was supposed to so that I was able to tell the teacher the story. I thought I was evil inside and took an overdose when I was about 8 years old because I thought my whole life would be bad and nobody seemed to take my concerns seriously. I tried to run away from home on several occasions.

By the time I entered secondary school I had a reputation as being one of those ‘bright but naughty’ kids, which is what I guess most kids with ADHD were called then. I gravitated towards similar kids and started experimenting with soft drugs and alcohol at around 11 years old. My only love in life was sport, and I swam, cycled, did athletics and surfed. I enjoyed high-risk activities, and rode around on older boys’ motorbikes, started taking hard drugs and had regular sex by the time I was 13. I didn’t listen to my teachers’ cautions and stopped attending school because I found it too difficult and either went to the beach to surf and have sex, or hung around town shoplifting and drinking. I got cautioned by the police several times. I often got into physical fights both in and out of school and started carrying a knife. I never really remember being satisfied with what I was doing. I got pregnant but didn’t follow it through, and chronically under-achieved at school.

My parents complained that I was too difficult to control, and they now say that they nearly separated because of my bad behaviour. My father had a terrific temper and we often got into verbal and physical fights. When I finished school I left home and drifted through a number of manual jobs, not ever being able to complete the tasks required of me. I met up with some travellers and bought a bus in which I travelled around the country financed by selling drugs. I developed a serious heroin addiction and had to steal a great deal to pay for my habit. I took lots of different types of drugs: LSD, opium, tranquillizers—just about anything I could get my hands on. I made quick and silly decisions; for example, I often stole cars and drove while drunk or drug-impaired. I got involved with credit card fraud and worked in a topless bar when I was sober. I spent a brief time in prison on drugs-related charges too. I had a problem with authority and was consistently defiant in my attitude to life. My self-esteem was very low and I took stimulants to control my weight after quitting heroin in a rehabilitation centre. I also tried to take my life again and had to be resuscitated, which led to short-term seizures.
I can put my success as an adult down to a few influential people in my life. They saw my potential and put in place the appropriate help and support to enable me to succeed. One of them helped me through a period of depression in my 20s, when I was institutionalised and given electroconvulsive therapy. I went into counselling and saw psychiatrists for 4 years which helped me sort out many issues. The other saw the potential in the poetry I wrote and convinced me to go to university to study English literature as a mature student with extra support for my dyslexia. I graduated with a first class degree and went on to study for a masters degree. Eventually I met someone at university who also saw my potential and only seemed to bring out the best in me. He is now my husband.

When our son Isaac was diagnosed with ADHD I realised that I had displayed many of his behaviours as a child myself (see personal account D below). I continued to have an issue controlling the amount of alcohol I drank, and had a problem with my temper, especially during pre-menstrual times. I was frightened I was going to physically hurt my child when I lost my temper, so my GP suggested I try SSRIs for my PMT. These worked really well, and I still take medication daily. I did however continue to indulge in high-risk behaviour, which led to a serious motorbike accident that has left me disabled. A few years ago I stopped drinking alcohol because I finally realised I only drank to get drunk; but I almost immediately developed problems with anxiety and mild obsessive-compulsive disorder. My GP doubled my dose of SSRIs, which has helped a lot. I have also recently stopped smoking cannabis on a daily basis—something I had done for nearly 25 years.

I realise now, from the stories my father has told me about his behaviour (being in trouble with the law, under-achieving at school, oppositional defiance, alcohol abuse, and so on), that he also probably would have had a diagnosis of ADHD if he was a child today.

With all the support I have received from counsellors, psychiatrists, friends and my husband I now have a successful professional career and have been married for 10 years. I believe my own insight into ADHD helps me to be a better mother to my own child, and is helping him achieve his potential without the struggles I faced.

Personal account (C)

When I was diagnosed with ADHD I was around 8 and when I was told I had ADHD I didn’t have a clue what it was or what it stood for. All I knew was that it was called ‘ADHD’. I do not think any life experiences I had before I was diagnosed led to the onset of the condition, I just believe that it is DNA-based—someone else in the family has or may have had ADHD.
I go to a private clinic for help with my ADHD; they originally diagnosed me and I go there every 6 to 8 months to see a consultant. From what I can remember not a lot of treatments were discussed with me, except different types of medication. I found that to start with the medication I was given, which was Ritalin, was not effective in controlling my bad habits and behaviour. We had to go back to the clinic more often over the years to try and get my medication sorted and get the right balance and also the right type of medication. After going through all of this process the clinic finally managed to get the medication right when I was about 14; I know I have to take a mixture of different types and strengths of medication. But now I am on the right medication my ADHD has got better in my mind. I have stopped all the tics that I used to do and I find that I am a lot calmer than I was. However, the only problem I have with taking my medication, Concerta XL, is that my body has built up a large tolerance to it because I have been on it for so long, so I have to have come off the tablet every weekend and have medication called Dexedrine.

Due to my medication being an expensive drug and a dangerous one if it is misused, my parents and I had many problems with my GPs. One of the problems was that they were not willing to pay for the drug and also some of them did not know what the drug is like so they did not want to administer it in case anything went wrong and they lost their job because of it. The other main problem was that most of the time GPs did not have a clue about ADHD. Because of this me and my parents got to have a better understanding of what ADHD is, and most of the time I just think that the GPs need to know more and also have a better general knowledge of what ADHD is.

I found that my ADHD had a big effect on my education in many ways. When I was just diagnosed and for a long period of time after, until I managed to get the medication balanced, I used to be aggressive at school. I also used to get in a lot of fights because when I got wound up I became aggressive because of my ADHD and I found it hard to control my aggression. I was also very disruptive in the classroom as I used to call out in class often and I was easily distracted. However, as I managed to get the medication right and as I moved into upper school and progressed through year 9 and year 10 I found that all of the disruptive behaviour in the classroom slowly went away. Since then I have had little problems in the classroom.

Now I have a full understanding of ADHD but there are still some things I have questions about, like will I always have ADHD, will I be able to drive and will I be able to have certain types of jobs? I know for a fact that my ADHD will have an effect on my future life.
4.2.3 Personal accounts from carers of people with ADHD

Personal account: parent (D)

My son Isaac is now 7 years old. When he was born I breast fed him on
demand. He shook his head and threw his arms around continuously which
made feeding him difficult. My breastfeeding counsellor described him as
‘fussy’ and demonstrated how to swaddle him to prevent his arms from
moving. This helped to control his writhing both when feeding and when he
slept in bed with my husband and me at night. At 6 months old he attended a
crèche on a part-time basis. When he was 18 months old the crèche began
asking if there were any issues at home they should know about because he
had become increasingly aggressive towards other children, displaying biting,
punching and other violent behaviours.

Within a few weeks of this conversation my husband and I moved to the
Philippines to begin new jobs. Looking back now I realise that Isaac never
took well to changes in routine, and the move overseas was probably quite
disruptive for him. He continued being aggressive and bit relentlessly any
people who cared for him. He attended a Montessori pre-school, and the
teachers often said how different he was from other children. His head
teacher said that he showed no signs of socialisation, as if he’d never been
exposed to other children, even though he’d attended a crèche in the UK for
over a year. Other children did not want to play with him outside of school
because they would often become injured or hurt from his robust play.

My husband and I made many trips to our Australian GP in the Philippines
for minor family health problems. When I finally mentioned that I had
concerns about Isaac’s behaviour, he said he’d been waiting for me to say
something for a long time. He immediately told us that he thought Isaac had
ADHD and could refer us to a specialist paediatrician in Australia for an
assessment.

During this time my marriage began to take the strain of a child who would
want to be continually played with and was often violent. Isaac did not like it
when my husband and I talked to one other, and would physically try to
separate us. He constantly moved from one activity to another, and displayed
increasingly impulsive and reckless behaviour. He climbed at every available
opportunity and would not respond to discipline. His impulsivity presented
as punching a dog, running after cars, eating dog faeces, or head butting me
when I read stories to him.

I took him to Australia when he was 3 years and 3 months old for an
assessment. My husband and myself, and Isaac’s teachers, completed a test
before the consultation. (I later learned this was the Connors’ rating.)
Travelling to Australia on my own was very hard with a hyperactive and
impulsive child. His behaviour was often exacerbated by environments with a
lot of stimuli. I lost him several times at the airport, and he even disappeared off the end of the baggage carousel. Isaac's assessment by the Australian paediatrician resulted in a diagnosis of ADHD; he was described as being at the 'extreme end of the ADHD spectrum'. It was recommended that he take medication, but we resisted. We spent another year attempting to modify his behaviour, trying as many alternatives as possible to medication. During this year he continued to be impulsive, lacked attention, and was violent—he punched a child's teeth out at school and was aggressive to his teachers.

When Isaac was 4 years and 4 months, a clinical psychologist assessed him and described him as having a range of problematic behaviours: fidgeting, climbing, being always on the move and easily distracted, having difficulty sustaining attention, being talkative, violent, aggressive and defiant. He averaged one accident a week. He liked routine and found transitions (for example, returning to school after the weekend) difficult. My marriage was becoming increasingly strained, so we decided to try medication and Isaac started taking methylphenidate. It seemed like a 'miracle'. He was able to focus, remain calm, play without being aggressive and make friends for the first time. He displayed slightly more anxiety immediately after taking the medication, but was able to tolerate it. He started on a low dose that was increased after 6 months. He now takes a long-acting preparation.

We returned to the UK in 2005. Since Isaac started the medication we have never looked back. Isaac does continue to be very challenging, and is clearly a very complex child. He has learning difficulties, finding it very difficult to produce legible writing and is significantly below the national average for reading. In addition to ADHD, Isaac also displays some autistic spectrum behaviours, though not enough for a formal diagnosis. We all regularly attend our local child and adolescent mental health service, and Isaac has assessments from an educational psychologist who visits his school.

Isaac is a really intelligent child, who is well liked and humorous. He channels a lot of his excess energy into sport and enjoys rugby, karate, rock climbing, gymnastics and skateboarding. He wants to be a stunt man when he grows up! He is excellent company and constantly asks questions and spends time thinking carefully about the answers. He shows a natural aptitude for science and constructive activities. Isaac still needs a lot of routine, continuous behavioural monitoring and moderation, a reward system for good behaviour and incentives to keep him on track. Our biggest challenge now is to maintain Isaac's interest in school and keep his self-esteem high as he struggles with formal literacy skills.

**Personal account: parent (E)**

I am the mother of a 15-year-old boy with ADHD (see personal account C above), who also has oppositional defiant disorder, a sleep disorder and vocal...
tics. From early infancy he was very active, never settling well to feed, and would only sleep for short periods. As soon as he could crawl he was into everything; we bought a playpen to put him in so we knew where he was, but he started to stand on his toys to climb over the top. Once he was walking we were unable to leave him unsupervised; he would climb over the stair gate and out of his cot, and would run everywhere. By the time he went to nursery school we had had many trips to casualty with our son for various injuries.

At nursery school he was very disruptive, constantly on the go, never wanting to share anything, playing in an ‘over-the-top’ way, not knowing when to stop, and alienating the other children so no one would play with him. This carried on into reception and years 1, 2, and 3, where he was also very disruptive in class, would not settle to work and was constantly fidgeting with anything he could get his hands on. By this time he was constantly being physically bullied, coming home with cuts and bruises. He was never invited to parties or out to play, and he became socially isolated. He had developed very low self-esteem, anxiety, poor social skills, vocal and physical tics, and learning difficulties. He would have panic attacks if put in a strange environment, and he self-harmed. His sleep pattern was totally out of the window—he would be up 15 and more times a night, running round the house barking like a dog. He was physically aggressive to me, kicking, punching and lashing out. He would fly into a rage that would last sometimes 2 hours or more; on some of these occasions we would have to physically restrain him, even resorting to sitting on him, just to try to stop him from harming himself or trashing the house. He would frequently destroy his toys, clothes, and his room, even tearing curtains from the wall and pulling the fitted carpet up. We learnt not to take him to the supermarket, which resorted in one of us going late at night on our own. We gave up clothes shopping in town, and would only take him in for shoes or a haircut. He once threw a huge tantrum in a department store; I walked out and left him lying on the floor under some clothes, and a security guard stopped me and asked if I had forgotten something! He became the child of nightmares, the child that you thought you could not possibly have, because we were ‘sensible’ parents!

We had great difficulty disciplining him, not because we did not want to, but because we had tried everything and anything that our friends suggested: sitting on the stairs, no toys, no telly, bed early, no playing outside, no treats. Nothing worked, he just shrugged his shoulders at us. We had reached breaking point, our marriage was suffering, and our other younger son was upset; he started to have night terrors and began pulling his hair out, resorting to hiding in a cupboard when his older brother was in one of his ‘rages’.

By the time our son had reached the age of 7 and a half we had become increasingly concerned by his uncontrollable behaviour at home and at school. I raised my concerns with his teacher about his behaviour and his
inability to concentrate, and also about the constant bullying he was receiving at school. We agreed that he may have a learning/behavioural disorder. I did some research into childhood disorders, contacting NHS Direct for information. They sent me literature on ADHD, and I read the book that it recommended (Understanding ADHD by Christopher Green); I thought, ‘this could have been written about my son’. I was actually relieved that there could be a reason for all of his ‘problems’, and it was not us being bad parents. I showed the book to my son’s teacher and she offered to write to my GP supporting my concerns. I took this letter, together with a diary I had started to keep of my son’s behaviour, to the GP. He listened and agreed to refer my son to the local Child, Adolescent, and Family Consultation Service (my son had just turned 8). However, they refused to see him because he did not meet their admission criteria; they were only taking ‘emergencies’ at the time, and because he was not displaying suicidal tendencies, he was not considered an emergency. They suggested that I should attend a ‘child behaviour management’ course instead, which when I contacted them had no spaces. My GP then referred our son to the same service ‘out of area’, but they too were unable to see him.

I was given details of a private clinic that specialised in ADHD and also took NHS referrals from GPs if funding was in place. My GP agreed to refer my son, and applied for funding from the local health authority. After 6 weeks of not hearing anything I contacted them directly myself. After describing the great distress that our son’s behaviour was causing him and everyone around him, they agreed to fund him, as they were unable to provide a service for him locally. During this period the school had requested an educational psychologist to assess him; she agreed that he required further ‘specialist’ assessment, and she supported his referral to the private clinic.

The clinic diagnosed our son with ADHD, oppositional defiant disorder and other comorbid conditions. We were offered various strategies to help cope with his behaviour, some very useful. The consultant suggested that our son should have a trial of methylphenidate. We decided that we would like to research the medication route before agreeing to follow this course of action. After much discussion, my husband and I decided this was the best way to offer our son some sort of ‘normal’ childhood. Our son was started on Equasym (5 mg every 4 hours), and there was an improvement in his concentration levels almost immediately, and he was also much calmer. The dosage had to be slowly increased and we found that it was effective for 3 to 3 and a half hours; he was therefore experiencing ‘peaks and troughs’. We had difficulties with the school as they refused to give our son his medication, insisting that I went and gave it to him. He got to the stage where he had to take medication before he went to school, at first break, lunchtime and then after school. Our GP at this time was fairly supportive, although he admitted that he had no knowledge of the condition, and was happy to be led by the guidance of the clinic, and my experience as a mother. It was suggested by the
consultant that we try Ritalin-SR, which my son took early morning and at lunchtime, followed by regular Ritalin in the early evening. This combination proved effective for approximately 6 months, during which time his sleep pattern was constantly disturbed. We also had problems with his appetite — it took him about 2 hours to eat a meal. The consultant suggested that we try melatonin to help him to sleep. Our GP (we had moved house by this time and changed GPs) refused to prescribe this medication, saying, in front of our son, that the drugs were very expensive and he had his budget to think of. We moved to a different surgery where all the GPs were very supportive, and happy to prescribe under the guidance of our son’s consultant. They remained supportive for 5 years, until we moved house, and had to change surgeries again.

Ritalin-SR became less and less effective. The consultant felt that he had become tolerant to this form of medication, so it was decided to change him to Concerta XL, which would provide him with a sustained dose for approximately 12 hours. It was also decided at this time to introduce him onto clonidine to help with his ODD, tics, and also to help him sleep; he had a small dose before school, and then a larger one an hour before bed. This medication regime proved very effective for a considerable time, but as my son grew, so did his tolerance to Concerta (at this stage he was taking 108 mg, plus 10 mg of Ritalin at lunchtimes and 20 mg of Ritalin after school). By the time he was 13 and due to start upper school his medication was not as effective as it had been. The consultant suggested that we ‘wash out’ his medication every school holiday (every 4 months), and this worked well for a year and a half.

Our son is now 15 and 6 feet tall and we have had to change the medication regime again. He is currently on the following on weekdays: 50 mcg of clonidine and 108 mg of Concerta XL on rising; 20 mg of Ritalin after school and 125 mcg of clonidine 1 hour before bed. At weekends he takes 50 mcg of clonidine and 15 mg Dexamphetamine on rising; 15 mg of Dexamphetamine at lunchtime, 10 mg of Dexamphetamine at teatime and 125 mcg of clonidine 1 hour before bed. This regime is proving extremely effective at present, and he displays no signs of sleepiness, and is doing well at school — far better than we ever thought possible. He takes reduced dosages when he does any sport, as the adrenaline helps him to self-medicate.

My son has remained at the private clinic, where the staff are extremely supportive; the provision of telephone support, offering the opportunity to speak to a consultant when needed, and even adjusting medication over the phone have proved really valuable. There is an educational psychologist who is able to offer advice, and he recently went through our son’s GCSE options with him; they also have a school liaison officer who is able to offer advice to teachers.
We have always encouraged our son to take a very active part in sports because we found that he was able to expend some of his energies that way. He has been a member of a swimming club since he was 4, and is now county standard, training for approximately 8 hours a week. He has been coaching the younger children at the pool and is really good with them. He also had karate lessons for 4 years and has done very well; we found that karate benefited his coordination and self-discipline tremendously. We also found that by encouraging our son to take part in these sports, and also by being able to achieve in them, it has helped his self-esteem greatly.

We learned not to put him into situations that he was not able to cope with, like going to the supermarket or into town. We also learned to try and focus on the good behaviour, to give praise, and to try and ignore as much of the bad/annoying behaviour as possible. By doing this, and also by virtue of the fact that he could concentrate at school, and was not constantly in trouble, we found that his self-esteem slowly increased, the self-harming stopped, and the panic attacks and anxiety abated, only occasionally appearing when he was extremely stressed.

Our son is at his worst and most oppositional in the early morning and late evening, which is before and after the medication is at its most effective. His vocal tics are also at their highest volume. He is quite happy to take his medication; he says he can ‘turn his brain off’. He actually went to school a few weeks ago having forgotten to take his medication—he said it was awful; he was unable to concentrate, he constantly fidgeted, and was very disruptive. He only escaped being excluded from school because the teacher recognised he was not his usual self, and when he explained that he had forgotten his medication, she let him off. Without the medication I am certain that our family would not have survived and that my son would have been permanently excluded from school, and worse, be in a young offender’s institution. Instead he has just achieved the highest grade for his GCSE IT coursework and exam.

Our son does not have fizzy drinks, rarely eats chocolate or sweets, and we try to avoid packet/processed food and ‘E’ numbers. He has also taken pure fish oil for several years, and this seems to help with his mood levels; he says that he feels he concentrates better when he is taking it.

However our son is still socially isolated. He does not get invited to parties and he never goes to school discos because crowds and noise are too much for him. He has many acquaintances at school but there is no one close and no one comes to our house to see him.

We have never received, or been offered, support from local NHS child development services, CAMHS, or community psychiatric nurses. There are no local support groups and our wider family has not been understanding of
our son’s condition and subsequent needs. Our close friends tried to offer us support, but they have children of their own.

The family environment has become easier in the last couple of years, and my relationship with my son has improved — I don’t ‘hate’ him any more for being a horrible child! Instead I am proud of what he has achieved and how far he has come.

Personal account: parent (F)

Before our son was born I believed that we were ‘good’ parents and I was proud of the way we parented our children and met their individual needs; however this soon changed as the youngest of our three children entered the world. We discovered that we had a baby who hated to sleep, constantly required attention and, as he began toddling, managed to destroy everything that got in his way. His tantrums, head butting, fear of enclosed and crowded areas made it impossible to take him shopping. He hated bright lights and loud noises; he was obsessed with his toy cars and lining them up in a certain way and by colour; and he was cruel to the family cat.

Our son’s behaviour concerned us, so much so that he was referred to child and family guidance at the age of 2 and a half. He was excluded from almost every nursery he attended due to his behaviour, and he was admitted into hospital on several occasions for drinking any liquids in sight (he was constantly thirsty). He was the only child on the children’s ward who required his parents to be there constantly because the staff were not able to deal with his behaviour and tantrums.

By the time our son was 7 he had more fixed-term exclusions from school than I care to remember and by age 12 there were services involved that I never knew existed. We sat in meeting after meeting with many professionals including a paediatrician, GPs, psychologists, educational psychologists, a child psychiatrist, staff from early years provision, education welfare officers, social workers, behaviour support workers, special educational needs case workers, a youth offending team, the police, and heads of schools and teaching staff. He was cautioned for arson, charged with theft and would constantly run away from school and not return home until he was found by the police or us.

A child psychiatrist was involved for almost 10 of the first 12 years of our son’s life but failed to assess and address our son’s needs. At no time during this period were the needs of our two older children considered; for example how the abuse, threats and behaviour inflicted on them by their younger brother may be impacting on their young lives, and also how our spending so much time in dealing with our youngest child denied them the quality time they should have had from us.
When our son went to high school we thought it would be a ‘fresh start’ and that the move would provide him with the much needed support he required. However, in the first 6 months we received numerous calls and letters from the school about our son’s behaviour. He was seen by an educational psychologist for special educational needs, and was assessed as having emotional and behavioural difficulties; during this assessment our son was permanently excluded from the school.

For almost 15 months our son was tutored at home but received little if any education because he would abscond before the tutors arrived. It was at this time that we were mistakenly sent a copy of a letter from the child psychiatrist who had written to the school’s educational psychologist and family GP providing his account of our son’s needs. The letter stated that our son’s behaviour was due to ‘parental inconsistency’ and ‘poor parenting’ and that he would benefit from local authority care, that is, removal from the family home.

I had always been taught to respect those in authority as professional people educated in their line of work. But seeing that our son was being failed by so many of these professionals, my respect for them was rapidly decreasing. Outraged by the letter, I wrote a strong response and requested that our son receive a second opinion from another child and adolescent psychiatrist. Within 4 months of making the request, our son was finally diagnosed with severe ADHD, sleep disorder, conduct disorder and moderate learning needs.

I had never heard of ADHD so how could I support my son and how would others support his needs? I learned what I could about the disorder; I undertook training on special educational needs and the law and fought for my son to be educated and treated appropriate to his needs. Because of this he was placed at a residential school outside the county, which was fully funded by the local authority. We demanded that he be allowed home at weekends as we did not want our son thinking that we were rejecting him—he had received enough rejection in his young life.

Over the summer, during the weeks prior to starting his new school, he was prescribed Ritalin for the ADHD and melatonin for his sleep disorder. The changes in our son were remarkable—we now had a child who sat around the table for family chats, took part in family outings and, most importantly, could sit and concentrate for more than a few minutes at a time. We had a happy child with so much love to give and receive.

Things were now going relatively well; our son settled into his new school and I continued to learn more about ADHD in order to support the school in meeting our son’s needs. His medication was administered by the school nurse on clear instructions from me. However, neither the teaching staff nor
the school’s in-house educational psychologist had any knowledge or 
understanding of ADHD. This contributed towards major conflicts; they 
stated that ADHD was just an excuse for ‘bad behaviour’ and excluded our 
son from taking part in after-school activities. When he was at home at 
weekends we began to notice that he was rather withdrawn; he would not 
communicate and would not show the same love and affection he had done 
over the summer. When he went back to school I enquired as to the cause and 
found that the staff were continually changing, which seemed to affect our 
son’s routine; also, the school nurse was not always on the premises to 
administer the medication, therefore our son was receiving his Ritalin as and 
when it suited the school.

Other students learned of our son being on medication prescribed by a 
psychiatrist and he was called names such as ‘psycho’, ‘crazy man’, ‘nutcase’ 
and so on, which led to our son refusing to take the medication to treat his 
ADHD symptoms because he thought it was for ‘psychos’. Things soon 
reverted back to the old ways; his behaviour was out of control, he was 
smoking cannabis, drinking, stealing and running away, all of which 
contributed towards his being permanently excluded from the school. He 
refused to take any medication apart from the melatonin and we were now 
left to pick up the pieces and fight for his education.

Feeling somewhat battered and bruised and totally exhausted, I approached 
my GP who handed me a prescription for Prozac and told me I was just 
depressed. This was the day on which I finally snapped and told a 
professional exactly what I thought of his prescription and lack of support for 
our son. From that day to this I have continued to fight for justice for our son 
and others like him and their families. I joined several other parents who had 
a child diagnosed with ADHD to meet for coffee and share our stories. 
Meeting other parents in a similar situation was like having a release valve to 
let off steam.

Another placement was found at a school nearer to home with boarding 
during the week; but this too was short lived as none of the teaching staff 
knew about ADHD. Once again our son was permanently excluded. (Several 
months later it was announced on local radio that the head and deputy head 
of the school had been suspended under investigation due to their 
disciplinary procedures.)

For children with a special educational needs provision, like our son, it is the 
duty of the local education authority to draw up a transition plan for ongoing 
school provision and review it when the child turns 14. All the local services 
and agencies involved in that child’s care should be invited to the transition 
review meeting. The local authority must also notify social care, who then 
decide whether the young person is defined as having a disability. Social care 
notified us that under the 1948 National Assistance Act our son was not
defined as being disabled. We challenged this decision using both the
National Assistance Act and the 1989 Children’s Act and we were successful
in our appeal. We then requested that our son be placed on the ‘Children with
Disabilities Register’; when this was denied we took the matter up with the
local government ombudsman and it was found that our authority did not
have such a register. Due to our actions we were delighted that children and
young people with ADHD can now be entered onto the ‘Children with
Disabilities Register’. We have never received any letters of apology from the
local authority and our son received no education from the date of his
exclusion at 14 plus.

When our son turned 16 we were told that he was no longer a child and that
he was responsible for his own actions. But he was a 16 year old who acted
like a 12 year old, who had little education and no knowledge of NHS
services, how to claim state benefits, and how to pay bills, shop or clean. Yet
he was expected to manage these affairs on his own. The understanding was
that I would be copied in to any appointment letters — this way I could assure
his attendance. All was fine until a new psychiatrist became involved; the
letters stopped arriving, our son failed to turn up one day and due to this the
CMHT decided to close his case file.

It would seem that our adult CMHT had very little knowledge of ADHD or
understanding of the needs of those with the disorder and of the impact it
was having on our son’s day-to-day life. (We educated our son as much as we
possibly could about ADHD; we felt this was necessary to help him
understand the disorder, as well as to help him explain his difficulties to
others, in particular service providers.) After letters were sent to the CMHT
chief executive, the services were reinstated and I was included in
correspondence. I believe that this was initiated after we requested that our
son be seen by experts who understood ADHD and related disorders.
However there has been no continuity with the psychiatrists my son sees and
this seems to have had a knock-on effect on him and his willingness to trust
new people involved in his care.

My son’s psychiatrist prescribed him antidepressants with no other form of
support strategies being delivered. I challenged this and asked why he was
not being offered anger management, behaviour management, counselling,
therapy and so on, or appropriate medication to treat his ADHD symptoms,
since the alternatives he was taking on a daily basis were clearly not working.
We felt that our son was still a child by rights, and therefore should have had
access to the same treatments and therapies as other children under the care
of children’s services. After this our son was prescribed Concerta XL, and the
transformation was the same as when he first took Ritalin. Once again we had
a son who seemed more compliant, and he started reducing the amount of
cannabis he had been using. (When asked why he used cannabis our son
explained that he felt ‘normal’, that he could socialise and communicate better
with his peers, and that it took away all the anger inside him.) Once again, however, due to changes in psychiatrists, our son’s appointments became few and far between and he stopped receiving his medication.

When our son was almost 17 he decided to leave home, which was a concern as we wondered how long he would survive. We registered him for social housing with the council but in the meantime we paid a deposit to a private landlord for a room in shared accommodation and made an application for appropriate housing and council tax benefits. He now considered himself a responsible adult so we let him do things his way, but this was short lived when he found himself without money or food, his flat was raided and while he lay drunk in his bed his belongings were stolen by individuals he thought were his friends. After contacting the local council regarding our son’s social housing needs and writing numerous letters, we involved the Shelter organisation. We continued to fight for his accommodation as well as the appropriate state benefits, thinking that if these were in place it would assist us as well as our son to live within the community as an adult.

Within 4 months our son received a one bedroom housing association flat. To this day, 8 years on, we have managed to keep this roof over our son’s head (as well as keeping him out of prison) by being guarantors for his rent, making applications and becoming appointees for this state benefits, making use of other services for grants, such as the Soldiers, Sailors, Airmen and Families Association (SSAFA) Forces help, decorating and furnishing the flat, undertaking regular cleaning, shopping and laundry, replacing furniture damaged or destroyed during outbursts of anger, and intervening with the housing association when they threatened eviction. We bailed him out of debt for credit cards and mobile phone bills, made sure he was ‘red flagged’ on the police system as requiring an appropriate adult in attendance when in custody (which we were at all hours of day and night), communicated with and educated the solicitors acting for our son on ADHD, wrote to the courts in order to put our son’s case across, acted as expert witnesses when our son when to court and advised the solicitor to seek an appropriate expert witness with knowledge of ADHD. When our son attempted suicide while detained in custody we referred the case to the Police Complaints Commission.

By the age of 22, our son underwent a private psychiatric assessment ordered by the courts; it was this assessment that initiated further assessments through the CMHT and at the Maudsley, and how we learned that our son not only had severe ADHD but also Asperger’s syndrome as well as other mental health and learning needs. Later, at yet another court hearing, further medical evidence was needed, which required an expert in ADHD and Asperger’s. The expert provided the much needed evidence that prison would have a severely detrimental effect on our son and on his safety.
This made us wonder how services and agencies could have misunderstood our son for over 20 years. It took the assessment and report of the expert witness involved in our son’s case, and ourselves as parents and carers, to highlight the areas of concern in relation to our son’s diagnosis and the impact the disorder has on his day-to-day life. It is crucial that professionals with great knowledge and understanding of ADHD are instructed by the legal bodies representing people like our son in order to provide the necessary evidence with which to demonstrate that a prison sentence would have serious outcomes.

Our son is now 25 and we still provide the support he needs. We have stood by him no matter what has been thrown at us throughout the years and to this day we believe that our parenting was our road to success in managing and dealing with our son, rather than his being another statistic within our penal system. He is now on a medication known as Strattera and is doing remarkably well. For the first time he has remained in a relationship for over a year, he has become engaged and is slowly dealing with matters relating to his own finances and household management.

It has certainly not been an easy task to access the appropriate healthcare, and social and educational services for our son; it has felt as though we have lived through a nightmare, and in a way we are still going through the tail end of one as we continue to support and care for our son. It angers and frustrates us that professionals see parents like us, who have gained the knowledge and experience of living with and managing ADHD within our family unit, as a threat. They should be working with us and using our knowledge in order to provide the best possible care and support package for their patients.

It would seem that there has been very little improvement in services for people with ADHD and their families in recent years. As parents and carers we have never been offered or directed to any support services relating to ADHD by health or social care professionals; we have managed to access advice and support through family members and the internet. Due to our experiences as a family it has helped us to support other families facing similar experiences. I am the chair of a local ADHD support group, which was set up in 1994. The group has received an award for community endeavour as well as local community volunteer awards. We are represented on various local working groups and boards and are also involved in local prisons and young offenders’ institutes. The group has assisted other service providers and authorities set up parent support for ADHD as well as presenting at many conferences on the subject.
4.3 Living with ADHD

This section is written from the perspective of people with ADHD and their families and carers. It also draws out some of the main themes from the personal accounts above and summarises the primary points of concern.

4.3.1 Children with ADHD

ADHD is a full-time disorder, extending beyond bad behaviour and problems at school, and impacts on all aspects of a person’s life. Children with ADHD are not problem children, but children with a genuine problem. They have a medical condition that is difficult for them and for those around them, and they stand out as different from peers and siblings at all stages of development (personal information, Dr Geoffrey Kewley, Learning Assessment and Neurocare Centre, UK, 2007).

Little social research has been undertaken about how children feel and behave with ADHD. Some children may be aware that they are different from others (see account B), but some may not have a highly developed self-concept of what it means to act differently from other children. Research indicates that children have dichotomous experiences when taking or not taking medication, which is reinforced by parents and teachers, for example feeling good/bad, happy/sad, playing nicely/fighting, and so on (Singh, 2006). This is also borne out by the accounts above (see accounts D and F). As the young man in account A explained, because some of his teachers treated him as if he were ‘bad’ then this became the ‘mould’ he would fit himself into. Children with ADHD have different social skills from those without ADHD; they may have tantrums and be aggressive towards others, and they find it harder to make and keep friends (Green et al., 2004). As a consequence the parents may attempt to fill the void, which can add to the pressures they face (see accounts A and F above). This is where teachers and other adults in positions of responsibility can alleviate some of the pressure at home, by being patient, attentive and supportive to the child at school, and understanding how ADHD manifests. The accounts above suggest that routine and a stable environment is very important in managing ADHD symptoms, as is continuity with the healthcare professionals that the child sees.

As children grow up their symptoms will probably change. For example, between the ages of 11 and 16 children with ADHD are more likely to be regular smokers and drinkers and are more likely to have taken drugs (Green et al., 2004). As the child in account F remarks to his parents, he used cannabis to feel ‘normal’, so that he could socialise and communicate better with his peers, and to take away ‘all the anger inside him’. In terms of treatment, children may decide by themselves to stop taking medication at a particular
time in their lives, or may continue into adulthood. As the mother in account F points out, it is important to recognise that delineations in the health service based on age may need to be more flexible when it comes to young people with ADHD; she cites the example of her own son who, when aged 16, had the outlook of a 12 year old.

4.3.2 Adults with ADHD

The professional discourse surrounding ADHD and adulthood is much less developed than with children; indeed most information regarding aetiology, symptoms or treatment comes from observations or studies of children (Weiss, 2001). Subsequently, adults with ADHD may encounter greater obstacles in terms of having the condition identified and recognised and being supported. It is claimed that between 30 to 50% of children with ADHD will carry the disorder through into adulthood (Wender, 1998). Adult experiences of the disorder may be characterised by similar feelings of restlessness and disinhibition as in childhood. In adulthood there is also a strong association with both depression and substance misuse.

Developmental changes may mean that sometimes levels of self-awareness or motivation towards a certain task may make the symptoms easier to manage – though this is not always the case. Living with ADHD as an adult can present daily challenges at work and at home and can impede the building of habits and routines upon which ‘normal’ lives are often grounded. Problem areas often centre on organisation, motivation and commitment. Organising a busy work and social schedule can present a constant challenge; any opportunity to habituate some practice or impose some routine structure may have a positive impact. While new projects and directions may be sought with some vigour, retaining this initial motivation may prove more of a challenge, and frequently taking the long view of events may cause some disillusionment. Strong relationships at home can be hugely empowering, though these too need commitment and hard work, and will frequently prove frustrating for both parties. In terms of managing the symptoms, regular exercise or another positive activity may help to provide structure and meaning and increase the individual’s self-esteem (as in accounts A and B above). Few people wish to see themselves contained or restricted by a disorder such as ADHD, however, it is helpful for people with ADHD to know their limits so they can step outside them.

4.3.3 Labelling and stigma

In addition to coping with a medical problem, an additional consideration for a child or adult diagnosed with ADHD, is adjusting to the experience of being labelled with a psychiatric diagnosis and the negative consequences this may have. Labelling theory in the social sciences (Goffman, 1968a; Rosenhan, 1973; Scheff, 1975) suggests that psychiatric labels can have effects on the bearer in terms of their own identity construction, that is, how they see themselves, and in terms of the social reaction to them.
The symptoms of ADHD describe a child who finds peer interactions difficult and is disruptive at home and school. As such, the child is likely to feel a sense of difference or alienation in social situations. Interventions at school, such as special needs provision or disciplinary procedures, may work to reinforce this difference. The child becomes a member of different groups of children who are known as ‘different’, ‘special’ or ‘problematic’. Such changes in group membership alter the way the child thinks about themselves as well as the way others think about them.

A label such as ADHD reinforces this difference by medicalising and highlighting certain characteristics that are perceived to have a negative social impact. The introduction of a medical label also institutes the concept of stigma and research suggests that stigma is one of the most keenly felt consequences of being labelled (Bauman, 2007; Fennell & Liberato, 2007; Hinshaw, 2005; Muthukrishna, 2006; Read, 2007; Stier & Hinshaw, 2007). Once a label has been introduced the bearer is obliged, regardless of what they may think of the label, to consider themselves in relation to it. Likewise, those around them will think about and react to that person differently as a result of the label. This process will necessarily affect changes in the bearer’s choices and actions, one consequence of which may be that they produce more of the behaviours associated with the label. As such labels are thought to accrue self-fulfilling prophecies for the bearer.

Many of the aspects of school, both in terms of curriculum and pedagogy, work to differentiate children from one another (Armstrong, 2003; Benjamin et al., 2003; Meo & Parker, 2004). One criticism that can be made of diagnoses such as ADHD is that they may ‘medicalise’ the child who for one reason or another finds themselves on the wrong side of these mechanisms. Once such a label is applied the bearer will be obliged to consider themselves in relation to it. Whether they accept the descriptions as fitting or reject the label and offer further resistance, their individual differences have now been fixed and medicalised, and they are now obliged to live with what has been termed a ‘spoiled identity’ (Goffman, 1968b). As such it is important to exercise caution in the application of such labels, and to make a full investigation into the child’s social situation, bearing in mind the forces that may have worked to mark them as different in the first place.

4.3.4 Impact of ADHD on family life and relationships

ADHD can have a significant impact upon family life and relationships with friends (World Federation for Mental Health [WFMH], Without Boundaries report, 2004). Parents of children with ADHD need a great deal of support to help them manage their child’s problems. It is not only a case of having to manage the day-to-day challenges of living with a child with ADHD; parents also have to deal with school problems which are so common in these children, with many requiring a statement of special educational needs (SEN).
Children with ADHD require much more support and guidance than their peers in most of their everyday lives. This is a full-time disorder, requiring full-time care. Professionals need to understand the stress and exhaustion that many parents experience.

Parents (as demonstrated by the mothers who have given accounts above) are concerned about the impact that the lack of understanding of ADHD from health and social care professionals, staff in schools and the wider society can have on their child’s life:

- 91% of parents were shown to be often stressed or worried about their child’s life
- 68% stated that their ADHD child had been excluded from social activities due to their ADHD symptoms
- 61% said their family activities were disrupted
- 51% said the diagnosis took too long
- 63% said their primary care doctor did not know much about ADHD.

According to the WFMH Without Boundaries survey results, the average length of time to receive an assessment and subsequent diagnosis is 2.44 years, with 17% waiting for more than 5 years (WFMH, 2004). As the accounts above suggest, parents and carers can provide a wealth of information to healthcare professionals about their child’s ADHD symptoms and behaviours, which can enable the professional not only to reach an accurate diagnosis, but also to deliver treatment and care that is tailored to the child’s individual needs.

There are a number of public misconceptions about ADHD that need to be addressed in the best interests of children and their families. In order to address these misconceptions, it is important to understand more about the impact of the disorder on families and specifically how well families’ needs are being addressed. For example, the impact on brothers and sisters living with siblings with ADHD cannot be underestimated (see parents E and F above), and professionals must always consider and be mindful of the disruption that can be caused to their lives.

As the mothers in the accounts above make clear, parents often feel that they are being judged and/or criticised by friends, family and other people. Professionals may also attribute the child’s ‘bad’ behaviour to the parents (see account F). This can significantly undermine parents; they can become overwhelmed and feel like failures, wondering why the behaviour regime that seems to work so well for others does not work with their child. If they have other children who do not have ADHD they may begin to question their own parenting skills (see accounts A and F) when their other child begins to show signs of ADHD. Parents may see no easy answers, and wonder what happened to the joys of parenting.
Families affected by ADHD will benefit from support from all agencies, such as education, social services, their GP, mental health services and in some cases the youth justice system and police. These agencies can best help families and those with ADHD by working together to offer a package of support for the child/adolescent and the family. Medication alone is not the answer; they still require a great deal of support to manage the disorder. Behavioural monitoring and moderation, structured activities and a reward system with incentives may also be beneficial, as the mother in account D suggests.

One or both parents of a child with ADHD may suspect the child is different from other children and actively seek professional support. Teachers are often the first to recognise signs of ADHD, seek referral and support both the parents and child alike. As the personal accounts from parents relate, and as the Mental Health of Children and Young People in Great Britain report states, teachers are ‘are likely to have complained about [the child’s] overactivity, impulsiveness and poor attention’ (Green et al., 2004, p. 156), which can lead to difficulties with learning basic skills at school: ‘Almost three-quarters (71 per cent) of children with hyperkinetic disorders had officially recognised special educational needs (compared with 16 per cent of other children’ (Green et al., 2004, p. 160). The accounts above all speak of the difficulties in finding the right educational environment where the child can be supported and flourish, and where his or her individual needs can be met.

Parents may also seek support from mental health services, primary care or specialist educational services. There are still questions about whether ADHD exists (or whether the child is just naughty) and at what age a diagnosis can be made, which may explain why some parents find it hard to get a referral to a healthcare professional. Parents may seek informal advice from family, friends, self-help groups or the internet (Green et al., 2004), although as the mother in account F states, this may be the only support available to them.

Parents will inevitably face the dilemma over whether to embark on treatment for ADHD symptoms, or whether to use alternative therapies or change their child’s diet. If parents choose medication, they may feel guilty, and in turn decide to have ‘medication holidays’ to allow the ‘real child’ to emerge (Singh, 2005). Parents may receive mixed messages from the media about medication for ADHD, and believe that too many children take medication.

---

8 ‘Almost all (95 per cent) parents of children with hyperkinetic disorder had sought some form of help in the previous 12 months because of concerns about their child’s mental health. Most (93 per cent) had accessed some professional service. The most commonly used source of professional help were teachers (70 per cent) but parents also sought help from, or were referred to, other professional sources such as mental health services (52 per cent), primary health care (46 per cent) and specialist education services, such as educational psychologists (37 per cent).’ (Green et al., 2004, Mental Health of Children and Young People in Great Britain, p. 159).
However, according to the *Mental Health of Children and Young People in Great Britain* report ‘about 2 in 5 (43 per cent) children with a hyperkinetic disorder are taking some kind of medication’ (Green et al., 2004, p. 159).

ADHD often goes hand-in-hand with other conditions, such as conduct disorder (Green et al., 2004), making behavioural and emotional challenges even more complex (see accounts A and F above). These complications have ramifications for other areas of children and adolescents’ lives; for example, the *Mental Health of Children and Young People in Great Britain* reports that almost one third of children with hyperkinetic disorders have been excluded from school (Green et al., 2004). Such children may also go on have problems with the law.

Given this set of circumstances, parents and carers of children with ADHD can find being a mother or a father challenging. They are more likely to separate if they are a couple, have emotional disorders and function less well as a family, when compared with parents without children with ADHD (Green et al., 2004).

Parent and carers therefore require support from healthcare professionals, who should consider:

- ensuring parents/carers have good support networks, for example access to a self-help group, and are aware of local and national organisations
- recommending useful resources (books, leaflets, websites, and so on)
- helping parents/carers find outlets for their child to boost their self-esteem (for example, sports or creative activities)
- keeping dialogue as open as possible with the parents and the child (social story books may be used for self-esteem issues)
- recognising that ADHD is a complex disorder, and rarely without comorbidities
- recognising that transition and change may be hard
- helping parents/families to obtain support for relationship/marriage problems and for any siblings
- encouraging parents to keep a diary of behaviours to feed back to CAHMS meetings and other healthcare professionals
- asking the parents to complete a questionnaire before medication is started so that they can compare differences.
4.4 The experiences of children and young people of stimulant medication for ADHD

4.4.1 Background
As there is little published research on the views and experiences of children taking stimulant medication for the symptoms of ADHD, researchers at the London School of Economics were commissioned to undertake a qualitative focus group study with children and young people, together with a review of the available literature on young people’s experiences. The study identified children and young people’s experience of the diagnosis of ADHD and treatments for it in general.

A summary of the findings of this study follows. The full version of the report by Singh and colleagues, including the extensive bibliography, can be found in Appendix 15.

4.4.2 Previous research
Qualitative studies of the experience of children with ADHD suggest a ‘trade-off’ between the positive and negative experience of stimulant medications (Efron et al., 1998; Kendall et al., 2003; Meaux 2006).

While these studies report that medication helped to control hyperactivity, increased concentration, improved grades and helped behaviour (Kendall et al., 2003, Meaux, 2006) negative physiological aspects such as the taste of the medication and side effects of stomach aches and headaches (Kendall et al., 2003) were also mentioned, along with psychological side effects of feeling less sociable and a sense of not feeling authentically themselves (Meaux, 2006).

Stigma associated with taking medication to manage behaviour was the source of considerable concern for interviewees in these studies. They did not want others to know about their taking medication for fear of being laughed at and a number did not want to take medication because they did not like the changes they experienced in themselves (Kendall et al., 2003). A similar source of concern involved frustration, anger, sadness, and embarrassment of having to leave the classroom to be given medication (Meaux, 2006).

As there is little research on children’s experiences of taking medication for ADHD, the commissioned study’s literature review included the experience of young people taking medication for other conditions. It was felt that the issues of stigma, labelling and difference would be common or at least similar to that experienced by children prescribed stimulants for ADHD. However, when compared with epilepsy, the stigma of medication-taking was more apparent for children taking medicine for ADHD. Similarly, more children with ADHD (40% versus 32.5%) categorised themselves as non-compliant,
and they reported being less likely to tell their friends about their medication than those with epilepsy (32.5% versus 55%) (McElearney et al., 2005), suggesting that the experience of stigma is more acute with ADHD than with epilepsy.

4.4.3 Principal areas of investigation

In the current study, the researchers looked principally at children’s:

- understanding of ADHD
- perceptions of how tablets helped them (or not)
- experiences of stigma
- experiences of non-drug interventions for ADHD
- impact of tablets on the children’s perceptions of personal agency
- experiences of psychiatric services.

In addition, the study aimed to contextualise children’s perceptions of their ADHD medication within the perceptions, understandings and experiences of other means of improving their behaviour. The study also elicited ideas from children about resources that could help them to have more positive experiences of their diagnosis and medication.

The investigations were conducted through a combination of broad open-ended questions, games and vignettes.

4.4.4 Participants

The participants were 16 children (14 boys, two girls) with an age range of 9-15 years. Fifteen children were white and one was mixed race. Fifty percent of the children were living in two-parent homes, 37% in single-mother homes (the others with single fathers or grandparents). They were recruited from three major hospital clinics in Richmond, Nottingham and London. All of the children had a primary diagnosis of ADHD, with approximately 30% having a secondary comorbid diagnosis such as conduct disorder or dyslexia. A fuller discussion of the methods employed can be found in Chapter 3.

4.4.5 Main findings

**Understanding of ADHD**

- Children in this study identified a similar range of behaviours as those listed as symptoms indicated in DSM-IV and ICD-10. The most frequently discussed types of behaviours were impulsiveness, physical aggression, and hyperactivity. Children felt that these types of behaviours were particularly annoying to others.

- Behaviours identified as symptomatic of ADHD were frequently discussed in terms of their positive dimensions by children in the study. Their peers were thought to fear how out-of-control and overwhelming children with ADHD could be. Participants were able to perceive the
tension between their experiences of the more negative and more positive aspects of their ADHD-symptomatic behaviours but the majority were not disturbed by this tension.

**Medication**

- The children in this study had generally positive experiences of stimulant medication. This does not mean they liked being on medication, but rather that they were willing to put up with the ‘annoying’ aspects of taking medication in return for the perceived benefits. Rather than seeing medication as a panacea, children had reasonable understandings of the benefits and limitations of the medication.

- The children associated their tablets primarily with helping to improve their social and disruptive behaviour and, consequently, relationships with peers (as opposed to improving their school work and academic functioning).

- Although side effects of the medication such as problems sleeping and reduction in appetite were commonly experienced, this did not make up a major theme of their discussions.

- All children interviewed felt they needed to be on their tablets; older children were more likely to be looking ahead to a time when they could manage without tablets.

- All children in the study believed medication to be the most effective available treatment for their ADHD symptoms, but they also understood that a diagnosis of ADHD and effective drug treatment did not mean that they were absolved of responsibility or of agency for their behaviours.

**Experience of stigma**

- One of the most strongly stated desires communicated by this group of children was for better public understanding of ADHD. Children felt this would create empathy for their situation and relieve them of some of the stigma of negative assumptions attached to a diagnosis of ADHD.

- Children reported experiences of stigma as a direct result of taking tablets; however, experiences of stigma as a result of ADHD diagnosis and symptomatic behaviours were far more frequently expressed. Feelings of being different and alienated were also stronger around diagnosis and ADHD behaviours, than around the need for medication.

- Stigma associated with a diagnosis of ADHD and the attendant behaviours was experienced through:
  - bullying and name-calling by peers
• negative assumptions made by peers, peers’ families, teachers and relatives
• being treated differently by peers, peers’ families, teachers and relatives.

• Close friendships were mentioned as an important protective factor against the initiation and/or continuation of fights that arose as a result of bullying. These friendships were mentioned as frequently as or more often than medication, as factors that helped children to restrain their impulse to fight and/or to continue fighting.

• The children in this study reported that their experiences of stigma resulted in a lack of self-esteem and low self-confidence. They reported less frequently the experience of stigma associated with their medication.

Perceptions of effective non-drug interventions
Interviewees were less likely to spontaneously identify effective formal non-drug interventions for their ADHD behaviours (such as CBT or parent training) but they did identify some key aspects that helped them or they thought might help them. These included:

• participation in sport, particularly boxing
• better public understanding of ADHD (the children reported that this would be likely to result in less bullying and less fighting)
• close friendships
• better understanding from teachers of the needs of children with ADHD.

Impact of tablets on the children’s perceptions of personal agency
The children in this study did not appear to be ethically compromised by their experience of taking stimulant medication. They were able to express personal agency and a willingness to take responsibility for behaviour associated with their ADHD. The children were also able to express appropriate moral evaluations of difficult social situations.

Experience of services
In view of the distress many children experienced in relation to an ADHD diagnosis, ADHD behaviours and tablets, only one child in this study viewed their clinical encounters within child psychiatry services as having a therapeutic component. While no child had any strong complaints about services, several children reported not being able to get in to see a clinician; and feeling that they would like more time with a psychiatrist. Some children felt that clinicians didn’t really care about them. A majority of children felt appointments were routine and boring, and that appointments were primarily for medication checks and for getting prescriptions.

ADHD diagnosis and medication in the context of other life stressors
• Although ADHD and medication were important in the lives of this group of children, with various daily reminders of the burden of mental disorder and the need to take medication, when compared with a list of other stressors, ‘ADHD diagnosis’ and ‘taking tablets’ were not listed as the most important worries. Younger children worried the most about friendships and global warming, while older children were most concerned about exams and friendships. While friendships and academic performance are often problematic for children with ADHD, these concerns are similarly shared by other children as well, as demonstrated in a study of a large cohort of UK children who identified them as their primary sources of anxiety (Alexander & Hargreaves, 2007).

• In the current study, a diagnosis of ADHD was ranked as more worrying than taking tablets for ADHD by almost all children. Results from this study suggests that children have relatively more positive experiences of medication, as compared with more negative experiences of ADHD diagnosis and behavioural symptoms.

4.5 Issues for adults diagnosed with ADHD and their partners

Many of the issues raised by the young people in Singh and colleagues’ study can also be found in studies of those who received a diagnosis of ADHD in adulthood, and of their partners. Young and colleagues’ (in press a) qualitative research into the impact of receiving a diagnosis of ADHD in adulthood, revealed a six stage model of psychological acceptance of the diagnosis:

• relief and elation
• confusion and emotional turmoil
• anger
• sadness and grief
• anxiety
• accommodation and acceptance.

The study asked participants to review the past, to discuss the emotional impact of the diagnosis and to give consideration to the future.

In terms of partners’ perceptions (Young et al., in press b), they expressed that the partners with ADHD felt inadequate, the emotional impact of the diagnosis on both them and their affected partners, and the issue that medication, however helpful, was not a panacea.
4.5.1 Reviewing the past
In reviewing the past participants described feeling ‘different’ from others and experiencing negative judgements from others, including family members, friends and teachers. Participants responded to these judgements by either accepting that what others said was true, or by ignoring them.

4.5.2 Emotional impact of a diagnosis of ADHD
Participants expressed an initial sense of relief at the diagnosis, that there was finally an external cause and explanation for their behaviour. This also gave them a sense of optimism for the future. This initial elation was quickly followed by a sense of turmoil, and anger that they could have been helped earlier. Some expressed sadness at the wasted years of the past and felt that their life experiences could have been more positive and more successful with an earlier diagnosis.

The next stage of the process was an adjustment to living with a chronic condition and the potential negative impact on their future lives. Ultimately this adjustment led to acceptance of ADHD as part of their lives and of who they are.

Partners also expressed the emotional impact of the diagnosis and their own need to come to terms with its implications. They stated that they felt emotionally ill-equipped to provide appropriate support and to cope with the situation. Having the diagnosis, however, allowed partners a framework in which to better understand the person with ADHD, shifting their perspective from the patient ‘being’ the problem to them ‘having’ a problem.

Partners identified an initial increase in self-esteem in the people with ADHD following the diagnosis. Partners also expressed a process towards acceptance of the diagnosis and the attendant status of the person with ADHD.

4.5.3 Consideration of the future
Participants expressed concern about the stigma attached to ADHD and hoped for this stigma to diminish in the future. Parallels with the acceptance of dyslexia were drawn.

Participants reported the positive influence of stimulant medication which they said allowed them to function as ‘normal’ people and improved their social interactions, motivation and focus. Importantly the medication allowed people to be optimistic about the future. Partners also expressed relief at the initiation of medical treatment and reported general improvements, particular in the ability to focus.
Despite the positive impact of the medication, participants noticed a rapid reoccurrence of symptoms, revealing that there was no ‘miracle cure’ for their condition. Nevertheless this experience allowed people to distinguish between problems strongly associated with their symptoms and those less influenced by symptoms, allowing them to take greater personal responsibility for their behaviours.

Similarly, partners expressed disappointment that medication was not a ‘cure all’, and that symptoms rapidly returned once the effects wore off. Also patients’ self-esteem was still an issue, reflecting a lifetime of repeated failures and under-achievement.

Partners identified that the patients could be better supported by mental health professionals and believed that they would benefit from non-pharmacological therapy.

**4.5.4 Conclusions**

The study indicates that adults receiving a diagnosis of ADHD tend to engage in a psychological process that involves a review of the past, an emotional journey towards acceptance of the diagnosis and a consideration of a future with ADHD. The lack of a diagnosis in childhood seems to have led to an internalisation of blame for their behaviours and a negative impact on their hopes for the future. In the long term, this may increase the risk of depression and low self-esteem.

Partners of adults diagnosed with ADHD also went through an emotional journey towards acceptance. They expressed uncertainty about the future of the relationship and how to provide support. Medication was seen as helpful initially but was not a cure, and many problems still remained, particularly low self-esteem.

Partners seem to report a better appreciation of functional improvements following treatment with medication than did the patients, particularly in respect to interpersonal relationships.

Young’s research reveals a need for psychological treatment (in particular cognitive behavioural techniques) for adults diagnosed with ADHD, and their partners, at the point of diagnosis to help them cope with the adjustment process. Psychological therapy can also have a role in helping adults diagnosed with ADHD to reframe their experiences through an encouragement to learn from the past.

Anxiety about the future could be alleviated by emphasising the positive aspects of the disorder and/or the individual’s particular strengths, and to capitalise on these.
Adults with a diagnosis of ADHD should be taught skills to help them anticipate future hurdles and challenges and to apply appropriate coping strategies.

Work with partners also indicates that it would be beneficial for adult patients with ADHD to be helped to develop realistic expectations for the future, and to develop skills to overcome ‘learned helplessness’.

Partners also believed that psychological treatments would be helpful for the patients with ADHD, to anticipate future challenges and hurdles, to apply appropriate coping strategies and managing ongoing difficulties with low self-esteem.

Information leaflets for partners of newly-diagnosed adults with ADHD, and/or directing them to local support groups would do much to support partners to deal with the process.
4.6 Recommendations

4.6.1.1 When working with people with ADHD and their families and carers, healthcare professionals should develop a trusting relationship with them by:

- providing relevant, age-appropriate information (including written information) at every stage of assessment, diagnosis and treatment, which should cover diagnosis, support and self-help, pharmacological and psychological treatment, and the proper use and likely side effects of medication
- being respectful of the individual’s and family’s knowledge and experience of the illness
- being sensitive to the issues of stigma and shame in relation to mental illness.

4.6.1.2 During assessment of a child or young person with ADHD, and throughout their care, healthcare professionals should make all efforts necessary to:

- enable the child or young person (of whatever age) to give their own account of how they feel; this account should be recorded in the notes
- engage the child or young person and the family/carer in treatment decisions
- take into account their expectations about treatment so that meaningful and properly informed consent is given before treatment is started. [Key priority]

4.6.1.3 Healthcare professionals working with children and young people with ADHD should:

- be familiar with local and national guidelines on confidentiality and the rights of the child
- be able to adequately assess the young person’s understanding (including Gillick competence), parental consent and responsibilities, child protection issues, and the use of the Mental Health Act and of the Children Act (1989).

4.6.1.4 Adults with ADHD should be given written information about local and national support groups, voluntary organisations for adults with ADHD, and other sources of advice and advocacy.
4.6.1.5 At a local level, healthcare and educational services should ensure that written materials about the characteristics and basic behavioural management of ADHD is available to teachers.

4.6.1.6 Healthcare professionals should ask families and carers about, and discuss concerns regarding, the impact of ADHD on themselves and other family members, including other children. Healthcare professionals should also:

- offer family members/carers an assessment of their personal, social and mental health needs
- provide verbal and written information and advice about ADHD and its treatment
- provide information about self-help and support groups for families/carers and encourage participation where appropriate
- consider providing self-instruction manuals for parents based on positive parenting and behavioural techniques.
5 Diagnosis

5.1 Introduction

This guideline is applicable to people above the age of 3 and of all levels of intellectual ability, who show symptoms of hyperactivity, impulsivity or inattention to a degree that severely impairs their mental or social development causing failure to make expected progress in the domains of intellectual development, personal relationships, physical or mental health or academic function. This includes people with ADHD whether or not they have other coexisting developmental or mental health disorders or whether the ADHD behaviours and symptoms result from genetic, physical environmental or social-environmental causes. This chapter sets out to look at the issue of diagnostic categorisation and assessment that should trigger the use of this guideline. It is in two parts. The first part addresses the validity of the diagnostic construct of DSM-IV ADHD and ICD-10 hyperkinetic disorder, as diagnostic categories that give rise to significant impairments. The second part provides guidance for clinical practice.

For ADHD the question is whether a diagnostic category associated with clear evidence of impairment, that most people would consider requires some form of medical, social or educational intervention, can be reliably defined. To provide guidance for clinicians involved in the medical component of such intervention, the validity of the diagnostic concept of ADHD is addressed using the definition of a clinical disorder or illness as any condition that causes discomfort, dysfunction, distress or social problems to the person concerned. This part of the guideline addresses the question of validity of the diagnostic construct of ADHD and provides practice guidelines for the diagnostic process.

5.2 Definitions of terms

The terminology applied to ADHD and related problems has been used in different ways at different times and by different groups of people. This section clarifies some of the major terms used in this chapter. A description of the diagnostic terms is provided in Chapter 2.

ADHD and hyperkinetic disorder

The terms ADHD (DSM-IV) and HKD (ICD-10) are used when talking about the specific diagnostic categories of ADHD as defined by DSM-IV and hyperkinetic disorder as defined by ICD-10 respectively. The criteria for HKD are more stringent that those for ADHD with HKD forming a subgroup of the DSM-IV ADHD combined type diagnosis (see Chapter 2). When discussing the disorder more broadly we will use ADHD as an umbrella term. Some of the earlier literature used the term ‘hyperactivity’ for the cluster of
hyperactive, impulsive and inattentive symptoms. In this guideline the term 'hyperactivity' will be restricted to mean the combination of symptoms that define overactive behaviour and the term 'ADHD symptoms' used to refer to the combination of hyperactive, impulsive and inattentive symptoms.

**Symptoms**

The behavioural phenomena that describe ADHD will be referred to as symptoms of ADHD throughout this chapter. This choice of wording is intended to reflect that the behavioural phenomena that characterise ADHD may not always be reported as observed behaviours, but may also be reported as subjective changes in mental state. For simplicity the term ADHD symptoms will be used whether the guideline is discussing impairing levels of behaviour or mental phenomena, or referring to the normal range of behaviour of these phenomena. For example many people have low to moderate levels of ADHD symptoms, which do not reflect an impairing condition or mental health disorder.

However, the GDG recognises that behaviours that describe ADHD are not strictly symptoms, as this term is usually used to refer to changes in physical or mental state associated with significant morbidity that is a change from a premorbid state: for example symptoms experienced during an episode of depression or attack of anxiety. The behavioural and mental phenomena that characterise ADHD are in contrast trait-like, in the sense that they are non-episodic and may have been present from early childhood. Furthermore, in children the criteria are usually applied on the basis of parent and teacher reports of behaviour, rather than subjective reports of mental state phenomena; although older children and adults are usually able to provide detailed descriptions of their subjective experiences of inattention, hyperactivity and impulsivity.

**Oppositional defiant disorder (ODD) and conduct disorder (CD)**

The use of these terms is restricted to mean the definitions of ODD and CD as described in DSM-IV. We recognise however that the terms ODD and CD are widely used outside of these narrow diagnostic definitions. Many studies have used rating scale measures for aspects of ODD and CD and people often use the term conduct disorder when they are talking about oppositional behaviour. We will therefore use the terms conduct problems or oppositional defiant problems when referring to these classes of behaviour where the DSM-IV definitions have not been strictly applied.

**5.3 The validity of ADHD as a diagnostic category**

The use of the diagnosis of ADHD has been the subject of considerable controversy and debate and the diagnosis itself has varied across time and
place as diagnostic systems have evolved (Rhodes et al., 2006). Points of
controversy identified by the GDG included both specific issues, such as the
wide variation in prevalence rates reported for ADHD and the possible
reasons for these differences, and the nature of the aetiological factors that
increase the risk for ADHD, as well as more complex broader sociological and
philosophical issues.

The GDG wished to evaluate evidence for the validity of the diagnostic
category of ADHD and formulate a position statement on the use of the
diagnosis. It is recognised that defining neurodevelopmental and mental
health disorders is a difficult process due to the overlapping nature of
syndromes, the complexity of the aetiological processes and the lack of a ‘gold
standard’ such as a biological test. In this regard ADHD is similar to other
common psychiatric disorders that rely on the identification of abnormal
mental phenomena. Although biological tests for ADHD do not exist, the
diagnosis can be reliably applied when data capture tools such as
standardised clinical interviews used by trained individuals and operational
diagnostic criteria are employed (for example, Taylor et al., 1986; Schwab-
Stone et al., 1993; Schwab-Stone et al., 1994; Faraone et al., 1995; Epstein et al.,
2006).

In keeping with most common mental health disorders the distinction
between the clinical condition and normal variation in the general population
is difficult to define on the basis of symptom counts alone. This is because
there is continuity in the level of ADHD symptoms between those with an
impairing mental health disorder and those who are unimpaired. The
distinction between ADHD and normal variation in the general population
requires the association of a characteristic cluster of symptoms and significant
levels of impairment. This is comparable to normal variation for medical traits
such as hypertension and type II diabetes, as well as psychological problems
such as anxiety or depression. Controversial issues surround changing
thresholds applied to the definition of illness as new knowledge and
treatments are developed (Kessler et al., 2002) and the extent to which it is
acknowledged that clinical thresholds are socially and culturally influenced
and determine how an individual’s level of functioning within the ‘normal
cultural environment’ is assessed (Sonuga-Barke, 1998; Rosenman, 2006). In
considering these issues, a key question is to define the level of ADHD
symptoms and associated impairments required to trigger the use of this
guideline.

Undertaking a systematic review of diagnostic categories is not a
straightforward exercise for behavioural and mental health disorders because
in most cases definitive diagnostic tests for the presence or absence of
disorder do not exist. The relative lack of a validated reference standard
(indicated by SIGN diagnostic study quality assessment, see Appendix 16)
means that the question of validity for the diagnosis of ADHD needs to draw
on evidence from a wide range of sources. There is also potential for
ascertainment bias, particularly in clinic-referred populations, and
considerable variability resulting from the use of different clinical and
demographic subgroups, differences in disease prevalence and severity
among various populations sampled for research, and the use of different
behavioural and symptom measures (Whiting et al., 2004). The GDG wish to
emphasise that psychiatric nosology is a dynamic and developing field and
changes are to be expected as more data are accrued over time.

5.4 Methodology

To ensure that a transparent, structured approach was taken, the GDG agreed
to use one similar to the Washington University Diagnostic Criteria (Feighner
et al., 1972). The methodology used to create the Washington University
Diagnostic Criteria has been widely accepted for this purpose, and similar
approaches have been taken to validate diagnostic categories for the Research
Diagnostic Criteria, the DSM and the ICD. The approach involves setting out
criteria for validating a particular disorder and seeing how far a particular set
of phenomena are consistent with those criteria. Using these criteria as a
framework this chapter sets out to answer the following questions:

A: To what extent do the phenomena of hyperactivity, impulsivity and
inattention, which define the current DSM-IV and ICD-10 criteria for
ADHD and HKD, cluster together in the general population and into a
particular disorder that can be distinguished from other disorders and
from normal variation?

B: Is the cluster of symptoms that defines ADHD associated with
significant clinical and psychosocial impairments?

C: Is there evidence for a characteristic pattern of developmental
changes, or outcomes associated with the symptoms, that define
ADHD?

D: Is there consistent evidence of genetic, environmental or
neurobiological risk factors associated with ADHD?

Studies were selected for inclusion in this review if they met the SIGN quality
assessment criteria for systematic reviews and cohort studies. For diagnostic
and factor analytic studies the GDG established a set of criteria approved by
NICE: 1) the study addresses an appropriate and clearly focused question (or
hypothesis) and 2) the sample population being studied are selected either as
a consecutive series or randomly, from a clearly defined study population.

A literature search was conducted for existing systematic reviews and meta-
analyses on CINAHL, EMBASE, MEDLINE, PsycINFO, which were
considered to be the best level of evidence. The initial search found 5,516 reviews of which 9 were relevant to the questions about ADHD and application of the Washington Diagnostic Criteria. Where insufficient evidence was found from previous systematic reviews, a search for primary studies was carried out (see Appendix 16).

In addition to the review of the literature, a consensus conference was held to bring together experts in the field who held a range of views and could address the concept of ADHD from different perspectives. This provided an opportunity to debate the key issues surrounding the use of the diagnostic category and thereby to assist the GDG with the task of deciding what should trigger the use of the guideline and for whom the guideline is intended. A summary of the consensus conference is provided in Section 5.14.

5.5 Reviewing the validity of the diagnosis: summary of the evidence

The first issue to be addressed is: To what extent do the phenomena of hyperactivity, impulsivity and inattention, which define the current DSM-IV and ICD-10 criteria for ADHD and hyperkinetic disorder, cluster together in the general population and into a particular disorder that can be distinguished from other disorders and from normal variation?

The evidence addressing this issue is divided into three main questions:

5.5.1: Do the phenomena of hyperactivity, inattention and impulsivity cluster together?

5.5.2: Are ADHD symptoms distinguishable from other conditions?

5.5.3: Are the phenomena of hyperactivity, inattention and impulsivity distinguishable from the normal spectrum?

5.5.1 Do the phenomena of hyperactivity, inattention and impulsivity cluster together?

No evidence was found from the systematic search of reviews that was of direct relevance to this question. This is because, despite a large primary literature, no systematic reviews in this area have been undertaken. Therefore a systematic search of factor-analytic and cluster analytic studies was carried out. Additional factor-analytic and cross-sectional studies were identified by the GDG (Appendix 17.1). None of these studies met the SIGN inclusion criteria that requires an appropriate reference standard for diagnostic measures, but did meet the extension to the SIGN criteria approved for this review, since the aim of the question was to evaluate whether the phenomena
of hyperactivity, inattention and impulsivity cluster together in the population, rather than to assess the accuracy of diagnostic tests.

The inclusion criteria for factor and cluster analytic studies were defined as follows: (i) that the study addresses an appropriate and clearly focused question, (ii) that the sample being studied was selected either as a consecutive series or randomly, from a clearly defined study population.

Evidence

Many factor analyses indicate a two-factor model: ‘hyperactivity-impulsivity’ and ‘inattention’. This has been replicated in population-based studies (Lahey et al., 1994; Leviton et al., 1993; Wolraich et al., 1996) and clinical samples (Bauermeister et al., 1992; Lahey et al., 1988; Pelham et al., 1992).

In an early study, ‘hyperactivity-impulsivity’ was reported as a single factor, where the factor ‘hyperactivity’ was defined as ‘impulsive, excitable hyperactivity’ (Dreger et al., 1964).

More recent factor analytic studies based on DSM-IV criteria support previous findings that the phenomena of inattention and hyperactivity-impulsivity form distinct symptom clusters in children (Molina et al., 2001; Amador-Campus et al., 2005; Zuddas et al., 2006) and adolescents (Hudziak et al., 1998).

Looking specifically at children identified as having a behavioural problem, Conners (1969) found ‘hyperactivity’ and ‘inattention’ as separate and distinct factors. The factor structure of adolescent self-report behavioural data was investigated by Conners and colleagues (1997): six factors were identified, including ‘hyperactivity’ and ‘cognitive problems’. The ‘hyperactivity’ factor included characteristics such as being unable to sit still for very long, squirming and fidgeting and feeling restless inside when sitting still. The ‘cognitive problems’ factor consisted of having trouble keeping focused attention, having problems organising tasks and forgetting things that were learnt. In a further study by Conners (1998) similar findings were reported. An attentional problem factor was found that overlapped with the DSM-IV criteria for the inattentive subtype of ADHD, with a similar overlap between the factor items for hyperactivity and the DSM-IV criteria for hyperactivity-impulsivity.

Some studies have identified three factors with ‘hyperactivity’ and ‘impulsivity’ as two distinct factors in addition to ‘inattention’, in both population (Gomez et al., 1999; Glutting et al., 2005) and clinical samples (Pillow et al., 1998). However, Gomez and colleagues (1999) showed that the model fit for the three-factor solution was only marginally better than the two-factor model. In the study of Pillow and colleagues (1998) of boys with ADHD, the impulsive and hyperactive symptoms formed a single factor.
when oppositional-defiant and conduct disorder items were also included in the factor analysis.

Werry and colleagues (1975), however, found that hyperactivity, impulsivity and inattention formed a single factor using both population control and ‘hyperactive’ samples.

Latent class analysis (LCA) identifies clusters of symptoms that group together. Using this approach, Hudziak and colleagues (1998) found that hyperactivity-impulsivity and inattentive symptoms cluster together as a ‘combined’ type latent class, as well as separate hyperactive-impulsive and inattentive latent classes. The latent classes map closely to the DSM-IV criteria, with DSM-IV combined type ADHD falling entirely within the severe combined type latent class, whereas individuals with the DSM-IV inattentive subtype fell either within the severe inattentive or the severe combined type latent classes.

The clustering of hyperactivity, impulsivity and inattention appear to be stable across a number of countries. Ho and colleagues (1996) found separate robust dimensions for ADHD symptoms, antisocial and neurotic behaviour in a sample of 3,069 Chinese schoolboys. Correlations among different dimensions were similar to those reported in European and US samples. Taylor and Sandberg (1984) compared data from 437 English schoolchildren with published data from the US and New Zealand. They identified a factor of hyperactivity-inattention that was distinct from conduct disorder. The comparisons supported the view that English schoolchildren were similar to their contemporaries in the US and New Zealand with differences in prevalence rates between different countries accounted for by discrepancies in diagnostic practice.

In adult population samples a two-factor model has been identified (DuPaul et al., 2001; Smith & Johnson, 2000) as well as a three-factor model (Kooij et al., 2005). Glutting and colleagues (2005) assessed university students aged 17 to 22 using parent-rated information in addition to self-rated data. They reported slightly contrasting findings within each set of data: exploratory and confirmatory analysis showed that DSM-IV ADHD symptoms generated a three-factor model in the self-report data and a two-factor model in the parent-informant data.

Although most studies show separate factors for inattention and hyperactivity-impulsivity, these are highly correlated in children (Gomez et al., 1999) and adult samples (Kooij et al., 2005).

There may be age-dependent changes in the factor structure. Bauermeister and colleagues (1992) found that there was a single attention/impulsivity-hyperactivity factor in pre-school children, and separation into two factors in
school-age children. Nearly all the studies of school-age children reported two
factors. In contrast, the study from Glutting (2005) using college students aged
17 to 22 found three factors, with the separation of hyperactive and impulsive
symptoms. Similarly Kooij and colleagues (2005) using adult samples
identified three separate factors.

Summary
There was strong evidence for clustering of inattentive and hyperactive-
impulsive symptoms in both population and clinical samples. Evidence for
one, two and three factor models was found, with most studies supporting a
two-factor model. Most studies found two correlated factors for
hyperactivity-impulsivity and inattention, while others were able to
distinguish between hyperactivity and impulsivity and a few found one
combined factor for all three domains. There is some evidence that the
number of factors identified depends on the age of the sample, with nearly all
studies of school-age children reporting two factors. These findings have been
observed in both population and clinical samples and in a number of different
cultural settings. Latent class analysis in population samples detects
clustering of symptoms into groups that are similar but not identical to DSM-
IV subtypes for ADHD.

5.5.2 Are ADHD symptoms distinguishable from other conditions?
No systematic reviews were identified in the literature that addresses this
question. The GDG considered that the most important and controversial
distinction to be made was between ADHD and oppositional-defiant and
conduct disorders. These are also the most commonly reported comorbid
problems in children and adolescents diagnosed with ADHD and define a set
of behaviours that might be difficult to distinguish from ADHD. It was
therefore decided to restrict a formal literature search to identify studies that
indicate whether a distinction can be made between ADHD, oppositional-
defiant and conduct problems. Additional references were identified by the
GDG members (see Appendix 17.1).

Evidence
ADHD and oppositional-defiant and conduct problems
Most of the studies using factor-analytic approaches for the analysis of ADHD
symptoms report separate factors for hyperactivity-impulsivity, inattention
and oppositional-defiant or conduct problems. These include most of the
studies reviewed in the previous section on the factor structure of ADHD
symptoms (for example, Bauermeister et al., 1992; Connors et al., 1969;
Connors 1997; Ho et al., 1996; Pelham et al., 1992; Taylor et al., 1984; Werry et
al., 1975; Wolraich et al., 1996). These studies are highly consistent in being
able to separate the items that describe oppositional-defiant and conduct
problems from hyperactivity-impulsivity and inattention. Although the
behavioural items fall into separate dimensions there are significant
correlations between the various behavioural the behavioural factors.
Two studies using latent class analysis came to different conclusions. Frouke and colleagues (2005) conducted a diagnostic study of 2,230 Dutch pre-adolescents from the general population. Latent class analysis revealed that ADHD symptoms clustered together with symptoms of ODD and CD. A further study from the Netherlands of disruptive behaviour in 636 seven-year-old children (Pol et al., 2003) came to similar conclusions. Latent class analysis identified three main classes of children with: (i) high levels of ODD and ADHD, (ii) intermediate levels of ODD and ADHD with low levels of conduct problems, (iii) low levels of all disruptive problems. No classes were identified with only ADHD, ODD or conduct problems.

In contrast, King and colleagues (2005) identified five distinct groups using a cluster analysis, which like latent class analysis identifies discrete groups of symptoms clusters: ADHD with inattention (ADHD-I), ADHD with hyperactivity-impulsivity (ADHD-H/I), ADHD with both hyperactivity/impulsivity and inattention (ADHD-C), ADHD-C with ODD, and ADHD-I with ODD. For both the inattentive symptoms and combined inattentive/hyperactive-impulsive symptoms they found clustering either with or without symptoms of ODD.

Latent dimension modelling by Ferguson and Horwood (1991) looking at children with ADHD and CD suggested that these could be seen as independent dimensions, although they are highly inter-correlated. However, the two often occurred independently of each other and only partially shared aetiological factors.

ADHD can be a precursor of other problems. When ADHD and disruptive behavioural problems coexist, the history usually suggests that symptoms of ADHD appear first before the development of disruptive behavioural problems. A follow-up of a community sample of children with ADHD symptoms but no oppositional behaviour between the ages of 7 and 17 found that children with ADHD symptoms could develop oppositional behaviour at a later stage, but that the reverse pathway from oppositional behaviour to ADHD was uncommon (Taylor et al., 1996).

Population twin studies find that symptoms of ADHD are distinct from but share overlapping genetic influences with conduct problems (Thapar et al., 2001; Silberg et al., 1996; Nadder et al., 2002). Multivariate twin modelling suggests that while the genetic influences on conduct disorder are largely shared with those that influence ADHD, there are in addition important environmental factors shared equally that influence the risk for conduct problems but not ADHD (Thapar et al., 2001). In nearly all twin studies of ADHD there is evidence for the influence of unique environmental factors but not shared (familial) environment; whereas for conduct problems, twin studies find evidence of shared environmental influences. Nadder and
colleagues (2002) conclude that the co-variation of ADHD and ODD/CD is the result of shared genetic influences with little influence from environmental factors. However there are substantial additional influences from shared environmental factors on ODD/CD, especially when they are not accompanied by ADHD (Silberg et al., 1996; Eaves et al., 1997).

**ADHD and other co-occurring conditions**

Population twin studies find that symptoms of ADHD are distinct from but share overlapping familial and genetic influences with other neurodevelopmental traits including reading ability (Gilger et al., 1992; Willcutt et al., 2000; Willcutt et al., 2007), general cognitive ability (Kuntsi et al., 2004), symptoms of developmental coordination disorder (Martin et al., 2006) and symptoms of pervasive developmental disorders (Roland et al., 2007).

ADHD is reported to co-occur with personality disorder in young offenders (Young et al., 2003). A prison survey found that 45% of incarcerated young adults had a previous history and persistence of ADHD symptoms (Rosler et al., 2004). The distinction between ADHD and personality disorder in adults raises important nosological questions and remains poorly investigated.

Dysthymia, depression and anxiety symptoms and disorders are frequently associated with ADHD in adults. In the US National Comorbidity Survey, adults with ADHD had increased rates of mood disorders, anxiety disorders, substance misuse disorders and impulse control disorders (Kessler et al., 2006). The causal links between ADHD and these co-existing symptoms, syndromes and disorders remains poorly investigated.

**Summary**

In the majority of factor-analytic studies, ADHD symptoms (inattention, hyperactivity and impulsivity) are found to represent separate but correlated factors from oppositional behaviour and conduct problems. This suggests that they exist as separate dimensions or traits.

When symptom clusters were considered using statistical approaches that aim to identify symptoms that group together, ADHD symptoms were found to group with oppositional behaviour in two studies that used latent class analysis; but in another study using a cluster analytic approach, two groups of children with ADHD symptoms were identified, one group where ADHD symptoms occurred with oppositional behaviour and a separate group where ADHD symptoms were not accompanied by oppositional behaviour. The GDG concluded that on the basis of these findings, symptoms of ADHD and oppositional and conduct problems represent distinct but correlated sets of behaviours that often co-occur. The relationship of ADHD symptoms and oppositional and conduct problems cannot be clearly defined on the basis of statistical analysis of child behaviour that makes use of cross-sectional data alone.
One study using longitudinal data suggested that ADHD represents a separate condition that is a risk factor for the development of oppositional and conduct problems, since ADHD came first and was associated with the future development of oppositional/conduct problems, whereas the reverse situation of oppositional/conduct problems leading to ADHD did not occur. There was however no other similar study with which to compare this result.

Twin studies suggest overlapping genetic influences on ADHD and conduct problems, but there are also shared environmental influences on ODD/CD that do not act on ADHD. Twin studies of ADHD and ODD/CD show different patterns of twin correlations suggesting the existence of shared environmental influences on ODD/CD but not on ADHD. This suggests that some aspect of the environment shared by children in the same family increases the risk for ODD/CD but not the risk for ADHD; this indicates a separation between the two at the level of aetiological risk factors.

The correlation between ADHD and several neurodevelopmental traits (cognitive ability, reading ability, developmental coordination, and pervasive developmental disorders) is due largely to the effects of shared genetic influences. For this reason ADHD may be viewed as one component of a general propensity to neurodevelopmental problems that arises from shared aetiological influences.

In adults, co-occurring symptoms, syndromes and disorders are frequently found to exist alongside the core ADHD syndrome, but their distinction from ADHD and the reasons for high rates of co-occurrence are not well addressed in the current literature.

5.5.3 Are the phenomena of hyperactivity, inattention and impulsivity distinguishable from the normal spectrum?

No systematic reviews were identified that were of direct relevance to this question. The previous search for primary studies revealed two factor-analytic studies relevant to this question. The GDG identified further factor-analytic and quantitative genetic studies that addressed this question (see Appendix 17).

Evidence

Many studies have found a strong correspondence between quantitative measures of ADHD symptoms and the categorical diagnosis (Biederman et al., 1993; Biederman et al., 1996; Bird et al., 1987; Boyle et al., 1997; Chen et al., 1994; Edelbrock et al., 1986). These studies show that children with ADHD appear to be at one extreme of a quantitative dimension of ADHD symptoms in the population and, that on this quantitative dimension of symptoms there is no
obvious bi-modality that separates children with ADHD from children who 
do not have ADHD.

Twin studies using individual differences approaches (reviewed in Thapar et 
al., 1999; Faraone et al., 2005) and De Fries-Fulker (DF) extremes analysis 
(Gjone et al., 2006; Levy et al., 1997; Willcutt et al., 2000; Price et al., 2001) 
estimate similar magnitudes for the proportion of genetic, shared 
environmental and non-shared environmental influences on ADHD 
symptoms in general population twin samples. These studies indicate that 
aetiological influences on ADHD symptoms are distributed throughout the 
population and there is no obvious threshold or cut-off between people with 
high levels of ADHD symptoms and the continuous distribution of symptoms 
throughout the population. These studies do not take impairment into 
account, but only investigate the proportion of genetic and environmental 
influences on ADHD symptom counts.

Using latent class analysis, ADHD symptoms can be divided into multiple 
groups, distinguished on the basis of three symptom groupings: attention, 
hyperactivity-impulsivity and the combination of these two symptom 
domains. In addition, the symptom groups are separated on the basis of low, 
medium and high levels into distinct severity groups. Twin data from female 
adolescents in Missouri and children in Australia both found a similar pattern 
of familial segregation for the latent classes suggesting that familial influences 
can distinguish between ADHD and the normal range of behaviour 
(Rasmussen et al., 2004). These data provide evidence for the distinction of 
ADHD into inattentive, hyperactive-impulsive and combined subtypes and 
suggest that ADHD might be distinguishable from the normal range on the 
basis of familial risks for the observed symptom clusters.

Summary

Most analytic approaches are unable to make a clear distinction between the 
diagnosis of ADHD and the continuous distribution of ADHD symptoms in 
the general population. Twin studies suggest that the genetic and 
environmental influences on groups with high levels of ADHD symptoms are 
of the same magnitude as those that influence ADHD symptom levels in the 
normal range. It is not yet known whether the same specific factors are 
involved, but the studies using DF analysis suggest that there are at least 
some overlapping genetic influences on ADHD symptoms and the continuity 
of ADHD symptoms throughout the population.

Twin studies have in most cases defined ADHD on the basis of symptom 
criteria alone and it is not yet known whether the results may be different if 
full diagnostic criteria, including impairment, were applied. In contrast, 
latent class analysis can distinguish groups with high, moderate and low 
levels of ADHD symptoms and suggests that these groups can be
distinguished on the basis of familial risks. The current literature does not address the difference in interpretation of the latent class and quantitative approaches.

The GDG concluded that on the basis of current evidence, ADHD was similar to other common medical and psychiatric conditions that represent the extreme of dimensional traits, such as hypertension, obesity, anxiety and depression. The disorder can therefore only be defined on the basis of high levels of symptoms and their association with significant clinical impairments and risk for development of future impairments.

5.6 Is the cluster of symptoms that defines ADHD associated with significant clinical and psychosocial impairments?

There were no systematic reviews that addressed this question. A search for cohort studies was carried out and additional primary studies were identified by the GDG members (see Appendix 17).

5.6.1 Evidence

Academic difficulties

Follow-up studies of people diagnosed with ADHD in childhood have consistently indicated impairment in their academic functioning. Children and adolescents with ADHD have been shown to have greater impaired attention, less impulse control, and greater off-task, restless and vocal behaviour (Fischer et al., 1990). They also have higher rates of both specific and generalised learning disabilities, poor reading skills (McGee et al., 1992) and speech and language problems (Hinshaw, 2002) when compared with healthy controls. These impairments often lead to grade retention (Hinshaw, 2002), to a lower probability of completing schooling when compared with children who do not have ADHD (Mannuzza et al., 1993), suggesting potential long-term ramifications for vocational, social and psychological functioning into adulthood (Biederman et al., 1996; Young et al., 2005; Wilson & Marcotte, 1996).

An important question about educational impairment of children with ADHD is whether, given an appropriate educational environment, this is determined primarily by the presence of high levels of ADHD symptoms or the association with co-occurring behavioural conditions such as conduct disorder, or learning disabilities. Wilson and Marcotte (1996) found that the presence of ADHD in adolescents increased the risk for lower academic performance and poorer social, emotional and adaptive functioning, but that the additional presence of conduct disorder further increased the risk for
maladaptive outcomes. In another study the association of conduct disorder with academic underachievement was found to be due to its comorbidity with ADHD (Frick et al., 1991).

**Family difficulties**

Impaired family relationships have been reported in families of children with ADHD. Follow-up studies indicate that mothers of children and adolescents with ADHD have more difficulty in child behaviour management practices and coping with their child’s behaviour (August et al., 1998), and display higher rates of conflict behaviours, such as negative comments, social irritability, hostility and maladaptive levels of communication and involvement (August et al., 1998; Fletcher et al., 1996).

Family impairment also permeates the parent’s lives. Parents of children with ADHD report having less time to meet their own needs, fewer close friendships, greater peer rejection, less time for family activities, which might lead to less family cohesion and a significant effect on the parent’s emotional health (Bagwell et al., 2001).

Co-existing conduct and emotional problems may drive the association between maternal expressed emotion (negativity, resentment and emotional over-involvement) and ADHD (Psychogiou et al., 2007).

**Social difficulties**

Girls with ADHD tend to have fewer friends (Blachman & Hinshaw, 2002) and greater problems with peers and the opposite sex (Young et al., 2005). Hyperactive children with or without conduct problems have higher rates of problems with peers and higher rates of social problems because of lack of constructive social activities (Taylor et al., 1996). In a study by Ernhardt and Hinshaw (1994) it was reported that a diagnosis of ADHD significantly predicted peer rejection; however aggressive and non-compliant disruptive behaviours were important and accounted for 32% of the variance in peer rejection.

**Antisocial behaviour**

Antisocial behaviour is more prevalent in children and adolescents with ADHD than non-ADHD groups. Some studies show increased rates of antisocial acts (for example, drug misuse) in comparison with children who do not have ADHD (Barkley, 2004; Mannuzza et al., 1998).

Follow-up studies have also shown that people with high levels of ADHD symptoms had significantly higher juvenile and adult arrest rates (Satterfield & Schell, 1997). Young adults with a diagnosis of ‘hyperactivity’ in childhood were more likely to have a diagnosis of antisocial disorder than healthy...
controls (32% versus 8%) and drug misuse (10% versus 1%) at follow-up (Mannuzza et al., 1991).

ADHD is also a risk factor for psychiatric problems including persistent hyperactivity, violence, antisocial behaviours (Biederman et al., 1996; Taylor et al., 1996), (Taylor et al., 1996), and antisocial personality disorder (Mannuzza et al., 1998).

In a prospective follow-up of 103 males diagnosed with ADHD, the presence of an antisocial or conduct disorder almost completely accounted for the increased risk for criminal activities. Mannuzza and colleagues (2002) reported that antisocial disorder was more prevalent in children with pervasive and school-only ADHD. However, Lee and Hinshaw (2004) reported that the predictive power of ADHD status to adolescent delinquency diminishes when key indices of childhood externalising behaviour related to ADHD are taken into account.

Boys with ADHD and high defiance ratings show significantly higher felony rates than healthy controls (Satterfield et al., 1994). However, ADHD diagnosed in childhood increases the risk of later antisocial behaviour even in the absence of comorbid ODD or CD (Mannuzza, 2004).

Adolescent and adult problems

A 10-year prospective study of young people with ADHD found that the lifetime prevalence for all categories of psychopathology were significantly greater in young adults with ADHD compared with controls. This included markedly elevated rates of antisocial, addictive, mood and anxiety disorders (Biederman et al., 2006).

In adolescence and adult life, symptoms of ADHD begin to associate with other diagnoses that are seldom made in childhood. Adolescent substance misuse, in particular, seems to be more common in people with the diagnosis of ADHD (Wilens et al., 2003), though it is not yet clear whether it is the ADHD per se that generates the risk or the co-existent presence of antisocial activities and peer groups.

Both cross-sectional epidemiological studies and follow-up studies of children with ADHD show increased rates of unemployment compared with controls (Biederman et al., 2006; Kessler et al., 2006; Barkley et al., 2006). Adults with ADHD were found to have significantly lower educational performance and attainment, with 32% failing to complete high school; they had been fired from more jobs and were rated by employers as showing a lower job performance (Barkley et al., 2006). The survey from Biederman (2006) showed that 33.9% of people with ADHD were employed full time versus 59% of controls.
An increased rate of road traffic violations and driving accidents in adults with ADHD has been documented by several authors (Biederman et al., 2007; Barkley et al., 2007; Thompson et al., 2007; Jerome et al., 2006; Fischer et al., 2006; Swensen et al., 2004; Brook et al., 2006).

5.6.2 Summary

ADHD symptoms are associated with a range of impairments in social, academic, family, mental health and employment outcomes. Longitudinal studies indicate that ADHD symptoms are predictive of both current and future impairments. Impairments also result from the presence of co-occurring problems including conduct problems, emotional problems and overlapping neurodevelopmental disorders. Adults with ADHD are found to have lower paid jobs and lower socioeconomic status and have more car accidents. Impairment is an essential criterion when considering the diagnosis of ADHD. The presence of high levels of ADHD symptoms is associated with impairment in multiple domains; however it is not possible to clearly delineate a specific number of ADHD symptoms at which significant impairment arises.

5.7 Is there evidence for a characteristic pattern of developmental changes, or outcomes associated with the symptoms, that define ADHD?

The search for systematic reviews and meta-analyses identified one review that was of relevance to this question. Additional reviews and primary studies were identified by the GDG members (see Appendix 17).

5.7.1 Evidence

There is evidence for continuity of ADHD symptoms over the lifespan. Faraone and colleagues (2006) analysed data from 32 follow-up studies of children with ADHD into adulthood. Where full criteria for ADHD were used approximately 15% of children were still diagnosed with ADHD at age 25. In addition, the meta-analysis found that approximately 65% of children by age 25 fulfilled the broader definition of DSM-IV ADHD ‘in partial remission’, indicating persistence of some symptoms of ADHD associated with continued clinically meaningful impairments.

Relative to controls, levels of overactivity and inattention are developmentally stable (Taylor et al., 1996). Longitudinal studies of children with ADHD show similar rates of ADHD in adolescence (Biederman et al., 1996; Faraone et al., 2002; Molina & Pelham, 2003).

Population twin studies have also addressed the stability of ADHD symptoms throughout childhood and adolescence. Rietveld (2004) reported that parent ratings of attentional problems were moderately stable from age 3...
to 7, and greater stability from age 7 to 10. They further showed that such
stability appeared to be mediated largely by overlapping genetic influences
such that most, but not all, genetic influences at one age influenced ADHD at
another age. Price and colleagues (2005) reported similar findings with
correlations around 0.5 between ADHD symptoms at ages 2, 3 and 4. This
stability was estimated to be mediated 91% by genetic influences. Kuntsi and
colleagues (2004) extended these data to age 8, and found similar moderate
stability between the data for ages 2, 3 and 4 and the data for age 8. Larsson
and colleagues (2004) completed a similar longitudinal twin study of 8 to 13
year olds and found fairly high stability between the two ages. They further
concluded that this stability was due to shared genetic effects. Change in
symptoms between childhood and adolescence was thought to be due to new
genetic and environmental effects that become important during adolescence.

5.7.2 Summary

There is evidence for the persistence of ADHD symptoms from early
childhood through to adulthood. Longitudinal studies confirm that ADHD
persists into adulthood but developmentally appropriate criteria have yet to
be developed for ADHD in adults. Using child criteria, approximately 15% of
children with ADHD retain the diagnosis by age 25 but a much larger
proportion (65%) are in partial remission, with persistence of some symptoms
associated with continued impairments. The profile of symptoms may alter
with a relative persistence of inattentive symptoms compared with
hyperactive-impulsive symptoms, however the evidence base for this
conclusion is poor and based on the analysis of developmentally
inappropriate measures of hyperactivity-impulsivity in adults.

The GDG concluded that there is currently insufficient evidence to warrant a
different diagnostic concept in childhood and in adulthood. However it is
envisaged that improved definitions that take into account developmental
changes will develop as further evidence is accrued. Familial and genetic
influences in ADHD symptoms appear to be stable through childhood and
early adolescence, but there is a lack of data on the factors that modify the
course of ADHD into adulthood.

5.8 Is there consistent evidence of genetic,
environmental or neurobiological risk factors
associated with ADHD?

The literature search identified eight systematic reviews and meta-analyses.
GDG members identified additional reviews and primary studies (see
Appendix 17). When interpreting this section it is important to note that
associations do not imply causal associations and may represent
epiphenomena of ADHD rather than causal processes.
5.8.1 Evidence

Cognitive experimental studies

Willcutt and colleagues (2005) reviewed 83 studies that had administered executive functioning measures and found significant differences between ADHD and non-ADHD groups where the former showed executive function deficits. The size of the difference between children with ADHD and unaffected controls, while significant, was moderate rather than large. The term *executive function* refers to a set of higher cognitive and emotional mental functions involved in the control and regulation of behaviour and performance. This includes concepts such as cognitive inhibition and initiation, self-regulation and motor output. The neural mechanisms by which the executive functions are implemented is a topic of ongoing debate in the field of cognitive neuroscience. It is not yet clear whether impairments in the performance of executive tasks is due to primary deficits in the brain processes underlying executive functions, or whether the performance deficits are secondary to more general processes.

Differences in executive functioning between ADHD and non-ADHD groups have also been reported in adults (Hervey *et al.*, 2004; Boonstra *et al.*, 2005; Schoelin *et al.*, 2005; Woods *et al.*, 2005). The results of studies of ADHD in adults suggest a wide variety of general and specific performance on cognitive-experimental tasks that are similar to those seen in children with ADHD. The review from Hervey and colleagues (2004) did not point to impairments in one area of cognitive performance, but rather impairments across a range of cognitive functions.

The interpretation of cognitive-experimental studies in ADHD remains controversial, but most authorities agree that both executive and non-executive processes are disrupted in people with ADHD. Although work has largely focused on the executive functions there is an interest in non-executive processes (Rhodes *et al.*, 2006; Berwid *et al.*, 2005). A recent meta-analysis of the stop-signal paradigm concluded that there are significantly slower mean reaction times, greater reaction time variability and slower stop signal reaction times in children with ADHD relative to controls (Alderson *et al.*, 2007). The pattern of findings suggested a more generalised impairment of attentional and cognitive processing rather than a primary deficit of behavioural inhibition alone. Recently it has emerged that intra-individual variability is one of the more consistent associations with ADHD in both children and adults (Klein *et al.*, 2006).

In an adoptive study conducted by Sprich and colleagues (2000), higher rates of hyperactivity were found in their biological parents of children with ADHD compared to their adoptive parents.
**Neuroimaging studies**

In an attempt to provide a robust summary of available fMRI studies, Dickstein and colleagues (2006) performed a quantitative meta-analysis of task-based imaging studies using 13 fMRI studies and four PET/SPECT studies that had published stereotactic space coordinates. The meta-analytic data showed reduced activation in regions in the left pre-frontal cortex, the anterior cingulate cortex, the right parietal lobe, the occipital cortex and in the thalamus and claustrum. When only response inhibition studies were included in the analysis, a more restricted network was identified, which included the right caudate (part of the striatum). The analysis also identified certain regions where the ADHD groups tended to show hyperactivation: these included parts of the left pre-frontal cortex, the left thalamus and the right paracentral lobule. The extent of neural networks remains uncertain since the available data were limited by the narrow selection of tasks. A major limitation was the small number of suitable datasets and the unavoidable inclusion of studies that differed in the specific aspects of design and quality.

A systematic review of available fMRI studies in ADHD reached several conclusions (Paloyelis et al., 2007). First, in tasks that examined brain activation during successful inhibitory control, there were large inconsistencies among studies in the direction of group differences. Group differences were also spread across many different brain regions, but the frontal lobes were predominantly involved. For this reason no firm conclusions can be drawn on the association of brain activation changes during response inhibition tasks in ADHD. Second, in analyses that examined inhibition errors, as well as in tasks that tapped attention processes, motor function and working memory, the ADHD group almost exclusively showed lower brain activity; in the attentional tasks this was mostly over temporal and parietal areas; in motor function tasks mostly over frontal areas. Third, among the different brain regions, the most consistent findings as regards direction of activation were observed in the striatum. In all but one study significant group differences were observed in which the ADHD group showed lower activity in the striatum. The only study where increased activation was observed had used a sample of adolescents of whom only half met full criteria for ADHD at the time of testing. Fourth, the review included a summary of findings from people with ADHD who had not used stimulant or other medication. These studies suggest that altered brain activation patterns in children with ADHD are not due to the effects of long-term stimulant treatment. Pliszka (2006) was the only study to compare individuals with ADHD on long-term medication with those that were drug naïve as well as healthy controls. The study found no differences between the treated and untreated ADHD groups on most comparisons. Where some differences were found the treated group was more similar to controls than the untreated group.
A systematic meta-analytic study of brain structural changes in ADHD analysed all brain regions reported by all the studies found (Valera et al., 2006). The study found global reductions in brain volume in ADHD cases compared with controls. Regions most commonly assessed and showing the largest differences included cerebellar regions, the splenium of the corpus callosum, total and right cerebral volume and right caudate. Several frontal regions examined in only two studies also showed significant differences. It was not possible to include or exclude the role of medication in the observed changes to brain volume and structure.

**Molecular genetic studies**

A systematic meta-analysis of molecular genetic association for associated markers in or near to the dopamine D4 (DRD4), dopamine D5 (DRD5) and dopamine transporter (DAT1) genes, found strong evidence for the association of DRD4 and DRD5 but not DAT1 (Li et al., 2006). Although there are many other individual and meta-analytic studies of genetic findings in ADHD, Li and colleagues (2006) compiled most of the available data for three of the best-studied findings to date, and found significant levels that were in excess of that expected from scanning the entire human genome: $8 \times 10^{-8}$ for DRD5 and $2 \times 10^{-12}$ for DRD4. A significance level close to $5 \times 10^{-8}$ is widely accepted to indicate a true association after adjusting for the number of potential false positive findings in a scan of the entire human genome (for example, Risch & Merikangas, 1996). Other reported genetic associations with ADHD, including DAT1, do not reach this level of significance in the literature and cannot be confirmed or refuted at this time. The level of risk associated with DRD4 and DRD5 is small with odds ratios in the order of 1.2 to 1.4. This level of risk is similar to that seen for genetic influences in common medical conditions such as diabetes (Altshuler & Daly, 2007). As with all other types of risk factor associated with ADHD, the individual genetic variants associated with the disorder are neither sufficient nor necessary to cause it, but contribute a small increase to the overall risk for ADHD.

**Quantitative genetic studies**

A systematic review of 20 population twin studies found an average heritability estimate of 76%. In most cases, heritability in these studies is estimated from the difference in the correlations for ADHD symptoms between identical and non-identical twin pairs, as reported by parents and teachers: with the correlation for identical twin pairs in the region of 60-90% and for non-identical twin pairs being half or less than half of this figure in most studies (Faraone, 2005). Under the equal environment assumption for the two types of twin pairs, heritability can be estimated as twice the difference in the two sets of correlations.
Although some people question the assumption of ‘equal environment’ for identical and non-identical twins this does not impact on the question of validity for the following reason. The high twin correlations observed in these studies indicate that ADHD symptoms are highly familial, in the sense that the level of ADHD symptoms in one child predicts that in the other. In other words ADHD symptom scores are correlated between siblings whether they are identical or non-identical twins. If ADHD were invalid as a familial construct then no correlation between siblings would be expected. Were the equal environment assumption violated, the estimated effect of genetic influences would decrease and that of shared environmental influences would increase.

Sibling correlations (the similarity between two siblings) can arise from either shared environmental or shared genetic influences. The equal environment assumption impacts on the estimate of the proportion of the familial risk that is due to genes or shared environment (for example, Horwitz et al., 2003). Because the estimated heritability of ADHD is less than 100% we know that environmental influences are likely to cause differences in siblings and contribute to why one child in a family might have ADHD while another child does not (so-called unique environmental effects). High heritability and low shared environmental factors estimated by twin studies does not exclude an important additional contribution of the environment, acting through mechanisms of gene-environment interaction (Moffitt et al., 2005) or gene-environment correlation (Jafee & Price, 2007). Much more work is needed to understand the complex interplay of genetic and environmental influences on the risk for ADHD.

Evidence for genetic influences also comes from adoption research. One study showed increased rates of ADHD among the biological but not the non-biological parents of children who develop ADHD (Sprich et al., 2000).

Physical environmental risk studies
Schab and colleagues (2004) completed a systematic meta-analysis of the effect of exposure to food additives (FA) on ADHD symptoms. They identified 15 studies that met initial inclusion criteria and estimated an effect size of around 0.2. However, many of the studies included was either in a non-ADHD sample, sample sizes were very small (n < 10) and/or were not properly randomised. The authors report associations between the use of FA and ADHD, but given the limitations of the studies included it is difficult to establish a clear conclusion.

More recently in the UK, Stevenson and colleagues (McCann et al., 2007) completed a double-blinded placebo-controlled crossover trial of FA in 3- and 8-year-old children. This study confirmed the association between FAs (artificial colours, sodium benzoate, or both) on increased levels
of ADHD symptoms in the child populations studied. These studies indicate
short-term toxic effects of FAs on the level of ADHD symptoms in children
whether they have ADHD or not and might contribute towards significant
impairment in some cases. There is no indication that FAs cause long-term
effects on child development.

Linnet and colleagues (2003) completed a systematic review of the evidence
for association between prenatal exposure to nicotine, alcohol, caffeine and
psychosocial stress. They concluded that exposure to tobacco smoke in utero
is associated with an increased risk for ADHD. In contrast contradictory
findings were found for the risk from prenatal maternal use of alcohol and no
conclusions could be drawn from the use of caffeine. Studies of psychosocial
stress indicated possible but inconsistent evidence for an association with
ADHD

Talge and colleagues (2007) completed a systematic review of studies that
indicate the association of antenatal maternal stress on aspects of child
development including ADHD symptoms, emotional and cognitive problems,
anxiety and language delay. These effects appear to be independent of
postnatal depression and anxiety. Two studies identified an increase in
ADHD symptoms in children between the ages of 4 and 15 (O'Connor et al.,
2002; Van den Bergh et al., 2005). The effect size of the association was
marked. Van den Bergh estimated that 22% of the variance in symptoms of
ADHD was accounted for by maternal anxiety during pregnancy. Exposure to
stressful events doubled the risk for ADHD in one study (Obel et al., 2003).
O'Connor and colleagues (2002; 2003) found that women in the top 15% for
symptoms of anxiety at 32 weeks’ gestation increased the risk of symptoms of
ADHD, CD, anxiety or depression by 5-10%. Prenatal maternal stress is
therefore associated with an increase in ADHD symptoms but is not specific
to ADHD. The mechanisms involved in this association are poorly
understood.

Non-physical environmental risk studies

As stated in the section on associated impairments, impaired family
relationships have been reported in families of children with ADHD. Follow-
up studies indicate that mothers of children and adolescents with ADHD
have more difficulty in child behaviour management practices and coping
with their child’s behaviour (August et al., 1998), and display higher rates of
conflict behaviours, such as negative comments, social irritability, hostility
and maladaptive levels of communication and involvement (August et al.,
1998; Fletcher et al., 1996).

Persistent problems with inattention and overactivity have been documented
in a sample of institution-reared children adopted from Romania before the
age of 43 months. The syndrome of inattention and overactivity was strongly
associated with early institutional deprivation lasting 6-months or more, with
higher rates in boys than girls, and was strongly associated with conduct problems, disinhibited attachment and executive function impairments (Stevens et al., 2007; Rutter et al., 2004).

In general, the diagnosis of ADHD is distributed unequally across different levels of deprivation and is mediated by social class and ethnicity (Bauermeister et al., 2005, Cunningham & Boyle, 2002). Maltreatment has been associated with higher rates of ADHD in addition to oppositional behaviour and PTSD (Famularo et al., 1992). McLeer and colleagues (1994) found very high rates of ADHD (46%) among children with a history of sexual abuse.

Work by Rutter and coworkers (1975) revealed that it was the aggregate of adversity factors (severe marital discord, low social class, large family size, paternal criminality, maternal mental disorder, and foster care placement) rather than the presence of any single factor that led to impaired child development (Rutter et al., 1975). Based on this work, Biederman and colleagues (1995), using a sample of 140 ADHD and 120 normal control probands and using Rutter's indicators of adversity, investigated whether family-environment risk factors were associated with ADHD. A positive association was found to exist between adversity indicators and the risk for ADHD as well as for its associated psychiatric, cognitive, and psychosocial impairments, supporting the importance of adverse family-environment variables as risk factors for children with ADHD.

5.8.2 Summary

There is consistent evidence from family, twin and adoption studies of both genetic and environmental influences on ADHD symptoms throughout the population. Under the equal environment assumption, twin studies indicate that sibling similarity for ADHD symptoms results mainly from genetic influences. Some supportive evidence is given by adoptive research. Unique environmental influences play a role in bringing about differences in ADHD symptoms within families. Environment may also play an important role in ADHD acting through mechanisms of gene-environment interaction and correlation. Environmental measures associated with ADHD have been identified, including maternal use of tobacco during pregnancy and prenatal maternal stress. Other associated environmental measures include early deprivation, maltreatment and sexual abuse, family factors including severe marital discord, low social class, large family size, paternal criminality, maternal mental disorder, and foster care placement. Some dietary components have been shown to increase the level of ADHD symptoms in children and are expected to contribute to increased levels of ADHD symptoms in all children. These may give rise to increased symptoms and impairments in a sub-group of individuals who go on to develop ADHD, although this has yet to be clearly demonstrated.
The causal relationships between environmental measures and ADHD are not well understood. In most cases it is not known whether specific associated environmental variables represent direct risks for ADHD, or indirect risks acting through correlated environmental or genetic factors, or are passively correlated with the ADHD symptoms themselves.

The GDG concluded that specific genetic variants associated with small increases in the risk for ADHD have been identified within the dopamine D4 receptor gene and close to the dopamine D5 receptor gene. These are the only two genetic findings where convincing levels of evidence have accrued as demonstrated by the recent meta-analytic study from Li and colleagues (2006). Other genetic findings require further data before they can be included or refuted as true associations with ADHD.

Analysis of ADHD versus non-ADHD groups has identified consistent changes in brain structure, function and performance on neurocognitive tests; however differences from controls are not universal, do not characterise all children and adults with a clinical diagnosis of ADHD, and do not usually establish causality in individual cases. It is not yet understood the degree to which the observed heterogeneity in the associations with neurobiological and psychological measures represent multiple aetiological contributions to a common causal pathway or independent contributions to multiple causal pathways. It may also be the case that these associations represent epiphenomena of the ADHD syndrome and play no direct causal role.

5.9 Limitations

In line with methodology agreed with NICE the approach adopted initially was to identify all available systematic reviews and meta-analytic studies that related to the questions on validity of the diagnosis. While this was possible for much of the neurobiological, genetic and environmental data, there were few systematic reviews in other areas such as the factor or cluster analytic studies. Where systematic reviews were not available for the studies of ADHD symptoms and studies that investigated the differentiation of ADHD from oppositional defiant and conduct problems, a systematic review of the primary literature was conducted. For other sub-questions addressed in this section, the systematic evidence was supplemented with expert opinion, drawing on evidence known to members of the GDG. Additional evidence was obtained following a review of the initial draft of this chapter by independent experts (see Appendix 16 for their commentary). The lack of specific reference standards for the diagnosis of ADHD led to an adaptation of the SIGN criteria to ensure sufficient quality of the data used to derive recommendations for this guideline. The revised criteria agreed by the GDG members were as follows: 1) the study addresses an appropriate and clearly focused question (or hypothesis), 2) the sample population being studied are
selected either as a consecutive series or randomly, from a clearly defined population.

When considering the Feigner criteria for validity of a psychiatric disorder, the question of whether there are characteristic responses to pharmacological, psychological, educational and other interventions for ADHD was excluded from this section, because the response of ADHD to these interventions is considered in detail elsewhere in this guideline. The related question of the specificity of the response to therapeutic interventions for ADHD was surprisingly difficult to determine on the basis of available published evidence. For example, behavioural, educational and pharmacological treatments can all alter the behaviour of children whether they have ADHD or not.

In relation to the use of stimulants we were unable to identify studies that investigated their effects on mental health disorders other than ADHD. The GDG identified a literature on the abuse potential of stimulants, indicating that methylphenidate and dexamfetamine increase ratings of subjective activity, alertness (wakefulness), and energetic and high feelings (for example, Stoops et al., 2004), but there were no direct comparisons with the effects of people fulfilling diagnostic criteria for ADHD. One paper was identified that addressed the effects in a normal population; it did not meet the quality control criteria for the evidence sections of this chapter, but it is mentioned here due to its potential importance. The authors reported the response to dexamfetamine and placebo in a group of 14 pre-pubertal boys who did not fulfil criteria for ADHD (Rapoport, 1978). When amphetamine was given, the group showed a decrease in motor activity and reaction time and improved performance on cognitive tests that was similar to that seen in other studies of children with ADHD. The very small numbers used in this study and lack of further similar studies means that caution must be taken in drawing firm conclusions from this one study. Nevertheless, the similarity of the response observed in children without ADHD to that reported in children with the disorder provides further evidence that the aetiological processes in ADHD are similar to those that influence levels of ADHD symptoms throughout the population.

The question of a paradoxical effect of stimulants on people with ADHD has been raised but is not well studied. For example, do stimulants impact on the same processes and in the same way in all people, whether they have ADHD or not; or is there a different pattern of effects in people with high levels of ADHD symptoms compared with people with low levels. The GDG concluded that the critical question for these guidelines is whether stimulants and other non-pharmacological interventions effectively treat the impairments associated with high levels of ADHD symptoms. The effectiveness and cost benefits of these interventions are addressed in other sections of this guideline.
5.10 Summary of validation of the diagnosis of ADHD

The diagnosis of ADHD is difficult and somewhat controversial for a number of reasons. Of particular concern has been the rapid increase in the recognition and treatment of children with ADHD and the very high prevalence rates reported in some studies, leading some people to question the validity of the disorder. In common with most mental health conditions there is no definitive biological test; diagnosis depending on the observation of clusters of symptoms in three main behavioural domains according to the DSM-IV and ICD-10 criteria. In order to examine the validity of the diagnosis the Washington University Criteria (Feighner et al., 1972) were applied to demonstrate whether there are well-defined clinical correlates, characteristic course and outcome, neurobiological underpinnings and associations with genetic and environmental factors. The review above identified clinical, genetic, environmental and neurobiological factors associated with ADHD or correlated with levels of ADHD symptoms in the general population that were sufficient to validate the diagnostic construct of ADHD.

One of the key issues addressed in the review was the question of whether ADHD represents a discrete clinical entity or the extreme end of a continuum of normal behaviour. Indeed, the debate between a categorical diagnostic view and a dimensional approach is longstanding in psychological and sociological research. The diagnosis of many common psychological conditions, such as anxiety and depression represents a line drawn at one end of a continuum of a population characteristic that is continuously distributed throughout the population; the threshold for diagnosis being drawn at a point where significant impairment arises.

The review concluded that on the basis of current evidence ADHD is best conceptualised as the extreme of a continuous trait that is distributed throughout the population; the distinction from normality being made by the presence of high levels of ADHD symptoms when they are accompanied by significant impairments. This highlighted the importance of defining what amounts to a significant impairment and ensuring that impairment is fully evaluated when applying the diagnostic criteria.

5.11 Defining significant impairment

The GDG wished to define more precisely the level of impairment indicating when the guidelines should be triggered. The GDG recognised the breadth of views on what amounts to a significant impairment. The existence of polarised views in this debate, and the implication for both under and over diagnosis, means that a balanced and pragmatic view is required that takes into account concerns on both sides. For example the GDG recognised that people with HKD (ICD-10) do not always receive a diagnosis and treatment.
despite the presence of marked impairments, while on the other hand in some cases stimulants have been used to boost academic performance in the absence of more pervasive and enduring impairments. The following criteria were discussed and agreed by a consensus within the group:

(1) The GDG wish to emphasise the importance of significant impairment in defining the difference between a set of mental health problems and a mental health disorder. An appreciation of this difference is helpful in preventing over diagnosis. In addition, the diagnosis of ADHD should not be applied to justify the use of stimulant medication for the sole purpose of increasing academic performance, in the absence of a wider range of significant impairments indicating a mental health disorder.

(2) Many mental health problems, including those with ADHD features, are transitory and related to psychosocial stresses. They often clear up spontaneously or do so after a basic level intervention by, for example, parents and teachers. In contrast, a mental health disorder implies something far more serious. Without a specialist professional or a higher level of intervention by others to ameliorate the problems, there is likely to be long-term adverse implications for the person affected as well as problems in the short and medium term. It is therefore important that the assessing clinician considers whether the clinical presentation is indicating a threat to general development and psychosocial adjustment that would be more likely than not to occur if expert help or some other significant intervention was not to take place. This would apply to the current presentation and also the longer-term outlook.

(3) The GDG concluded that impairment should be pervasive, occur in multiple settings and be at least of moderate severity. Significant impairment should not be considered where the impact of ADHD symptoms are restricted to academic performance alone, unless there is a moderate to severe impact in other domains: these would include self-esteem, personal distress from the symptoms, social interactions and relationships, behavioural problems, and the development of comorbid psychiatric syndromes.

5.12 Position statement on the validity of ADHD

On the basis of the evidence reviewed above the guideline development group draw the following conclusions:

- Symptoms that define hyperactive, impulsive and inattentive behaviours are found to cluster together.
- Hyperactivity, inattention and impulsivity cluster together both in children and in adults and can be recognised as distinct from other symptom clusters, although they frequently co-occur alongside other symptom clusters.
• Symptoms of ADHD appear to be on a continuum in the general population.
• ADHD is distinguished from the normal range by the number and severity of symptoms and their association with significant levels of impairment.
• The importance of evaluating impairment and the difficulty in establishing thresholds on the basis of symptom counts alone needs to be addressed. It is not possible to determine a specific number of symptoms at which impairment arises.
• There is evidence for psychological, social and educational impairments in both children and adults with ADHD.
• ADHD symptoms persist from childhood through to adulthood in the majority of cases. In a significant minority the diagnosis persists and in the majority, sub-clinical symptoms continue to be detectable and are associated with significant impairments.
• In adults the profile of symptoms may alter with a relative persistence of inattentive symptoms compared with hyperactive-impulsive symptoms.
• There is evidence of both genetic and environmental influences in the aetiology of ADHD. It is not known the extent to which there is diversity in the aetiology of the disorder. Current evidence indicates the presence of multiple risk factors of minor effect.
• The complex interplay between genes and environment is not well understood. Environmental risks may interact with genetic factors, be correlated with genetic factors or have main effects. Similarly genetic factors may interact or correlate with environment, or have main effects. There will be a different balance of factors in individual cases.
• There is evidence of genetic associations with specific genes, environmental risks and neurobiological changes in groups of children with ADHD. However, no neurobiological, genetic or environmental measure is sufficiently predictive to be used as a diagnostic test.
• The diagnosis remains a descriptive behavioural presentation and can only rarely be linked to specific neurobiological or environmental causes in individual cases.
• Hyperkinetic disorder (ICD-10) is a narrower and more severe subtype of DSM-IV combined type ADHD. It defines a more pervasive and generally more impairing form of the disorder. Both concepts are useful (Santosh et al., 2005).
• There was limited evidence to support a different concept of ADHD in children and adults. However age-related changes in the presentation are recognised. Theses changes are not yet reflected in the current diagnostic criteria.
• All current assessment methods have their limitations. There is evidence of the need for flexibility and for a consideration of levels of impairment in assessments and when deriving appropriate diagnoses.

5.13 Consensus conference

In addition to a review of published evidence on the question of validity, a consensus conference was held to bring together experts in the field with a range of views, in order to debate the key issues of the use of ADHD as a diagnostic category. The aim was to provide a range of contemporary perspectives that would assist the GDG with the task of deciding what should trigger the use of the guideline and for whom the guideline is intended (see Chapter 3, Methods). The speakers delivered a 15-minute presentation addressing the key questions relating to the validity of the ADHD diagnosis set out by the GDG followed by questioning from the GDG members and a subsequent discussion of the presentation among members of the GDG. Each presenter was subsequently asked to provide a summary of their presentation and these are presented in Appendix 16.

The consensus conference involved presentations from professionals who came from a range of backgrounds and with differing perspectives on the validity and aetiology of ADHD. The range of views contributed to highlight the importance of an interdisciplinary approach to the diagnosis and treatment of children and adolescents with ADHD. The conference did not consider diagnosis and treatment of adults with ADHD.

Here some of the issues that were raised, and the areas of controversy arising from differences in the perceptions of the speakers at the consensus conference, are discussed. Some of the complex areas of controversy relate to broader sociological and philosophical issues representing two conceptual paradigms, broadly characterised as medical scientific and social scientific. The latter perspective casts doubts on the utility and legitimacy of ADHD as a diagnostic category by emphasis on: the problematic nature of the meaning of ADHD, the social determinants of the behaviours of which come to be labelled as ADHD, and the spectrum of human behaviour that results in indistinct boundaries of many medical diagnostic categories. While it is important to acknowledge the validity of the social scientific paradigm and its body of literature, in the context of the development of practical clinical guidelines, it is not possible to offer alternative processes for clinical assessment or treatment. It is accepted that the research literature reflects the dominant medical scientific paradigm and hence the nature of the evidence base.

The evidence presented at the consensus conference indicated that there was a high degree of unanimity across most but not all of the the presenters about...
the fact that there is a group of people who could be seen as having distinct
and impairing difficulties and who should trigger the use of this guideline.
While recognition of a particular group was agreed upon, uncertainty about
the breadth of diagnosis was discussed, namely, whether the use of a narrow
(ICD-10 HKD) versus a broad (DSM-IV ADHD) diagnosis should be used.
The problems of using a narrow diagnosis are: (i) the under-recognition of
people that are in need of help and, (ii) the lack of connection with the
research literature, which is based mainly on the broader definition of DSM-
IV ADHD. It was established that the main differences between people falling
into narrow or broad diagnoses are the breadth of symptoms (requirement for
both inattentive and impulsive-overactive behaviour versus only one domain
being sufficient), more or less stringent criteria for situational pervasiveness
and the requirement for no major comorbidity (apart from ODD or CD) under
ICD-10. Both groups present similar problems of impairment. Overall there
was general agreement that both the use of broad DSM-IV ADHD diagnosis
and narrow HKD criteria were useful.

It should be emphasised that the current definitions of ADHD are
descriptions of a behavioural syndrome with associated mental phenomena,
and does not imply specific causal pathways. Validation of the cluster of
symptoms that contribute to the diagnosis of ADHD, occur at the level of
their association with impairments, familial risks, genetic risks, environmental
risks and the association with measures of changes in cognitive function and
brain structure and function. However few direct causal inferences have yet
been established. For example the associations with changes in cognitive and
brain function may represent epiphenomena of ADHD rather than imply a
causal process. Environmental measures associated with ADHD may not
themselves represent direct risk factors, but may be correlated with more
proximal environmental or genetic risks. A common conceptualisation is that
both intrinsic and extrinsic processes are involved in generating the cluster of
behavioural symptoms that we call ADHD. Extrinsic factors, such as parental
coping and consistency, might exacerbate problems of behavioural control in
a child with intrinsic difficulties in regulating core processes such as attention
and activity level. The child’s difficult behaviour may further exacerbate the
difficulties in providing consistent parenting. Parental behaviour itself will
also be influenced by both genetic and environmental factors, further
increasing the complexity of the aetiological relationships involved. The GDG
do not seek here to put forward a particular causal model due to the
complexity of this question, but do wish to point out the role that both genes
and environment play on both intrinsic and extrinsic factors in generating the
clinical syndrome of ADHD.

One of the major issues of controversy in the UK setting is the very high and
variable prevalence rates reported in the literature. For example, recent
prevalence figures range from 6.8 to 15.8 for DSM-IV ADHD (Faraone et al.,
2003) while the British Child and Mental Health Survey reported a prevalence
of 3.6% in male children and less than 1% in females (Ford et al., 2003). Reasons for this are discussed in Faraone and colleagues (2003) who conclude that prevalence rates derived from symptom counts alone, or from ratings in one setting, were higher than those that took into account functional impairment and pervasiveness. For example Wolraich and colleagues (1998) estimated prevalence to be 16.1% on the basis of symptom counts, but 6.8% when functional impairment was taken into account. A study in the UK that specifically addressed the role of impairment found that among 7- to 8-year-olds, 11.1% had the ADHD syndrome based on symptom count alone (McArdle et al., 2004). In contrast, 6.7% had ADHD with Children Global Assessment Scale scores (CGAS: measuring impairment) less than 71 and 4.2% with CGAS scores less than 61. When pervasiveness included both parent- and teacher-reported ADHD and the presence of psychosocial impairment, prevalence fell lower to 1.4%. The literature on prevalence therefore indicates that the rate of ADHD is sensitive to the degree of impairment associated with the symptom criteria and the degree to which the disorder shows situational pervasiveness.

All the speakers acknowledged the importance of functional impairments in relation to diagnosis. In other words, that diagnostic threshold should be based on pragmatic grounds such as impairment and the need for treatment. There was also agreement that defining suitable thresholds for impairment is difficult, since different people hold a range of views on what amounts to significant impairment. The fear was expressed that too broad a definition would lead to the over-diagnosis of children as a way of justifying the use of stimulant medication to enhance academic performance, in the absence of a wider range of pervasive and enduring impairments. Given the sensitivity of the prevalence rates of ADHD to definitions of impairment, this could potentially lead to very high numbers of children being treated when educational or psychological interventions may be sufficient, or where the level of impairment does not warrant a therapeutic intervention at all. The GDG concurred with this view, but were equally concerned to ensure that the thresholds for the diagnosis were not so restricted as to leave children with ADHD, who by definition have significant impairment, undiagnosed and therefore untreated.

The level and types of behaviour that define impairment remain a contentious issue and are to some extent dependent on the cultural and environmental context. For this reason expert clinical advice is required to evaluate the level of impairment, ensure that the child’s view is taken into considered and not just that of the child’s parents and teachers; account, and to ensure that everyone’s perspective is taken into account; and to take into account cultural factors.

Considering when this guideline should be triggered, the GDG concluded that it would be difficult to be prescriptive for any individual case, but that
measurement of impairment linked to the symptoms of ADHD is a key component of the decision. Significant problems can arise at various levels, including personal distress from symptoms of the disorder, difficulties in forming stable social relationships and emotional bonds, difficulties with education and long-term risk for negative outcomes such as emotional problems, antisocial behaviour and addiction disorders. The GDG concluded that those responsible for initiating diagnosis and treatment must take into account the severity of the disorder in terms of clinical and psychosocial impairments. When monitoring treatment response, evidence of improvement in such impairment is critical and should be monitored in addition to the narrow focus on changes in reported levels of ADHD symptoms.

One of the areas of controversy highlighted in the consensus conference was the degree of impairment and severity of ADHD needed to trigger the diagnosis and, related to this, treatment with medication. Concern was expressed that the diagnosis automatically leads to treatment with medication and this is not always desirable when the breadth of the definition includes people who might gain substantial benefit from education or psychosocial interventions alone. However even the most ardent supporters of non-pharmacological interventions in ADHD recognised the importance of pharmacological treatment in the most severe cases. In this context the participants in the consensus conference made an important contribution by raising the important question of suitable thresholds for ‘significant impairments associated with ADHD symptoms’ and hence the proportion of children fulfilling criteria for the disorder and triggering use of the guideline. The related issue is the importance of considering the full breadth of effective interventions (including educational, social and psychological support and pharmacological treatment), depending on the severity of the disorder, the extent of impairment and needs of each individual case.

One conclusion is that the acceptable thresholds for impairment are partly driven by the contemporary societal view of what is an acceptable level of deviation from the norm and level of impairment that requires treatment. Impairment in ADHD should be based not only on the views of others because people with ADHD, particularly older adolescents and adults, have strong subjective experience of the impact of their condition on themselves.

However the GDG did not consider that the diagnosis should be reserved only for the most serious cases, since the broader concept of ADHD is important in triggering educational and behavioural support in addition to pharmacological approaches. The GDG concluded that defining appropriate thresholds of impairment associated with the disorder was important, but that treatment implications might be different for individuals falling above or below particular thresholds.
Confirmatory factor-analytic studies clarify that ADHD symptoms represent a distinct set of symptoms and behaviours that co-vary together in both clinical and control populations. However these cross-sectional studies are far less informative than longitudinal studies that can clarify the predictive outcomes of early ADHD. There are, however, a few studies that provide suitable data on the relative outcomes of ADHD and other disruptive disorders such as ODD, which are important in delineating specificity in the outcomes related to ADHD. The available evidence suggests that when considering the link between ADHD and conduct problems, ADHD comes first and conduct problems develop later. In contrast there is no evidence that conduct problems in the absence of ADHD lead to the later development of ADHD. The small amount of suitable longitudinal outcome studies highlights an important area for future research.

The aetiology of ADHD remains another area of controversy. In the view of the GDG this largely stems from the complex nature of ADHD and the many factors involved in aetiology. Major identified risk factors associated with the disorder include having a first-degree relative with ADHD and prenatal maternal stress, however these are likely to be proxy markers of processes that are themselves expected to be highly complex. At the level of specific factors such as individual genes or direct environmental stresses, the increased risk to ADHD is expected to be small. There is an ongoing debate about the degree to which ADHD represents a homogeneous disorder, with multiple risk factors of small effect contributing to the disorder, or whether ADHD represents the syndromic end-point of multiple different processes. Further research is required to provide a full understanding of the complex aetiology involved.

One important question raised by the consensus conference was the interpretation of family, twin and adoption studies and the relative contributions between genetic and environmental influences indicated by these studies. The argument against important genetic influences is not strong unless one questions the conventional interpretation of twin and adoption data. The findings from twin studies are not, however, controversial since they have been replicated many times. The main finding is that parent and teacher reports of ADHD symptoms show high correlations around 70-80% in MZ (identical) twins, and around 20-40% between DZ (non-identical) twins. The usual interpretation of these findings is that the large difference in MZ and DZ correlations result from genetic influences. The alternative argument that the equal environment assumption is incorrect would not alter the basic conclusion that ADHD tends to run in families and is therefore a familial disorder, since the level of ADHD symptoms in one child is highly predictive of the level of ADHD symptoms in their siblings. It is therefore non-controversial that ADHD is familial and this in itself is strong evidence that the construct is sufficiently delineated to show clear familial effects.
Interestingly there are limited data from twin studies using ADHD cases (for example, concordance rates for the clinical disorder), so the literature mainly uses extremes analysis of rating scale data for ADHD symptoms and does not take into account other important aspects of the clinical disorder such as pervasiveness and impairment. Similarly there is a lack of twin data in adult populations.

Adoption studies also indicate that genetic as well as environmental influences increase the risk for ADHD. All adoption studies show that adopted children with ADHD are more similar to their biological parents than to their adoptive parents. These studies, except for one (Sprich et al., 2000) are however limited by small sample size and in most cases the interviewers were not blind to psychiatric or adoptive status and have therefore not been used as evidence of validity in this chapter (reviewed in McMahon, 1980).

There was broad agreement that environmental influences play an important role in the aetiology of ADHD. However the nature of the specific risk factors and the mechanisms involved are poorly understood and remain an area of controversy. Twin studies indicate that unique environmental effects are expected to cause differences between siblings and would explain in part why one child in a family has ADHD while another child from the same family does not. Environmental risks may be the sole or main cause of ADHD in some cases; for example where there is extreme deprivation in early childhood (Rutter). However one important question is whether the evidence of genetic influences in ADHD can be reconciled with the view that environmental influences play a critical role in development of the disorder.

In fact, high heritability is consistent with the existence of environmental risks for ADHD that are very common, and for this reason explain little of the observed variance in ADHD symptoms in the population. Environmental risks may also be modified by genetic risks (gene-environment interactions) or correlated with genetic risks (gene-environment correlation). The complexity of the interplay between genes and environment in the risk for ADHD is not well understood and for this reason is one of the main focuses for contemporary research. The GDG considered that polarised positions in this debate are not helpful since the contemporary understanding of complex behavioural disorders emphasise the interplay between nature and nurture.

The GDG wish to stress that the role of genetic influences in ADHD does not exclude an important role for environmental influences for several reasons. Individual differences in genetic risk factors are likely to alter the sensitivity of an individual to environmental risks. Either genetic or environmental risks alone may play a prominent role in individual cases. Reducing environmental risks would be expected to reduce the risk for ADHD under most models of gene-environment interplay in the contemporary literature. There are expected to be many different ways in which environmental interventions might be used to benefit people with ADHD and reduce levels of impairment.
The GDG also wish to emphasise that the extent to which the disorder results from genetic influences has no direct bearing on the choice of treatment and in particular, does not provide sufficient justification alone for the use of pharmacological interventions. For example traits such as obesity or diabetes are influenced by both genetic and environmental factors, yet individual changes in lifestyle as well as the use of medication in some (but not all) cases is indicated. In ADHD educational, social, psychological, and pharmacological treatments all need to be considered and could be important in improving levels of impairment and preventing the development of negative long term outcomes. The evidence base for treatment of ADHD is dealt with in other sections of this guideline.

5.14 Summary from review of the diagnosis

On the basis of this review the guideline development group summarised the evidence, upon which the guideline recommendations are made for the diagnosis of ADHD:

- ADHD is a valid clinical condition that can be distinguished from co-occurring disorders and the normal spectrum.
- ADHD is distinguished from the normal spectrum by the co-occurrence of high levels of ADHD symptoms when they are associated with significant clinical, psychosocial and educational impairments. These impairments should be enduring and occur across multiple settings.
- There is no specific biological test for ADHD, so the diagnosis must be made on the basis of a full developmental and psychiatric history, observer reports and examination of the mental state.
- In the absence of a biological test for the diagnosis of ADHD or hyperkinetic disorder, validity is based on the association of ADHD symptoms with genetic, environmental, neurobiological and demographic factors; and the association of high levels of ADHD symptoms with impairments in multiple domains.
- Hyperkinetic disorder (ICD-10) identifies a sub-group of people with ADHD with severe impairment in multiple domains.
- ADHD commonly persists throughout childhood and into adult life, either as the full diagnostic criteria or in partial remission, where it continues to cause significant clinical and psychosocial morbidity.
5.15 Implications for practice

5.15.1 General principles for diagnostic process

The aim of this section of the guideline is to provide a commentary and further recommendations on the implementation of the diagnostic process. As reviewed above there is sufficient evidence that ADHD is a valid diagnostic category to apply to relevant children, young people and adults. The GDG concluded that on the basis of current evidence ADHD is a complex disorder resulting from multiple genetic and environmental risk factors, representing the extreme and impaired tail of a normally distributed trait in the population. The disorder is recognised by the presence of a high level of pervasive and enduring problems with attention, overactivity and impulsiveness when they lead to a significant degree of clinical, psychosocial and/or academic impairments.

The current operational criteria for ADHD (DSM-IV) and hyperkinetic disorder (ICD-10) are highly reliable, when they are applied by trained individuals following the careful evaluation of reported behaviours and symptoms, and the criteria define a group with clear clinical implications. The diagnosis depends on the evaluation of two necessary components, both of which are required to trigger the use of this guideline. The first is the presence of the symptom cluster of age-inappropriate levels of inattentive, hyperactive and impulsive behaviours; and the second is the presence of significant clinical and psychosocial impairments. Other key criteria include onset during childhood and situational pervasiveness. Behaviours and symptoms that are restricted narrowly to one environmental setting only (for example, school), or one set of impairments (for example educational attainment alone) would not be considered sufficient grounds to make the diagnosis.

The implementation of the diagnostic and treatment process should be within the framework of a structured stepped pathway as described in Chapter 6. Within this framework a flexible approach to assessment should be adopted that enables an evaluation of individual and family needs, drawing on the experience and expertise of the individual clinician and other professionals involved, and taking into account different perspectives using an interdisciplinary approach.

5.15.2 Implementation of the diagnostic criteria

Diagnostic criteria are constantly evolving in the light of new information. The GDG reviewed the current diagnostic criteria and made recommendations that reflect the current state of knowledge and clinical practice. Below is a list of common questions with the summary statements upon which the recommendations are based.
(A) Should ADHD be recognised in the presence of pervasive developmental disorders (PDD)/autism spectrum disorders (ASD)?

ICD-10 unequivocally says this is not permitted and DSM-IV effectively says that ADD should not be recognised in the presence of PDD stating that, ‘symptoms should not occur exclusively in the course of a pervasive developmental disorder’; yet PDD once established is in most cases always present.

The evidence that core symptoms of ADHD do occur together with those of ASD/PDD is strong and therefore the GDG recommend that for effective practice, ADHD should be recognised on the basis of core symptoms of ADHD, even when PDD or ASD is present (Reierson A et al. 2007).

Summary statement: ADHD can be diagnosed in the presence of pervasive developmental disorders

(B) Should ADHD be recognised in the presence of general learning disability?

Both DSM-IV and ICD-10 state that symptoms of ADHD must be developmentally inappropriate. This means that the levels of ADHD symptoms should be inappropriate and impairing in comparison to other people at the same developmental stage taking into account both age and general cognitive ability. DSM-IV states that symptoms should be ‘excessive for mental age’. The GDG recognised the importance of an appropriate developmental comparison group and recommend that adjustment is made for mental age.

For example a mental age of 5 in a 10-year-old should have the same standard of what is expected for impulsiveness and inattention as a mental age of 5 in a 5-year-old. However, derivation of ‘mental age’ through standardised cognitive assessment does not always correlate with emotional and behavioural age. Professionals undertaking clinical evaluation should have expertise in both ADHD and learning disability, and awareness of the normal range of behaviour in the equivalent peer group of comparable age and general cognitive ability.

Summary statement: ADHD can be recognised in the presence of a general learning disability, with behavioural symptoms compared to a group with similar mental age.

(C) How should impairment be judged?

The GDG agreed that the presence of impairment associated with the core behavioural symptoms of ADHD, is critical to recognising the disorder; but difficulties arise since impairment is itself a continuum. The GDG considered
that impairment needs to be considered relative to a comparable peer group since this represents the potential of each individual. For example, relative impairment would include a child with a chronological age of 7, a mental age of 10, but an academic achievement age only of 7. Importantly, impairment should be pervasive and enduring, affecting several aspects of an individual life. This would mean that impaired academic achievement alone would not be sufficient to trigger the diagnosis, but would be sufficient where this were accompanied by significant impairments in other areas such as emotional or social development (see Section 5.6).

Summary statement: Impairment should be pervasive and enduring, affecting several aspects of an individual life.

(D) Should the age of onset before 7 years be strictly applied?

The GDG recognised the inadequacy of the current age of onset criteria, which would exclude individuals with typical ADHD with an apparent onset after the age of 6. Symptoms may not be recognised in young children and impairments may not be pronounced. This is likely to be particularly true where the predominant symptoms are those of inattention rather than impulsive or overactive behaviour and because it can be the later development of comorbid problems that draw attention to the difficulties that a particular child is having. Recent evidence indicates that the level of impairments are similar for individuals with onset before and after age 7 leading to the recommendation that ADHD should be diagnosed in some cases where onset is dated between the ages of 7 to 12 years (Applegate et al., 1997).

Summary statement: ADHD should be diagnosed in some cases where onset is dated between the ages of 7 to 12 years

(E) Should we exclude some kinds of aetiology?

The GDG recognised that ADHD is a complex heterogeneous disorder with a range of different aetiologies, including environmental, genetic and non-genetic neurobiological factors. The DSM urges the distinction of ADHD from ‘children from inadequate, disorganized or chaotic environments’.

The GDG considered that there is not yet sufficient data to include or exclude individual cases on the basis of aetiology. For example exposure to chaotic environments might be one potential cause of ADHD, and prenatal exposure to alcohol another. The GDG therefore recommend that the diagnosis of ADHD should be distinguished from other behavioural disorders on the basos of the pattern and type of behaviours, rather than on the basis of specific aetiologies. This is an important point since the diagnosis might be excluded in the present of a severe environmental risk such as child abuse.
The view that child abuse is the cause of behavioural problems, while likely to be important in an individual case, should not lead to the exclusion of the individual from these guidelines if they fulfill the diagnostic criteria for ADHD.

**Summary statement:** In the current state of knowledge, ADHD should be considered whenever diagnostic criteria are fulfilled, regardless of the presence of any specific aetiological factors.

**Can the diagnosis be made from rating scales only?**

Despite reasonably high sensitivity and specificity from rating scales, the GDG took the view that diagnosis of ADHD should not rely on rating scale measures alone. Rather, it is important to complete a full evaluation including diagnostic clinical interviews with parents, children (especially older children and adolescents) and other corroborative evidence such as school reports. The use of rating scale data alone will generate both false positive and negative diagnoses and would remove the critical element of in an in-depth appraisal of the entire clinical picture including onset, cause, associated developmental and mental health exacerbating and causal factors.

**Summary statement:** The diagnosis of ADHD should only be made after a full clinical and psychosocial evaluation, and never on the basis of rating scale data alone.

**Can the diagnosis be made on the basis of observation alone?**

Direct observation of an individual with ADHD, particularly in older adolescents and adults, for short periods of time during assessment sessions, may not demonstrate any obvious features of the condition. This should not exclude the diagnosis where there is a clear account of inattentive, impulsive or hyperactive behaviours in usual situations. The reason is that some people with ADHD can regulate their behaviour for short periods of time and because ADHD behaviours are typically reduced in situations where a person is engaged in a salient task. The GDG advises that diagnosis should only be made on the basis of a full assessment.

**Summary statement:** The diagnosis of ADHD should not be made on the basis of observational data alone.

**How should social, cultural and economic circumstances and factors be taken into account in making the diagnosis of ADHD?**

At a general level, diagnoses of ADHD are distributed unequally by relative level of deprivation, mediated by social class and ethnicity (Bauermeister et al., 2005; Cunningham & Boyle, 2002; Dahl et al., 1991; Timimi, 2006). While
these factors are not thought to cause the behavioural symptoms of ADHD, such immediate environmental circumstances may have a role to play in mediating the experience of symptoms and impairment (Isaacs, 2006). Relative deprivation increases the likelihood that a child will be subject to various environmental risk factors, potentially increasing the risk of ADHD and associated disorders (Hartl et al., 2005; Lahti et al., 2006; Neuman et al., 2007; Rodriguez & Bohlin, 2005). Additionally the ethics and beliefs of those responsible for the daily care of children have a role to play in their perception of symptoms and impairment (Couture et al., 2003; Curtis et al., 2006; Epstein et al., 2005; Rey et al., 2000; Singh, 2003; Wolraich et al., 2003). As such, some attempt should be made to investigate and if possible either discount or provide for the immediate environmental circumstances of the child.

If existing evaluations of the social, cultural and economic circumstances have already been made through multi-agency collaboration then this information may be readily available at the time of referral (Burgess, 2002; San Roman, 2007). However, if these investigations have not been carried out by the relevant services (for example, social services, health visiting services or school health services), or for some reason this information has not been made available, then they should be made part of the medical assessment.

There is a growing literature on the measures that can be taken to help the child with ADHD in the school and at home and as a minimum it should be ensured that such measures have been taken (Hughes & Cooper, 2006; Lloyd et al., 2006; Merell & Tymms, 2002; Prosser, 2006). Regardless of socio-cultural circumstances, psychiatric diagnosis and treatment will have a significant impact on these circumstances, and this needs acknowledging by the individual and family concerned (Singh, 2004; 2005). The active participation of the child or young person should be sought at all stages of the diagnostic process (Wright et al., 2006).

Summary statement: Social, cultural and economic should always be evaluated by an expert and whenever possible by a multidisciplinary team.

5.16 Differentiating ADHD in adults from other co-occurring disorders

5.16.1 Personality disorders

There is currently considerable nosological confusion that stems from the early onset and persistence of ADHD behavioural symptoms that therefore appear as stable traits or personality characteristics rather than symptoms. The difference in definition between a trait and a symptom is that symptoms represent a change from a normal pre-morbid state, such as the onset of adult depression or psychosis, whereas traits are considered to be enduring
characteristics. Current psychiatric training in adult mental health tends to
focus on the distinction between symptoms and traits and gives rise to a
nosology that does not fit well with the concept of ADHD. First, because of
the trait-like quality of ADHD phenomena, significant psychopathology often
goes unnoticed or is regarded as a personality characteristic; resulting in a
different set of treatments and expectations for the clinical course and
outcome compared to ADHD. Second, because ADHD phenomena are
sometimes associated with persistent disruptive and oppositional behaviour
or development of poor interpersonal skills, it is often assumed that this
represents an ingrained and therapeutically resistant set of behavioural traits.
Further confusion stems from the definition of cluster B personality disorders,
like antisocial, borderline and emotionally unstable personality disorder,
which include symptoms such as mood instability, impulsivity and anger
outbursts that are commonly seen to co-occur in adults with ADHD.

The diagnostic issue is to recognise when there is evidence for ADHD, that is
whether the operational criteria were fulfilled in childhood and whether
ADHD symptoms that started in childhood have persisted and continue to
bring about significant impairments. While the diagnostic focus should be on
the main symptoms that define inattention, hyperactivity and impulsivity it is
also important to remember that mood instability and impulsivity are
commonly seen in adults with ADHD. Care must be taken to distinguish
between uncontrolled, impulsive, oppositional and antisocial behaviours that
arise in the context of a specific ADHD syndrome from those that do not. For
this reason it is often useful to make particular enquiries about symptoms that
are more specific to ADHD such as short attention span, variable
performance, distractibility, forgetfulness, disorganisation, physical
restlessness and over-talkativeness rather than focus only on the occurrence of
maladjusted and disruptive behaviours.

5.16.2 Mood disorders

Depression

A volatile and irritable mood is frequently seen in adult ADHD and is not
usually the consequence of comorbid depression or bipolar disorder. The
overlap of mood symptoms does mean that care must be taken to exclude the
possibility of a major affective disorder and that mood lability does not occur
solely within the context of such disorders. Attending to the time-course of
the symptoms and psychopathology can help to distinguish the two. Early
onset, chronic trait-like course, frequent mood swings throughout the day, no
recent deterioration or severe exacerbation frequently accompany ADHD,
whereas extreme low or high moods, sustained mood change for long
periods of time and recent onset are more indicative of a primary affective
disorder. Some individuals previously diagnosed with atypical depression,
cyclothymia or unstable emotional personality disorder will have a primary
diagnosis of ADHD.
Bipolar disorder

Traditionally, the distinction between ADHD and bipolar disorder has been fairly easy to make. Bipolar disorder has been associated with euphoria, grandiosity, and a cycling course with each episode lasting at least for several days. ADHD, by contrast, has been regarded as a persisting disability in which euphoria is not particularly a feature. The goal-directed over-activity of mania is usually seen to be in contrast with the disorganised and off-task activity of ADHD. Individuals with ADHD often have difficulty sleeping but unlike mania or hypomania they complain about their lack of sleep and often feel exhausted during the day. In general individuals with ADHD report that they cannot function effectively and this is often associated with chronic low self-esteem, very different from the feelings of heightened efficiency seen in mania. In ADHD thoughts are often described as ‘on the go’ all the time, but unlike mania or hypomania, these are experienced as unfocused, muddled and inefficient and there is no subjective sense of improved efficiency of thought processes.

There has, however, been a broadening of the concept of bipolar disorder, to include cases where the mood change is not euphoria but irritability or chronic mixed affective states, and where the cyclical nature consists of many changes within a single day (indistinguishable from a volatile, labile mood). This leads to a very considerable similarity in formal definitions between this so-called ultradian version of bipolar disorder and ADHD. An unstable and over-reactive mood is very commonly seen in ADHD, even though it is not part of the diagnostic definitions, and the development of an oppositional disorder, in which frequent tantrums are common, can be described as an ‘irritable’ state and therefore contributes to a bipolar diagnosis.

One of the main questions to be addressed relates to how valid a diagnostic concept broadly-defined bipolar disorder is, or whether mood instability/irritability in the presence of ADHD may be more adequately described by a new dimension, such as mood dysregulation. Until the relevant empirical data become available, the classic definition of mania, so should be maintained, so that a diagnosis of bipolar disorder requires euphoria, grandiosity and episodicity, and the differential between ADHD and bipolar disorder remains explicit.

5.16.3 Anxiety disorders

Individuals with ADHD commonly report high levels of anxiety on rating scales. However a more detailed enquiry about the psychopathology shows that in some cases the ADHD syndrome mimics some aspects of anxiety. Individuals with ADHD may have difficulty coping with social situations because they are unable to focus on conversations, difficulties with travelling because they be unable to organise the journey, and difficulties with shopping because they may become irritable standing waiting in queues and their
experience of forgetting things and high levels of disorganisation. The
difficulties coping with simple every day tasks that most people take for
granted are a source of considerable concern and are often accompanied by
avoidance of stressful tasks and poor self-esteem. In combination with
ceaseless mental activity, these legitimate concerns and responses may take
on the appearance of a mild to moderate anxiety state, although lacking the
systemic manifestations of anxiety disorders. An important distinction is to
consider whether the symptoms have a similar onset and time course to
ADHD or whether they arise episodically and in response to stressors, which
is characteristic of anxiety.

5.16.4 Psychotic disorders

Severe inattention may rarely mimic the thought disorder symptoms seen in
some psychoses, such as derailment, tangential thought processes,
circumstantiality and flight of ideas. Careful monitoring of both psychotic
symptoms and ADHD symptoms is advised but it may be difficult to
distinguish residual symptoms of a major mental illness from persistence of
ADHD symptoms.

5.17 Recommendations
5.17.1.1 There is no specific biological test for ADHD, so the diagnosis should be made on the basis of a full developmental and psychiatric history, observer reports and examination of the person’s mental state.

5.17.1.2 A diagnosis of ADHD should not be made on the basis of rating scales or observational data alone.

5.17.1.3 The diagnosis of ADHD should only be made by specialist psychiatrists or paediatricians following a full clinical and psychosocial assessment of the child, young person or adult; this should include all relevant domains and settings that the individual inhabits.

5.17.1.4 For the diagnosis of ADHD or hyperkinetic disorder to be made, and for this guideline to be considered appropriate, symptoms of ADHD (DSM-IV) or hyperkinetic disorder (ICD-10) should be sufficient to reach a formal diagnosis in DSM-IV or ICD-10 (except that the ICD-10 exclusion on the basis of a pervasive developmental disorder being present, or the time of onset being uncertain, is not recommended). In addition, the level of impairment resulting from symptoms of hyperactivity and inattention should be:

- at least moderately clinically significant on the basis of interview and/or direct observation in multiple settings, and

- pervasive, that is, occur in all important settings including social, familial, educational and/or occupational settings. [Key priority]

5.17.1.5 ADHD should be considered in all age groups (children, young people and adults), with symptom criteria adjusted for age-appropriate changes in behaviour.

5.17.1.6 In determining the clinical significance of impairments resulting from the symptoms of ADHD in children, the views of the child should be taken into account, wherever this is possible.

5.17.2 Post-diagnostic assessment of children and young people

5.17.2.1 Following diagnosis, healthcare professionals should undertake a comprehensive assessment of comorbidities, parental mental health, and the child or young person’s social, familial, and educational circumstances and physical health and status prior to the commencement of treatment. [Key priority]

5.17.2.2 Following diagnosis, a clinical assessment should include a full physical examination for features of associated conditions, such as macro/microencephaly, dysmorphic features, neurocutaneous markers.
5.17.3 Post-diagnostic advice for parents and pre-school professionals

5.17.3.1 Following a diagnosis of ADHD, healthcare professionals should ensure that general advice is given to parents and carers of all children with ADHD about positive parent–child contact, clear and appropriate rules about behaviour, and the importance of structure in the child’s day.

5.17.3.2 Following diagnosis of ADHD for a child of pre-school age, and with the parent or carer's consent, healthcare professionals should contact the child's nursery or pre-school class, advise them about the child's diagnosis and determine whether special educational needs are likely to be present.

5.18 Research recommendation

5.18.1.1 Grounds for diagnosis of ADHD in adult life

- What is the prevalence of inattention, impulsivity, and hyperactivity/restlessness in males and females in the adult population; how far do the core symptoms of inattention, impulsivity, and hyperactivity/restlessness cluster together; to what extent are they comorbid with other forms of mental disturbance; and to what extent are they associated with neuropsychological and social impairment? (This would be best conducted as an epidemiological survey).

- Why this is important: There is evidence that ADHD symptoms can persist into adult life and be associated with impairment, but there are no clear conclusions about the level of ADHD symptoms in adults that should be considered as grounds for intervention, or about whether the symptoms take a different form in adulthood. The costs to society and to the affected individuals and their families make it pressing to know whether, and how far, services should be expanded to meet the needs of this group.
The organisation of care for ADHD

6.1 Introduction

This chapter describes a stepped care model of service delivery for ADHD. A chronic disease management model similar to approaches employed for conditions such as depression, asthma or diabetes may be useful. Such a population-based model involves several components including the identification of children with high levels of hyperactivity, inattention, and impulsivity; encouraging self-help approaches (in this case, management approaches by parents and teachers); training and support of primary care and school professionals; and the development of care pathways that enable access to treatment.

6.2 Stepped care model for ADHD – school-aged children and young people

Stepped care traditionally reflects the primary-secondary care interface for chronic conditions. In a stepped care model, children and families move up (or down) a step in the care pathway according their particular needs and outcomes as well as what has already been tried.

6.2.1 Self-help approaches

Parents may have noticed hyperactivity, impulsivity and/or inattention in their child, or these features may have been brought to their attention by other family members, friends, or a professional who is in contact with the child. At this stage, self-help approaches (for example, national and local parent organisations, parenting books, manuals, video or DVD, materials from the internet) are available, but were not evaluated as part of this guideline.

6.2.2 Tiered model of CAMHS

For illustrative purposes, a modified tiered model that reflects the key specialist role of both paediatric and mental health professionals in diagnosing and treating ADHD is described here. An assessment could be carried out by either CAMHS or paediatric services, depending on local availability, resources and skills. Nationally, there is huge variation in models of service provision. Ideally, there should be a locally agreed multidisciplinary and multi-agency integrated care pathway, management guidelines between the different tiers, and shared care protocols.

Children with suspected ADHD will usually present initially via tier 1 services, either via general practice or through school or nursery services. In those children presenting via primary care, parental concern is often the most
important trigger for referral (Sayal, 2002). It has been suggested that there
may be significant delays between a parent seeking help and the actual
diagnosis of ADHD (Adore, Coghill), so a robust referral pathway from tier 1
is essential.

**Tier 1**

The parent has an initial discussion with a tier 1 professional (for example, a
teacher, health visitor, GP, school or practice nurse, any other health
professional that may be seeing the child for any reason, or someone in the
voluntary sector). These professionals should have a basic understanding of
ADHD and be able to ask key questions to ascertain possible symptoms and
level of impairment. This can be backed up by the use of rating scales (broad-
band rating scales such as the Strengths and Difficulties Questionnaire or
narrow-band rating scales such as the Conners scales). For this to be feasible,
and to enhance awareness and accurate knowledge about ADHD and
associated conditions, tier 1 professionals will require access to appropriate
training or materials.

At this point, the parent and the professional can agree to a period of watchful
waiting (encouraging self-help and simple behaviour management) or, if
there are more severe problems, a referral to a child and adolescent mental
health professional or paediatrician. Management within the pre-school or
school would be at the level of ‘School Action’, that is the child should be
registered as having Special Educational Needs involving the Special
Educational Needs Co-ordinator (SENCO), and an Individual Education Plan
developed. If indicated, an external referral (increasing the level to ‘School
Action Plus’) might be made to an education psychologist, to outreach
specialist teaching services through Behaviour and Learning Support, or to a
child and adolescent mental health professional or paediatrician.

Tier 1 professionals (including healthcare professionals and teachers) working
in settings where children at high risk of ADHD might present should
consider the possibility of ADHD. Early case identification might be
appropriate in high-risk groups such as children born pre-term and those
who have behaviour or developmental problems (such as cerebral palsy,
epilepsy, and co-ordination difficulties) and poorer reading ability (Ford *et al.*, 2004).

Who can refer depends on local circumstances, it could include the SENCO,
educational psychologist, health visitor, general practitioner, school or
practice nurse, or any other health professional that may be seeing the child
for any reason. If someone has been diagnosed with ADHD and/or is on
medication but has not been seen by secondary care, or if they have pervasive
high scores on appropriate rating scales, such as the Strengths and Difficulties
Questionnaire or Conners’ scales, they should be referred.
As part of the collection of information for this, the referrer should liaise with the GP and the school. Similarly, if the GP or school professional is the referrer, then they should liaise with each other.

Where appropriate, Tier 1 professionals should consider the possibility of referring a child for an ADHD assessment. Access to parent training courses (such as Webster Stratton parenting intervention) should be available at tier 1 where there is associated ODD and CD. Referral criteria here should be in keeping with the NICE Technology Appraisal on CD (NICE, 2006). This means that there are two options for a referral: either referring for an ADHD assessment or referral to a parent training course. At the end of the parent training course, the referrer should carry out a review and assess what problems still remain. If the ADHD symptoms remain prominent, then the child should be referred for an ADHD assessment.

Standard 9 of the Children’s NSF (2004) emphasises that tier 3 CAMHS and/or paediatricians have a remit for training tier 1 professionals. At a local level, service commissioning should take this into account and provide funding for this remit to be met.

**Tier 2**

Following a referral, depending on local service configuration, further assessment regarding the possibility of ADHD can be carried out by a CAMHS primary care mental health worker (who obtains further information from the family, school, and primary care), another uni-disciplinary child and adolescent mental health professional (that is, tier 2 CAMHS) or a paediatrician (if appropriate, to identify a general developmental level or any specific learning disorders). Ideally, this should be a single assessment to avoid any additional delay. The key competencies of this professional are to carry out a generic assessment in order to consider the possibility of ADHD and to know whether to refer to tier 3.

**Tier 3**

If ADHD seems likely following the initial wider mental health and developmental assessment, there should be a multi-disciplinary assessment involving a specialist clinician (a specialist paediatrician, child and adolescent psychiatrist, learning disability psychiatrist, specialist nurse, or clinical psychologist). Depending on the findings of the initial assessment and information from other sources (especially educational), other professionals may be involved such as speech and language and/or occupational therapists.

Following a diagnosis of ADHD, a healthcare professional could be allocated to the role of case manager or care co-ordinator. Their roles might include providing feedback, education and information for the family and child,
guidance for basic behavioural management, identifying multi-agency needs, 
organising follow-up, and liaising with the child’s school as well as any other 
appropriate agencies. The care co-ordinator will also ensure that local shared 
care protocols with primary care are followed.

**Tier 4**

Where there is a high level of uncertainty about a diagnosis, marked severity 
or complexity, or complex issues around psychopharmacology, there should 
be access to a regional ADHD service that supports tier 3 CAMHS or a 
paediatrician. There is a need for tier 4 capacity building nationally, 
particularly for treatments going beyond these guidelines.

### 6.2.3 Transitional arrangements from child to adult mental health services

The services required for the treatment of ADHD in adults are described in 
detail in Section 6.5. A key issue for people diagnosed with ADHD in 
childhood and adolescence, and who still require continuation of their 
treatment beyond the childhood years (usually consider to be the school 
leaving age, or 18 years), is the transition of care from child and adolescent 
mental health or paediatric services to adult mental health services. At a local 
level, tier 3 CAMHS/paediatricians should collaborate with adult services to 
develop a transitional service and, where required, to ensure the adequate 
training of psychiatrists and other adult mental health workers.

### 6.3 Stepped care model for ADHD - pre-school children

**Tier 1**

In many parts of the country, there are specialist health visitor services for 
assessing and managing behavioural disorders in the preschool population. 
Health visitors should be able to suggest basic behavioural and other 
strategies to be used in the home to address overactive, impulsive and non- 
compliant behaviour. In some areas, special programmes, either managed or 
staffed by health visitors are also available, such as SureStart, Child Behaviour 
Intervention Initiative, and Positive Behaviour Intervention Service. These 
programmes are designed to help parents of pre-school children in a more 
systematic way and will often involve group parent effectiveness training 
programmes. Staff in kindergarten and nursery settings may also have basic 
skills to address similar difficulties in these pre-school settings although this 
will be variable depending upon initial and in-service training, and the fact 
that attendance at pre-school settings is not a legal requirement.

**Tiers 2/3**
Children aged 2 to 5 with ADHD symptoms or behavioural problems unresponsive to initial tier-1 intervention could be referred to paediatric services or CAMHS if the ADHD symptoms are causing significant impairment to the child’s development, and social and family functioning. The choice may be determined by local care pathways but it may be appropriate for a referral to be made to a developmental paediatric service for a general developmental paediatric assessment where it is suspected that there are associated developmental disorders, such as global developmental delay, learning disabilities or autistic spectrum problems.

When a firm or provisional diagnosis of ADHD is made by professionals within a tier 2/3 service, group-based parent effectiveness training could be provided if it has not been provided in tier 1. This should be accompanied with information about ADHD and perhaps dietary advice if food intolerance or reactions to food additives/preservatives are suspected. Where group parent effectiveness interventions have been provided at tier 1 a more individualised approach using behavioural therapy principles could be offered in tier 2/3 services. If such interventions are effective it would be appropriate to monitor the child until school entry because at such times of transition symptoms may re-emerge. If the interventions prove ineffective, and the child is 4 years or older, stimulant medication could be considered.

### 6.4 Services for adults with ADHD

Currently there are few established adult mental health or psychological services for adults with ADHD in the UK. This poses considerable problems for individuals who require diagnostic evaluations and treatment programmes for ADHD beyond the school years. In a few areas excellent services have been established and this guideline draws on their experience. In this section we provide guidance on the healthcare services that are required for this group of people and indicate how such services might be established.

In considering the care pathway needs for adults with ADHD there are several categories of need that can be distinguished:

1. **Currently treated group:** Diagnosed and treated for ADHD in childhood and still requiring treatment. This group can be further sub-divided into:
   1. Stably maintained on medication, no need for psychological treatment.
   2. Stably maintained on medication, need for psychological treatment.
   3. Not stably maintained on medication, requires further titration of pharmacological treatments and/or
psychological treatment.

(2) **Currently untreated group:** Diagnosed with ADHD in childhood and currently untreated.

(3) **Never diagnosed:** Diagnosis of ADHD not made in childhood.

For people in each of these groups, a psychiatric evaluation is required by a specialist in adult mental health with the training to diagnose and advise on treatment for ADHD. Full psychiatric evaluations are required for all groups apart from those that are previously diagnosed and stably maintained on treatment (group 1a) and require no further intervention part from a follow-up service for drug monitoring. The other groups require follow-up services to monitor the current and future needs for medical and psychological interventions. The benefits and disadvantages of both pharmacological and psychological treatments for each individual case need to be considered and both should be available.

The following services need to be available:

(1) **Drug monitoring service:** For patients taking stimulant or other medication there needs to be a drug monitoring service. Any suitable trained specialist including adult psychiatrists, nurse practitioners and primary care physicians can provide this. In most cases shared care protocols should be established in which primary care takes responsibility for routine prescribing and health checks (pulse, blood pressure, weight), and specialist services monitor the dose and continued need for treatment.

(2) **Psychological treatment services:** Psychological support should be available, targeted at the particular problems related to ADHD. This includes a wide range of treatments and could include psychoeducation, anger management, daily living skills and treatment of comorbid anxiety and depression. Counselling may be required particularly with emotional problems related to chronic impairment from early childhood. Adults starting on pharmacological treatment for the first time will often need advice on how to best take advantage of potential improvements in their mental state and level of functioning. ADHD coaching or long-term support will be important in some cases where short-term psychological interventions are insufficient. For those with a high level of impairment, community healthcare provision may be required on a longer-term basis. Occupational care will be important in some cases.
Diagnostic services: Specialist services for the diagnosis of ADHD in adults should be available. This includes the diagnosis of adults who were and were not initially diagnosed with ADHD in childhood. Since the recognition of ADHD in children was rare before the mid-1990s, there is a large population of people who went undiagnosed and untreated in childhood and present for the first time as adults.

The diagnosis of ADHD should be made by a specialist with training in general adult psychiatry, who can take account of the full range of mental health problems (usually a consultant or other trained psychiatrist, or child and adolescent psychiatrist working within an adult mental health team). Where medication is indicated, diagnostic services should initiate and monitor treatment during the titration phase. Prescribing during this initial phase can however be devolved to the primary care physician where a shared care protocol is established.

6.5 Models of care in established services

Currently (December 2007), mental healthcare provision for this group of people is very poor in the UK. However services in several regions are developing and in a few are highly developed:

(1) Transitional care: In several regions transition services from child to adult mental healthcare have been established and these provide the treatment and monitoring of adults who started treatment in childhood and need to continue treatment as young adults. In some cases this service is provided by child and adolescent psychiatrists, and in other cases by adult psychiatrists. Arrangements for the transition of care from child to adult mental health services should however be available in all regions.

(2) Diagnostic services: In addition to managing the transition from child to adult mental health services, a service is also needed for the first time diagnosis of adults with ADHD and those that were treated as children but ‘fell-out’ of treatment during their adolescent years and seek help later on as young adults. It is very important that people who stop treatment during adolescence, but still require (and request) treatment as adults, have access to diagnostic and treatment services.

There are two broad models for healthcare provision, both of which have been successfully adopted in different regions:
(a) **Generic services:** Trained psychiatrists and adult mental health teams have included the diagnosis and treatment of ADHD within their general adult psychiatric practice. This model is recommended since the symptoms of adult ADHD overlap with a range of other common psychiatric disorders, and the specialist should be aware of the full range of adult psychopathology when evaluating adults with ADHD. Common disorders that need to be differentiated from ADHD include dysthymia and atypical depression, personality disorder (particularly borderline), anxiety, cyclothymia and type II bipolar disorder.

(b) **Specialist neurodevelopmental services:** An alternative model is to establish a specialist service for common neurodevelopmental disorder in adulthood that could incorporate overlapping conditions such as autism and mild learning disability. The advantage of this model is that an expert team can be developed to optimise sensitivity to the diagnosis and care pathways, including both pharmacological and psychological treatments. Where such services have been successfully established, they have usually incorporated transitional services in addition to the evaluation of new patients.

### 6.6 Competencies for evaluation of ADHD in children and young people

A central problem confronted when drawing up guidance in this area is the difficulty of providing a standardised national guideline that addresses the importance of diagnosing the individual in their family and sociocultural context, while retaining the clinical independence of the individual clinician. Another factor that impacts on local care pathways is the wide national variation in the organisation of services for individuals with ADHD. To overcome these difficulties, this section focuses on the competencies and skills required by individuals involved at various stages of the care pathway, rather than stating which specific professionals should be involved. This however places greater responsibility upon the individual professionals and their experience and expertise. The GDG also wishes to emphasise the importance of different perspectives and the benefits of a multidisciplinary approach in providing a complete picture of the individual within various environmental settings.

#### 6.6.1 Skills required by those involved in Tier 1 detection of ADHD

*Specific areas of competence for Tier 1 should include the following:*
1. Recognition of the three core symptoms of ADHD: inattention, hyperactivity and impulsivity. Core symptoms need to have been present since a young age. It is worth noting that direct observation of a child for a short time in a primary care setting may not demonstrate any obvious features of the condition and is not necessarily a helpful diagnostic approach. Children with predominate symptoms of inattention are less likely to be diagnosed.

2. An awareness that symptoms should occur in all environments (although may not be impairing in all settings). If a child presents via primary care then some form of feedback from the school or nursery is very helpful.

2. Consideration of the use of symptom check lists for parents, child or teacher may be helpful in determining which children need further referral (for example, Conners, SDQ, DSM-IV checks) if used in association with clinical assessment.

4. An awareness of the comorbid conditions that may occur with ADHD, such as oppositional defiant disorder, conduct disorder, autistic spectrum, and so on.

5. An awareness of family circumstances. In particular recent changes in behaviour which may be linked to life events are far less likely to be due to ADHD.

6. An awareness of the child’s developmental and medical history; issues such as hearing problems or inadequate sleep may be particularly relevant.

6.6.2 Skills required for assessment in tier 2/3

Services providing facilities for the diagnostic assessment of ADHD need to be competent in a number of related areas. The skills required will in most cases be acquired during the training of consultant paediatricians (those specialising in mental health, community child health or neurodisability) and child and adolescent psychiatrists, but can usefully be extended to training of GP in primary care, as well as specialist nurses and psychologists. The required skills are not specific to any class of professional healthcare worker and can be acquired by people from a range of backgrounds as listed in Section 6.2.2. Assessments by an interdisciplinary team will in many cases increase the range of expertise and the quality of the assessments. These competencies are therefore those expected of the service rather than of individual clinicians.

Specific areas of competence should include the following:
1. A sound understanding of the normal patterns of infant, child and adolescent development.

2. An ability to differentiate behaviours/symptoms of ADHD from the normal patterns of cognitive function and behavioural features, appropriate for the developmental age.

3. An ability to differentiate the behaviours/symptoms of ADHD from the patterns of cognitive function and behavioural features of other developmental disorders (such as global or specific learning disabilities, including specific reading difficulties, developmental coordination disorder, autism and related spectrum disorders, and Tourette syndrome).

4. An ability to identify and assess the contribution of mental health disorders, such as anxiety (including obsessive-compulsive disorder), mood disorders (including depression and bipolar disorder) and schizophrenia.

5. An ability to identify and assess the contribution of medical predisposing factors (such as foetal alcohol conditions, extreme prematurity) and co-existing conditions (such as epilepsy).

6. An ability to identify and assess the contribution of family and social adversity, including neglect and abuse.

7. An ability to identify and assess the contribution of the above co-existing disorders and risk factors to the behavioural/symptom profile and level of impairment.

6.7 Assessment framework and competencies for evaluation of ADHD in adults

Adults with ADHD are usually identified in several ways:

(1) Individuals with a previous history of childhood ADHD referred from paediatric services, CAMHS or primary care.

(2) Individuals with a previous history of treatment for childhood ADHD, but no longer being monitored or treated for it.

(3) Individuals who were not diagnosed with ADHD in childhood and where ADHD is recognised by a primary care or secondary care physician.

Adults would usually be referred to specialist diagnostic services for ADHD (general adult psychiatry or specialist service within adult mental health) by child and adolescent psychiatrists (transitional service) or by non-specialist doctors in primary care and/or psychiatrists with no training in the diagnosis.
and treatment of ADHD and psychologists in mental health. ADHD in adults is more likely to present within certain specialist clinics including addiction services, personality disorder and affective disorder clinics.

To enable the recognition of ADHD non-specialists should be aware that ADHD persists into adulthood as the full disorder in around 15% of cases or in partial remission with persistence of some symptoms associated with significant clinical impairments in a further 50%. ADHD in adults should be considered for all adult mental health problems that appear to start in early childhood and where the specific problems associated with the disorder (inattention and impulsivity-hyperactivity) persisted through into adult life. Awareness of the typical early onset and persistent (non-fluctuating) course of the symptoms are important for recognition of potential cases. Mood symptoms such as chronic low self-esteem, volatile mood (irritable and unstable mood, easily frustrated) are commonly seen in adults with ADHD and should not exclude the possibility of the diagnosis. People with ADHD may not show marked symptoms of ADHD (fidgety restlessness, poor attention span) during brief clinical assessments – but they may report such problems in their daily lives. Absence of other major psychiatric conditions such as bipolar disorder, major depression or somatic anxiety states that explain the disorder – these can usually be excluded as a cause because they are typically episodic. People with personality disorder should be referred for evaluation of ADHD if they present with significant levels of hyperactivity-impulsivity accompanied by inattention.

Family history of ADHD or other neurodevelopmental problems in close family relatives is common. Screening tools can be used to assist in recognition of the disorder, such as the Adult ADHD Self Report Scale or the Barkley scales based on the DSM-IV checklist for ADHD symptoms. Services providing facilities for the diagnostic assessment of ADHD need to be competent in a number of related areas. The skills required will in most cases be acquired during the training of consultant psychiatrists and other professional groups dealing with common adult mental health problems. However, training in this area of mental health is very poorly developed in the UK, and this combined with a lack of service provision is currently a major impediment to implementation of these guidelines in the adult population. Professional groups who require this training include psychiatrists, psychiatric nurses, psychologists, occupational therapists and primary care physicians involved in the treatment of common psychiatric disorders. Assessments by an interdisciplinary team will in many cases increase the range of expertise and the quality of the assessments. The GDG recognises the need for the following services: (1) Routine monitoring and follow-up of people with ADHD stably maintained on drug treatments for ADHD, (2) Provision of social and psychological support services for people with ADHD, (3) Diagnostic services to for people with ADHD who were not diagnosed during childhood or adolescence. It is recommended that the
formal diagnosis and initiation of treatment for ADHD be carried out in secondary care. For the adult population this will usually mean general adult psychiatrists who have received training in the diagnosis and treatment of ADHD. This might also include child psychiatrists working with colleagues in adult mental health services.

Specific areas of competence should include the following:

1. An understanding of the normal patterns of infant, child, adolescent and adult development.

2. An ability to differentiate behaviours/symptoms of ADHD from the normal patterns of cognitive function and behavioural features, appropriate for the developmental age. Recognise the three core symptom domains of inattention, hyperactivity and impulsivity and understand the way that these behaviours/symptoms present in adults.

3. An ability to differentiate the behaviours/symptoms of ADHD from the patterns of cognitive function and behavioural features of other developmental disorders (such as global or specific learning disabilities, including specific reading difficulties, autism and related spectrum disorders).

4. An ability to identify and assess the contribution of mental health disorders, such as anxiety, depression, bipolar disorder and schizophrenia.

5. An ability to identify and assess the contribution of co-existing conditions (such as epilepsy).

6. An ability to identify and assess the contribution of family and social factors.

7. An ability to identify and assess the contribution of the co-existing disorders and risk factors to the behavioural/symptom profile and level of impairment.

6.8 Recommendations

6.8.1 The organisation and planning of services

6.8.1.1 Mental health trusts, and children’s trusts that provide mental health services for children, should consider developing a multidisciplinary specialist team and/or clinic with specific expertise in the diagnosis
These teams should:

- provide diagnostic, treatment and consultation services for people with ADHD who have complex needs, or when general psychiatric services are in doubt about the diagnosis
- develop systems of communication and protocols for information sharing among paediatric, child and adolescent mental health and adult mental health services for people with ADHD, including arrangements for transition between child and adult services
- develop local protocols for shared care arrangements with primary care providers, and clear lines of communication between primary and secondary care
- ensure age-appropriate psychological services are available for people with ADHD and their parents/carers, as recommended in this guideline.
- The size and whole-time commitment of such teams should depend upon local circumstances such as the size of trust, the population covered, and the estimated referral rate for people with ADHD.

6.8.2 Training

6.8.2.1 Specialist ADHD teams for adults and children should jointly develop age-appropriate training programmes on the diagnosis and management of ADHD for mental health, paediatrics, social care, educational and primary care providers who may have contact with people with ADHD. [Key priority]

6.8.2.2 Adult psychiatrists, other adult mental health professionals, child psychiatrists and paediatricians should ensure that they undertake training so that they are able to diagnose, and provide basic treatment for, people with ADHD.

6.8.3 Care pathway: identification, pre-diagnostic intervention in the community and referral to secondary services

6.8.3.1 Because referral from the community to secondary care may involve a wide range of health, educational, and social care professionals (such as GPs, general paediatricians, educational psychologists, SENCOs, social workers and others), and care pathways vary from one locality to another, the GP should be informed when children and young people are referred to secondary care, irrespective of who makes the referral, the GP should be informed.
6.8.3.2 When a child or young person presents in primary care with problems with behaviour and attention that suggest a possible diagnosis of ADHD, primary care practitioners should assess the child and parents to determine the severity of the problems and the extent to which they pervade different domains and settings.

- If the child’s behavioural and/or attentional problems are severe, referral should be made to secondary care (either a child psychiatrist, paediatrician, or specialist ADHD child and adolescent mental health services [CAMHS] practitioner) for assessment.

- If the child’s attentional and/or behavioural problems are mild to moderate:
  - a period of watchful waiting may be considered
  - the parents should be considered for referral to a parent-training programme (this should not wait for a formal diagnosis of ADHD)
  - if the problem persists with evidence of at least moderate impairment, the child should be referred to secondary care for assessment.

6.8.3.3 Primary care practitioners should not undertake the initial diagnosis or start drug treatment for children or young people with suspected ADHD.

6.8.3.4 If a child or young person is currently being treated in primary care with methylphenidate, atomoxetine, or dexamfetamine, or any other psychotropic medication for a presumptive diagnosis of ADHD and has not been assessed by a specialist in ADHD in secondary care, the child should be referred as a matter of clinical priority for assessment by specialist services.

6.8.3.5 Adults presenting in primary care or general psychiatric services without a childhood diagnosis of ADHD should be referred for assessment of possible ADHD if there is evidence of the following:

- typical behavioural manifestations of ADHD
  - (hyperactivity/impulsivity and/or inattention)

- behavioural manifestations that began in early childhood, have been persistent throughout life and are not explained by other psychiatric or personality disorder diagnoses (although there may be other coexisting psychiatric problems)
• psychological, social, and/or occupational impairment resulting from or associated with the persistent behavioural manifestations.

6.8.4 Transition to adult services

6.8.4.1 At age 17, a young person with ADHD in receipt of treatment and care from CAMHS or paediatric services should be re-assessed to establish the need for continuing treatment into adulthood. If services are deemed to be necessary, arrangement should be planned for a smooth transfer to adult services at 18 years of age. Precise timing of arrangements may be varied locally, subject to agreement between all trusts involved.

6.8.4.2 In the transition of young people with ADHD between children’s and adult services, a formal meeting involving CAMHS, paediatrics (if appropriate) and adult psychiatric services should be considered and full information provided to the young person regarding adult services. Where necessary, the Care Programme Approach should be used.

6.8.4.3 After transfer to adult services, healthcare professionals should carry out a comprehensive assessment of young people with ADHD that includes their personal, educational, occupational, and social functioning, and the assessment of any comorbidities, especially drug misuse and personality disorder.
7 Psychological interventions and parent training

7.1 Introduction
This chapter reviews the evidence on non-pharmacological interventions for ADHD. Psychological interventions for ADHD include a range of cognitive behavioural approaches, including behavioural interventions and parent training, cognitive training and social skills training. Interventions with parents or carers of children with ADHD that do not fall into the category of parent training are also addressed, for example psychoeducation in the form of written material for parents. For younger children with ADHD (up to 6 years) behavioural approaches, primarily parent training interventions, are the main focus of research, while for older children other approaches such as CBT, social skills training and self-instructional training coupled with parent training predominate. There is also some research on the use of other types of therapy for ADHD, such as biofeedback and relaxation training, and these are also discussed addressed along with the use of environmental manipulation and management (see section 6.4).

Despite the predominance of pharmacological management of ADHD symptoms psychological interventions for ADHD have attracted the interests of clinicians and researchers for a number of reasons as set out below.

Short-term effects of medication
Despite the effectiveness of stimulants in achieving a reduction in core symptoms, there have been questions over their long-term effectiveness, with some studies indicating that improvements may not be maintained over the longer term and into adolescence (Swanson et al., 1993). Similarly, some studies have indicated that many of the benefits of stimulant medication may be state dependant – effects may only last for as long as the person is receiving the medication and may not generalise to situations in which treatment is absent (Whalen & Henker, 1991). Therefore other forms of intervention have been considered as a way perhaps of prolonging drug effects.

Narrow clinical benefits of medication
Children and adults with ADHD typically have secondary problems which are not resolved with medication. For example, Pelham and Gnagy (1999) point out that although stimulants may improve parent-child interactions in analogue settings (that is, settings where measures may be taken, such the clinic), families of children with ADHD are dysfunctional in multiple domains with problems that may include maternal stress and depression, paternal
alcohol misuse and inappropriate parenting skills. Furthermore, problems of low self-esteem, poor peer relationships and other secondary or comorbid problems may exacerbate ADHD symptoms and may not be improved by medication alone. Equally, studies have not demonstrated clear effects of stimulants on academic performance or learning (Swanson, 1993).

**Non-responsiveness to medication**

A significant number of children and adults with ADHD fail to respond to stimulant medication (Safren et al., 2005; Swanson et al., 1995). These significant sub-groups of those with ADHD have legitimate interventional needs.

**Weak responsiveness of ADHD symptoms to medication**

Of those children who do respond to medication, the improvement may not necessarily bring them within the clinically normal range (Pelham & Murphy, 1986) and so, even if medication has some beneficial effects, there may be a need to enhance them.

**Intolerance to medication**

A significant number of children and adults with ADHD may be intolerant to stimulant medication. Side effects of stimulants can be significant and interfere with treatment adherence or cause treatment discontinuation (see Chapter 10 for a review of the side effects of stimulants). Side effects sometimes occur only in the early stages of treatment as they may be removed by adjustments to dosage. Nevertheless, the issue has been important for the development of alternative or complimentary psychological approaches given that Schachar and colleagues (1997) found that 15% of children treated with methylphenidate terminated treatment at 4 months because of side effects.

**Clinical needs of younger children**

Manufacturers of stimulant medications for ADHD do not recommend their use for the treatment of children under 6 years and yet ADHD may present and require intervention before this age. Other types of therapy, particularly behavioural, have therefore proved attractive to clinicians and researchers for this age group.

**Ethical and other objections to medication**

Even if medication has proved to be a complete solution, some professionals and parents have objections and ethical concerns about the use of medication (Perring, 1997). The reasons are varied and include a general unhappiness about using any type of psychotropic medication in children, concerns about possible side effects and long-term harms, concerns that medication may take away individual responsibility for problems, and an unease that the focus of treatment should be solely on the child instead of the interface between them and the social and educational systems of which they are a part.
7.1.1 The aims of psychological interventions for ADHD

In addition to the limitations and objections to medication discussed above, there are other reasons why psychological interventions may be chosen. Most presentations of ADHD in children and adults are associated with behavioural problems and comorbid mental disorders, commonly depression, anxiety, defiant and oppositional behaviour, poor self-esteem, relationship difficulties and learning problems. A complete and comprehensive therapeutic intervention devised for a given individual might therefore include non-pharmacological therapies of proven benefit. A further objective might be to use psychological interventions to reduce the dosage of stimulant medication that might be required to achieve a positive clinical outcome.

The main aim of all psychological interventions for ADHD is to improve the daily functioning of the child or young person by improving their behaviour and family and peer relationships. Interventions for parents are designed to help parents develop optimum strategies to cope with the difficult behaviour secondary to, or comorbid with, ADHD rather than addressing the core symptoms of inattention, hyperactivity and impulsivity.

7.1.2 Outcome measures for the review of the effectiveness of psychological interventions for ADHD

Most studies tend to include a wide range of outcome measures from different sources (parents, teachers, clinicians and self) to explore the wider clinical benefits of interventions for ADHD. In addition to being of research interest, this wider approach to outcomes probably mirrors general clinical practice and as such is of particular value to the evaluation of psychological interventions for ADHD.

When undertaking the meta-analysis evaluating the effectiveness of psychological interventions for ADHD, in addition to looking at the impact of interventions on measures of the core symptoms of ADHD the GDG looked at measures of other outcome categories reflecting aspects of behaviour and functioning that ADHD may have an impact upon: conduct problems, social skills, emotional outcomes and self-efficacy. For each of the included studies the GDG considered whether any of the reported outcomes were acceptable measures of any of these additional outcome categories. Where studies reported useable outcomes they were used in the meta-analysis for the additional outcome categories.

For each outcome category, a hierarchy of the most suitable outcome measures was agreed upon by the GDG members. If a study reported more than one relevant measure (or subscales) for a given outcome category, only the measure highest in the agreed outcome hierarchy was included in the analysis. For each outcome category separate analysis was undertaken for parent-, teacher-, other observer, or self-reported outcomes. Generally studies...
reported outcome measures for only some of the outcome categories. Only
outcome measures that were judged to be established and valid were used in
the analysis; outcome measures that were developed for a study and
behavioural observations were therefore not used.

In addition, analysis was undertaken to look at the effects of interventions on
measures of reading and writing as these were agreed as the key educational
outcome categories.

7.1.3 Definitions of psychological interventions for children and young
people

Although there are many types of psychological therapies the three main
types used to treat ADHD are CBT, social skills training and family therapy.
CBT approaches that are relevant to the treatment of children with ADHD
include behavioural therapy, parent training and cognitive therapy. CBT
techniques have been extensively used with the aim of helping to improve
motor behaviour, inattention and impulsivity. CBT helps clients understand
links between thoughts, feelings and behaviours and how these may result in
unhelpful, inappropriate or maladaptive consequences. A second component
of the therapy is learning to change these thoughts feelings and behaviours to
produce more desirable outcomes. Essential to the therapeutic process is
putting any identified changes into practice. CBT approaches often combine
behavioural and cognitive aspects, but in work with children CBT therapies
have often had either a behavioural or cognitive emphasis. The main
psychological interventions for ADHD are described below.

*Behaviour therapy*

The chief technique involves the use of rewards or reinforcers that are judged
likely to encourage the young person to implement targeted changes in
motor, impulse or attentional control. This may involve tangible rewards such
as extra time for recreational and leisure activities or the means to obtain
items that the young person values. Schemes using ‘tokens’ (such as stars,
chips, marbles, and so on) may for younger children be rewarding in their
own right, whereas for older children tokens may be exchanged for items of
value to them. Another type of reward is social approval such as praise or
achievement certificates and this may also include self-praise. Care is required
in the choice of rewards because they may be specific to an individual – what
is of value to one child is not necessarily of value to another. There are also
practical, financial, cultural and moral issues that make some rewards more
suitable for some parents than others.

A further set of techniques involves negative consequences. Although less
frequently used than rewards, this approach may have a valuable function,
especially where a particular behaviour is disruptive or offensive to others
and needs to be stopped immediately – impulsive behaviour frequently falls
into this category. Verbal reprimands, which have the merit of being simple
and effective, may be delivered by parents, other carers and teaching staff.
Response cost techniques involve the loss of a potential reinforcer. These can
take the form of deductions either from rewards already earned or from an
agreed set of rewards given in advance but from which deductions can be
made for inappropriate behaviour.

The third most common technique is ‘time out’ (short for ‘time out from social
reinforcement’), which involves the young person being placed away from
the attention of others for a set period during which time they are expected to
be quiet and cooperative, otherwise the procedure is implemented again.
This particular approach is helpful where it is felt that inappropriate,
overactive or impulsive behaviour is being maintained by the attention of
others such as parents, siblings or peers.

Parent training

Parent training (or parent effectiveness training) is effectively a behaviour
therapy intervention in that it teaches the parents to use behaviour therapy
techniques with their child. Parent training originated in the 1960s and was
based on behavioural learning theory and play therapy, although play
therapy was not acknowledged as being as important. The intervention has
developed further into addressing issues such as beliefs, emotions and wider
social issues along with issues that hinder the effectiveness of parents such as
poor self-confidence, depression, social isolation and marital difficulties
(Scott, 2002).

The main goals of parent training programmes are to teach the principles of
child behaviour management, increase parental competence and confidence
in raising children and to improve the parent/carer-child relationship by
using good communication and positive attention to aid the child’s
development. These programmes are structured and follow a set curriculum
over several weeks; they are mainly conducted in groups, but can be modified
for individual treatments. Examples of recognised programmes are the Triple
P (Sanders et al., 2004) and Webster-Stratton (Webster-Stratton, 1981). The
focus is primarily with the child or young person’s main care giver although
some programmes add a child-directed component based on the principles of
social skills training.

Cognitive therapy

Self-instructional training is probably the most commonly used cognitive
therapeutic approach in the psychological treatment of ADHD. It comprises
several different techniques, including self-instructional training, cognitive
modelling, self-evaluation, self-reinforcement and response cost.

The therapy involves helping the young person develop a more planned and
reflective way of thinking and behaving by learning how to adopt a more
reflective, systematic and goal-directed approach to tasks and problem solving. The learning strategies typically involve abstract self-instructional schemas along with more concrete step-by-step approaches and perhaps physical cues and reminders.

An early example of teaching an abstract strategy was the ‘Think Aloud’ programme by Camp and Bash (1981) based on ideas by Meichenbaum (1977) and Meichenbaum and Goodman (1971). Children are encouraged to adopt a four-point schema when faced with a problem or task:

1. What is the problem?
2. What is my plan?
3. Do I use my plan?
4. How did I do?

The strategy is taught initially using cognitive modelling involving an adult verbalising their response to a problem-solving task. The young person then emulates this by first by talking out aloud, then whispering and finally using covert (inner) self-talk. Self-evaluation is then encouraged.

More task-specific strategies can also be taught and may be related to particular situations such as school work, relationship issues and recreational and leisure pursuits (for example, Kendall & Wilcox, 1980; Kendall & Braswell, 1982). Programmes may also feature other techniques, such as teaching self-reinforcement (for example, “I did well!”) and response cost techniques in which the young person pays penalties for making mistakes or alternatively earns rewards for success in implementing the strategies taught (Kendall & Finch, 1978).

Social skills training

Social skills training was developed in the early 1970s and according to Jacobs (2002) its aim is to teach the micro skills of social interaction such as eye contact, smiling and body posture. Children and young people who have ADHD often present with difficult family relationships and may have poor social skills and peer relationships. Social skills are described as the behaviours and skills necessary to engage in developing and maintaining constructive social relationships. Social skills training uses techniques from cognitive and behavioural approaches and is conducted within groups.

In addition to social skills training, problem-solving approaches have been developed and are concerned with the child and young person’s ability to self-regulate (the capacity of the child and young person to initiate, delay, modify or modulate the amount or intensity of a thought, emotion, behaviour or psychological response) and cope with stress (the ability to self-regulate responses to perceived stressful events) (Compas et al., 2002).
The practice of family therapy varies widely and is based on the recognition of interpersonal relationships within families. Family therapy aims to produce changes in the ways that families function. There are different models of family therapy:

- Structural family therapy is based on the assumption that all well-functioning families have an intergenerational hierarchy with demarcated roles and boundaries. The role of the therapist is to challenge family functioning and difficult interpersonal relationships, and thereby enable family disorganisation to be resolved.

- Strategic family therapy is based on the view that difficulties stem from repeated patterns of dysfunctional family communications.

- Brief solution-focused therapy focuses on when the problems are not evident or less problematic in order to examine what is different about these interactions to prove that the family already possess the solution.

7.1.4 Support for parents of children with ADHD

Relationship and family issues are well documented for children and families with a diagnosis of ADHD (Johnson, 2001). Parents often feel that they are unable to manage the complexity of their child’s difficulties and this places a strain on the parents themselves as well as the family and siblings who do not have ADHD. Parents/carers of children with ADHD therefore often need support, including information about ADHD and the disorders that occur with it, and information and support to help them to cope. Local parental support groups can provide peer support and an opportunity for parents to exchange experiences and advice about caring for a child or young person with ADHD on a day-to-day basis; they may also be helpful in providing a source of advocacy.

7.1.5 Psychological therapies for adults with ADHD

CBT interventions may be used with adults to help them to develop strategies and learn practical techniques to reduce the impact of their ADHD symptoms on their functioning, for example by teaching problem-solving skills, techniques to reduce distractibility and stress management skills. These interventions, which may be offered on a group or individual basis, vary in duration and may be provided only as brief intensive treatments, for example in the form of brief solution focused therapy. The development of CBT for adults with ADHD has lagged behind its development for children (Ramsey & Rostain, 2003), partly as a consequence of the under recognition of AHDH in adults.
Other approaches with adults are brief solution focussed therapy and coaching. Coaching is an intervention that aims to help people with ADHD identify and draw on their personal strengths as well as to negotiate their problems and cope with life on a daily basis. The coaching relationship has a collaborative focus with the coach and client working together in partnership. The aim is to change old behaviour patterns by developing new ones, as well as to identify personal goals and generate strategies to counter potential obstacles to achievement and success. The coaching or mentoring role is not prescribed in terms of there being a recommended level of contact or number of sessions as it operates along the lines of a ‘buddy system’ whereby the coach is an ally who provides encouragement and support, especially when the client must face and manage difficult situations. The process of the intervention and level of commitment varies immensely. Much depends upon the quality of the coach/client relationship as personal coaching involves an individualised approach that focuses on the client’s goals and needs.

7.1.6 Current practice

Little is known about the extent and quality of non-pharmacological treatment patterns of children, young people and adults with ADHD in the UK. There are very few adult clinics specialising in ADHD and services for children are variable and provided by community health services, CAMHS and education services. A recent 5-year follow-up study of 115 children with ADHD between the ages of 5 and 16 years (Ford et al., 2007) indicated that 67% had received some family-orientated therapy guidance in the previous 12 months from mental health services. In 9.7% of cases some individual therapy (unspecified) had been received, with parents seen individually in 2.6% of cases. Other agencies and resources were also involved–22.6% of cases had received extra help in the classroom, 8.7% had received support and reassurance from primary mental health services, 22.6% had found internet resources helpful and 9.6% had received help from voluntary agencies.

Current practice in the use of psychological interventions for ADHD is, in all probability, variable. It is likely that the pattern of the availability of psychological interventions will vary according to locality and the resources within that locality. Much will also depend on the individual diagnosis, with a care plan being tailored to each individual’s needs rather than a universal intervention package being offered within each setting. Furthermore, the accessibility of services for children and families may vary. Services may not be accessible to all children and families unless they are delivered in a venue that is local and accessible to children and families, has flexible delivery hours (including evenings and weekends), and provides crèche facilities for families with younger children.

Children

Nationally, the responsibility for providing services for children with ADHD is shared between paediatric services and CAMHS, with the former probably
seeing the majority of cases. The exact configuration of services at the local level is highly variable – services for children with ADHD may either be shared between these services, or primarily the remit of either one or the other service.

The most common initial intervention is the provision of parental advice and guidance on an individual basis. This may be delivered informally, for example by nurse specialists. Where indicated, this may be combined with a parent effectiveness training programme using behaviour therapy principles on an individual or group basis. Such programmes are offered by CAMHS and some paediatric services, primary health services or by voluntary organisations, but the provision of such interventions is patchy with marked geographical variations. In addition it is common for CAMHS professionals to offer additional psychological and other therapies to children and their families to address comorbid or secondary mental health problems that may present with ADHD. It is recognised that in some paediatric settings local psychological interventions may not always be available and therefore not routinely offered.

It is less usual for individual or group work to be undertaken with children – the most widely used interventions are those that aim to improve social skills or ‘self-control’, with the latter focusing on anger management or problem-solving skills. The provision of these types of intervention is again variable, but of the two, social skills training is probably the most frequently offered.

The provision of help in primary schools is very limited and rarely specific to the needs of children with ADHD. However, some schools offer group training for anger management and social skills, and while such programmes are often related to anti-bullying initiatives they may be of some help to children with ADHD.

An informal intervention is assisting children to engage in a variety of leisure and recreational pursuits, usually to meet their need for stimulation and also as a release for physical energy. This is often arranged on an intuitive basis by parents, but some therapists may address such needs as part of a wider intervention package.

**Adolescents**

With young people there is much more of a focus on individual work to reduce identified impairments in functioning which may be continuing to threaten general development and psychosocial adjustment. In CAMHS settings individual therapy using cognitive-behavioural principles is commonly employed to target social skills, self-esteem, behaviour and emotional adjustment. In more complex presentations approaches that may be employed include family therapy and individual work with parents on behavioural management techniques for younger adolescents.
As with primary schools, secondary schools are unlikely to offer interventions specifically for ADHD. Nevertheless, they may offer individual support and counselling as well as group programmes for social skills difficulties and reducing aggressive and bullying behaviours, which may be a consequence of, or associated with, ADHD. In addition to the core ADHD problem of inattention many children with ADHD also have learning difficulties, including literacy problems. These young people may have help individually or in small groups, which are often overseen or run by Special Educational Needs Coordinators (SENCOs) in each school. Self-instructional training using cognitive therapy principles are often employed in such contexts but the provision is probably quite limited and variable nationally.

**Adults**

When treating adults with ADHD, current practice in the UK does not routinely include the provision of psychological treatment. There are, however, many reasons why psychological treatment might be appropriate for individuals who often do not achieve their personal potential by young adulthood because they have been hampered by their symptoms and/or comorbid problems. When psychological therapies are used with adults with ADHD they are generally considered as additive to treatment with medication. However, as young adults mature and their symptoms remit, and treatment with medication may no longer be recommended, a need for psychological treatment may continue, if not arise, to address feelings of helplessness and low self-esteem.

Individuals who have not received their diagnosis until adulthood will require psychological support as they often appear to undergo a process of acceptance and understanding associated with their late diagnosis (Young et al., in press). Often these adults have a history of multiple presentations to child and adult services in an attempt to access help (Dalsgaard et al., 2002; Young et al., 2003), with their need for psychological treatment being recognised by both themselves and their partners (Young et al., in press; Young et al., in press).

### 7.2 Psychological interventions for children with ADHD

#### 7.2.1 Introduction

This section reviews the evidence on the clinical effectiveness of psychological interventions for children with ADHD. Evidence on the types of psychological interventions for children and young people discussed in the section on definitions in the introduction (see section 7.1.3) is included, but evidence on other non-pharmacological interventions and interventions for carers is not reviewed here.
The GDG took the decision to analyse data from studies of parent training programmes for ADHD together with data from studies of child directed interventions on the grounds that parent training is in effect a behavioural intervention with the child as parent training teaches parents to implement behaviour management techniques. This decision was further justified by the available evidence as in general interventions were not discretely parent or child focused (see Limitations and rationale, below).

The GDG also considered the issue of the medication status of participants in studies of psychological interventions for ADHD and concluded that trials should be included as long as the medication status of the participants in the intervention group and control group was similar. Included trials therefore fall into three groups: those with no participants on medication, those in which some or all of the participants in both intervention and control groups continued to receive medication for ADHD as part of their usual care, and those where no information on the medication status of participants was given. In trials where participants received medication as part of usual care, individual participants might receive a variety of types and doses of medication. Where no information was given on the medication status of the participants in a trial they were assumed to be receiving usual care and possibly on medication for ADHD.

At the outset the GDG proposed that separate analyses should be undertaken for studies where participants were not medicated and studies where some or all participants were on medication for ADHD. However, due to the relatively small number of trials the data was all included in one analysis for any medication status. The analysis thus represents a naturalistic population as it includes both medicated and unmedicated children with ADHD.

Trials of the combined use of medication and psychological interventions for ADHD (that is, where the medication regimen and psychological interventions were both determined by the trial protocol) were excluded and analysed separately (see Chapter 11). Trials were also excluded if the medication status of the group receiving the psychological intervention differed from that of the control group. For example, trial data was not included where the intervention group did not receive medication for ADHD but some or all of the control group were on medication as part of their usual care. Data from the MTA trial (MTA Cooperative Group, 1999) was therefore excluded from the analysis of psychological intervention versus control as the behavioural treatment group were not medicated whereas two thirds of the community care comparison group were receiving medication for ADHD.

### 7.2.2 Limitations and rationale

The nature of the experimental psychological interventions for ADHD that have been evaluated and reported in the literature is such that it is difficult to identify which specific attributes of an intervention are key to any beneficial...
effects of treatment. In general the interventions evaluated by studies investigating the effectiveness of psychological therapies for ADHD do not involve only the child with ADHD or only their parents. Where the focus of an intervention is on the child there is often some additional parental involvement, such as sessions for parents that relate the content of the intervention and aim to encourage parental reinforcement of what the child is learning in the intervention. In some cases teachers are also involved with a similar aim. Likewise, parent training interventions may include some work with the child. It is also the case that the experimental interventions generally consist of a number of sessions with a therapist or trainer and might cover a number of approaches and techniques that might be of therapeutic value, including cognitive approaches and problem solving, social skills training, and behavioural techniques. Furthermore, whilst most experimental interventions involve a broadly comparable number of sessions and are spread over a comparable duration, some are longer lasting and more intense.

7.2.3 Databases searched and inclusion/exclusion criteria

Information about the databases searched and the inclusion/exclusion criteria used for this section of the guideline can be found in Table 5.

| Table 5. Databases searched and inclusion/exclusion criteria for clinical evidence |
|---------------------------------|----------------------------------------------------------------------------------|
| **Electronic databases**        | CENTRAL, MEDLINE, EMBASE, CINAHL, PsycINFO                                        |
| **Date searched**               | Database inception to 18.12.08                                                    |
| **Study design**                | RCT                                                                               |
| **Patient population**          | Children diagnosed with ADHD                                                      |
| **Interventions**               | Any non-pharmacological intervention used to treat ADHD symptoms and/or associated behavioural problems |
| **Outcomes**                    | ADHD symptoms*, conduct problems*, social skills*, emotional outcomes*, self-efficacy*, reading, mathematics; leaving study early due to any reason, non-response to treatment. |

*Separate outcomes for teacher, parent, self, and independent ratings.

7.2.4 Studies considered

From the primary RCT search, the review team identified trials comparing a psychological intervention with a control group. Acceptable control conditions included no treatment, assignment to a waiting list, treatment as usual and benign interventions with comparable contact times but lacking the active therapeutic components of the experimental intervention. Studies were excluded if the comparison group received an active and potentially therapeutic intervention. The included studies varied in relation to two key characteristics of the sample populations that might impact on the
effectiveness of a psychological intervention – the medication status and age of the children with ADHD.

Ten trials met the eligibility criteria set by the GDG, providing data on 549 participants. All were published in peer-reviewed journals between 1997 and 2007. In addition, 71 studies were excluded from the analysis. The most common reasons for exclusion were related to study design or because there was no appropriate intervention. One study of a parent training intervention was excluded from the analysis as the level of attendance was poor to the extent that any difference between the intervention and control groups might not be attributable to the intervention (BARKLEY2000). In this trial only 13% of parents assigned to parent training attended a minimum of nine out of 14 sessions, and while the majority did attend at least one session (67%) under half (42%) attended a minimum of five sessions. The children in this study also differed somewhat from others as they were younger (mean age 4.9 months) and were included on the basis of a parent measure of disruptive behaviour (14 symptom items for ADHD and eight symptom items for ODD). Further information about both included and excluded studies can be found in Appendix 17.

In trials where participants continued to receive usual care medication for ADHD the type and dose of medication participants received might vary. This contrasts with trials of combination treatment for ADHD, where both the pharmacological and psychological interventions are determined by the study protocol. As discussed above, the GDG concluded that trials of combination treatment for ADHD should be excluded from the analysis of the effectiveness of psychological interventions for children with ADHD, even where they had a group on medication only that could be compared with a group receiving medication plus a psychological intervention (studies of combination treatment for ADHD are reviewed in Chapter 11). Studies were also excluded if the intervention and comparison groups differed in terms of their receipt of medication for ADHD. The MTA study (MTA Cooperative Group, 1999) was therefore excluded as two thirds of the community care comparison group received medication for ADHD whereas the group receiving the intensive MTA behavioural intervention did not receive medication.

In all included studies, the psychological interventions were broadly based on CBT principles, with the different approaches used reflecting clinical practice for the age range of the study population. The studies involving only pre-school children with ADHD looked at parent training interventions (BOR2002; SONUGA-BARKE2001), as did the studies involving school-age children with ADHD where the mean age of participants was under 8 years (HOATH2002; HOOFDAKKER2007). Studies involving participants with a mean age of 8 or 9 looked at the effects of work with both the child and the
parents or family (BLOOMQUIST1991; FEHLINGS1991; PFIFNER1997; TUTTY2003) or just the child (ANTSHEL2003; GONZALEZ2002).

Five of the included studies were three arm trials. For the purposes of this review, only two arms of each trial were included in the analysis. For BLOOMQUIST1991 and PFIFNER1997, Group 1 and 3 were included; for BOR2002 and GONZALEZ2002, Group 2 and 3 were included; for SONUGA-BARKE2001, Group 1 and 2 were included (further information about each group can be found in Appendix 17).

No RCTs of family therapy interventions for ADHD were identified that allowed a comparison between the family therapy intervention and a control condition.

7.2.5 Clinical evidence for psychological interventions for children with ADHD

Important study population characteristics and a summary of the evidence are presented in Table 6. The associated forest plots can be found in Appendix 18.

### Clinical evidence summary for psychological interventions for children with ADHD

For individual outcomes, the quality of the evidence was generally moderate to high. Overall, the evidence shows that compared with control conditions, psychological interventions for children with ADHD have moderate beneficial effects on parent ratings of ADHD symptoms and conduct problems at the end of treatment. These beneficial effects are sustained at follow-up 3 to 6 months after the end of treatment. If the small study by Pfiffner and McBurnett (PFIFFNER1997) is excluded from the analysis, the effect of psychological interventions on conduct problems at the end of treatment remains positive, but beneficial effects do not reach statistical significance at the later follow-up. The meta-analysis therefore cannot be regarded as establishing that psychological interventions have sustained effects on conduct problems in children with ADHD. There is no evidence that psychological interventions for children with ADHD have positive effects on teacher ratings of either ADHD symptoms or conduct related behaviours. Beneficial effects of psychological interventions for ADHD therefore do not appear to transfer to the classroom environment.

In the context of this lack of evidence that psychological interventions have beneficial effects on teacher ratings of ADHD symptoms and conduct behaviour it is necessary to downgrade the assessment of the quality of the evidence for beneficial treatment effects as measured by parent ratings of these outcomes. This is because it is possible that parent ratings may be

subject to bias. In trials of psychological interventions for children with ADHD it is not possible for parents to be blinded with respect to the child’s receipt of the intervention, and therefore there is a risk of bias in ratings given by parents of children receiving the intervention. Even where teachers are also aware which children are receiving the intervention it is possible that there is a greater risk of bias in parents’ ratings as they have more invested in the child and may therefore be less objective. However, it is impossible to determine whether bias has contributed to the findings on parent outcomes, indeed an alternative explanation for the discrepancy between parent and teacher ratings is that behavioural symptoms are less severe in the more structured classroom environment and there is therefore less scope for a psychological intervention to deliver measurable benefits. A further consideration is that the primary focus of psychological interventions, particularly parent training interventions and other interventions that involve the parents or family as a whole, may be to improve behaviour in the home environment, in which case greater improvements might be expected in parent ratings of behaviour.

With respect to the other outcomes that it was considered might be targeted by psychological interventions, or that psychological interventions might have a greater impact on (social skills, emotional state as represented by internalising symptoms and anxiety, self-efficacy, and academic performance), beneficial effects were not generally in evidence. Positive effects were detected for self-efficacy at follow-up 3 to 6 months after the end of treatment, but this finding comes from only one small study that reported a self-efficacy outcome at this follow-up time point (FEHLINGS1991). At the end of treatment neither this trial nor the overall meta-analysis pointed to positive effects of psychological interventions on self-efficacy, and the one finding at follow-up therefore cannot be taken as establishing an effect of psychological interventions on self-efficacy in children with ADHD.

Unfortunately, owing to the limited number of RCTs meeting inclusion criteria there was insufficient data to allow robust subanalyses to be performed to look at the circumstances in which psychological interventions might be effective for children with ADHD. Questions of particular interest are whether:

- psychological interventions are effective in the subgroup of children with ADHD not on medication for ADHD
- psychological interventions are effective in the subgroup of children with ADHD continuing to receive medication for ADHD as part of their usual care
- psychological interventions are effective in pre-school children with ADHD
- psychological interventions are effective in school-age children with ADHD
• psychological interventions targeting parents are effective for children with ADHD
• psychological interventions targeting children with ADHD are effective
• psychological interventions targeting both children and parents, and family interventions, are effective for children with ADHD
• psychological interventions delivered to groups are effective for children with ADHD
• psychological interventions delivered individually are effective for children with ADHD.

However, it is notable that when separate analyses were undertaken for trials where participants were not on medication (BOR2002; FEHLINGS1991; SONUGA-BARKE2001) and for trials where some or all of the participants were on continuing medication for ADHD or where no details of the medication status of participants were given (ANTSHEL2003; BLOOMQUIST1991; GONZALEZ2002; HOATH2002; HOOFDAKKER2007; PFIFFNER1997; TUTTY2003), similar effects or trends were found to those reported in the overall analysis. While only tentative inferences can be drawn from these subanalyses, they tend to support the validity of analysing trials with participants not on medication and trials with participants on usual care medication together. The analysis conducted here therefore suggests that CBT interventions for ADHD can have beneficial effects whether delivered in the absence of medication or as an adjunct to continued routine medication for ADHD.

The evidence for the benefits of CBT for children with ADHD is based on studies including children between 3 and 13 years. In all the studies that included children up to 12 or 13 years the mean age was 9 or under and children aged 12 or over were more that one standard deviation above the mean age for the sample (ANTSHEL2003; FEHLINGS1991; GONZALEZ2002; HOOFDAKKER2007; TUTTY2003). One other study of CBT for school-age children with ADHD did not specify the age range, but participants were drawn from a US ‘elementary school’ population (BLOOMQUIST1991). The RCT evidence on the effects of CBT for children therefore does not apply to adolescent populations with ADHD.

7.2.7 Clinical evidence for other interventions with parents/carers for children with ADHD

For the review of other interventions with parents/carers for children with ADHD, important study characteristics and a summary of the evidence are presented in Table 7. The forest plots can be found in Appendix 18.

Parent training is included in the review of the effectiveness of psychological interventions for ADHD (see 7.2.5) as it is effectively a behavioural...
intervention in that the parents are trained to use behavioural training
techniques with their child. However, other types of intervention targeting
the parents or main carer may also aim to address the child’s ADHD
symptoms. Studies were included where they were RCTs that compared a
group receiving an intervention for parents or carers of children with ADHD
(other than parent training) with a control group not receiving the
intervention. Only studies giving outcome data for the child with ADHD
were included (outcomes for parents were not included in the analysis).
Studies were only included if the medication status of the children in the
intervention and control groups was comparable.

7.2.8 Clinical evidence summary for other interventions with parents /carers for children with ADHD

One small trial (32 families) of psychoeducation for parents of children with
ADHD (LONG1993) met the inclusion criteria for this review. In this study,
parents were given a manual outlining various behavioural techniques for
managing oppositional child behaviour. The findings suggest that children
with ADHD may benefit from their parents being given written material on
behavioural management techniques (see Table 7). Outcomes measured
around 2 months after the material was given to parents point to a significant
benefit of the intervention on teacher ratings of conduct problems. While
parent ratings of ADHD symptoms and conduct problems favoured the
intervention, neither reached significance (teacher ratings of ADHD
symptoms were not reported). Given the focus of the intervention on the
management of oppositional behaviour an effect on conduct problems might
be expected. These findings indicate that a larger scale RCT of a similar
psychoeducation intervention might be of value to clarify whether written
materials on behavioural management are an effective intervention for ADHD
symptoms and other behavioural problems associated with ADHD.
While there are other interventions for parents and carers of children with ADHD, including counselling, CBT, and peer support groups, these are more directed at improving the parents’ or carers’ well-being and helping them cope, for example by teaching stress management techniques or providing mutual support. Such interventions would have been included in the review if there were RCTs that reported outcomes for the child with ADHD. However, where studies of support for parents and/or carers only reported outcomes for the parents they were excluded as they were outside the scope of the guideline.

RCTs of approaches currently used to support parents and carers of children with ADHD would be valuable. In order to determine whether those interventions are effective for ADHD study protocols would need to include measures of outcomes for the child, particularly measures of ADHD symptoms and conduct problems.

**7.2.9 NICE guidance on parent-training/education programmes in the management of children with conduct disorders**

NICE, in collaboration with the Social Care Institute for Excellence (SCIE), recently published a technology appraisal on the use of parent-training/education programmes for the management of children with conduct disorders (NICE, 2006). In the context of this technology appraisal the term ‘conduct disorders’ is used to refer to conduct disorder and ODD and the term ‘parent’ applies to the main carer of the child. Conduct disorders are characterised by a repetitive and persistent pattern of antisocial, aggressive or defiant conduct and are often seen in association with ADHD. The high prevalence of comorbid conduct disorders in children with ADHD – estimates suggest that somewhere between 43% and 93% of children with ADHD will have a comorbid conduct disorder (Jensen *et al.*, 1997) – supports the generalisation of this technology appraisal guidance to children with ADHD, and in particular those who have conduct problems in addition to core ADHD symptoms.

For children with ADHD, the relevance of the NICE technology appraisal is further supported by the relatively inclusive population sample and by the inclusion of populations with comorbidities including ADHD. The evidence on which the guidance is based comes from studies that include a wider population than just those with diagnosed conduct disorders. Studies were included where children were defined as having behavioural problems either by scales that measure aspects of child behaviour or by descriptive criteria without any attempt to classify or grade behaviour.

In seven of the included studies some or all children had ADHD – indeed while only 24% of the total sample had diagnosed conduct disorders, over 12% either had a diagnosis of ADHD or were on stimulant medication (some of those with ADHD had comorbid conduct disorders). Furthermore, though...
the actual level of ADHD in the sample population on which the guidance is based is impossible to determine, it is likely to be substantially higher than 12%. Firstly, this estimate does not include studies where some participants with ADHD are included in the sample but there are no details of the number of participants with comorbidities. Secondly, in studies where participants have diagnosed conduct disorders, and in the absence of the exclusion of comorbid populations or details on comorbidity, it might be assumed that the proportion of participants who have comorbid ADHD would be consistent with the estimates of the prevalence of ADHD in children with conduct disorders in the general population. Thirdly, studies that include children with behaviour problems, whether defined by behavioural scales or descriptively, are likely to include children with ADHD unless comorbidities are explicitly excluded. Conversely, it should be noted that a number of the studies included in the analysis for the technology appraisal excluded children receiving treatment – a criterion which would exclude some children with ADHD but which might not necessarily exclude children with ADHD who were not receiving treatment at the time of recruitment for the trial.

The technology appraisal guidance along with a summary of the supporting background information in the guidance document is given below (for more detailed information see www.nice.org.uk/TA102 / NICE, 2006).

**Guidance from the NICE technology appraisal**

The technology appraisal guidance on parent-training/education programmes in the management of children with conduct disorders only applies to the management of children aged 12 years or younger or with a developmental age of 12 years or younger. The guidance states:

1. Group-based parent-training/education programmes are recommended in the management of children with conduct disorders.

2. Individual-based parent-training/education programmes are recommended in the management of children with conduct disorders only in situations where there are particular difficulties in engaging with the parents or a family’s needs are too complex to be met by group-based parent-training/education programmes.

3. It is recommended that all parent-training/education programmes, whether group- or individual-based, should:
   • be structured and have a curriculum informed by principles of social-learning theory
   • include relationship-enhancing strategies
   • offer a sufficient number of sessions, with an optimum of 8–12, to maximise the possible benefits for participants
   • enable parents to identify their own parenting objectives
• incorporate role-play during sessions, as well as homework to be undertaken between sessions, to achieve generalisation of newly rehearsed behaviours to the home situation
• be delivered by appropriately trained and skilled facilitators who are supervised, have access to necessary ongoing professional development, and are able to engage in a productive therapeutic alliance with parents
• adhere to the programme developer’s manual and employ all of the necessary materials to ensure consistent implementation of the programme.

4. Programmes should demonstrate proven effectiveness. This should be based on evidence from randomised controlled trials or other suitable rigorous evaluation methods undertaken independently.

5. Programme providers should also ensure that support is available to enable the participation of parents who might otherwise find it difficult to access these programmes.

**Parent-training/education programmes for conduct disorders**

The main goals of parent-training/education programmes for conduct disorders are to enable parents to improve their relationship with their child and to improve their child’s behaviour. Interventions are structured, with the key components documented so that programmes can be reliably applied by different workers with appropriate training. Many programmes are conducted primarily with the parents and involve no direct intervention with the child, although in some individual programmes both parent and child will be observed in order to see how the parents are relating to their child with a view to individualising the intervention.

Most programmes combine elements of the two main approaches: behavioural programmes, which focus on teaching the parenting skills needed to address the causes of problem behaviour; and relationship programmes, which aim to help parents understand both their own and their child’s emotions and behaviour and to improve their communication with the child. Programmes tend to be focused and short term (around 1 and a half to 2 hours every week for 8 to 12 weeks), and can be conducted in small groups of 6 to 12 or individually. Settings, which may include the hospital, clinic, community or home, should be congenial and accessible to parents, and have crèche facilities.

Programmes can be run by psychologists, therapists/counsellors, social workers or community workers, but in some cases voluntary agencies or parents who have been through programmes themselves can be involved. Self-administered programmes in the home use printed or audiovisual training materials. Some programmes combine parent training with other
Interventions such as child training or have additional elements to address factors interfering with effective parenting, such as marital problems, depression and lack of adult social skills.

**Population characteristics**

The scope for the technology appraisal defined the population as children diagnosed with conduct disorders (including ODD), aged up to 12 years or with a developmental age of 12 years or younger. Forty-one RCTs were included in the analysis, giving a total sample population of 2436 children. However, only 14 studies used the DSM-III, DSM-IIIR or DSM-IV diagnoses of conduct disorder and/or ODD for the inclusion of their population. In the majority of studies children were included if they were above a set cut-off point on scales measuring child behaviour problems or were described as having behaviour problems, and it is therefore likely that many of the children in the included studies would not meet diagnostic criteria for conduct disorders. Studies were not excluded if children had comorbidities, providing that more than 50% of children had a behavioural disorder.

The majority of studies involved only pre-adolescent children (12 years or under) and boys made up around two-thirds of the total population included in the analysis (based on those included studies that provided information). In terms of the family characteristics, parents involved in the studies were from a wide range of socioeconomic backgrounds; there were similar proportions of one- and two-parent families but a large proportion of the parents were white. Recruitment to studies was commonly by media advertisements or fliers in community centres, medical practices, kindergartens, schools or similar, where parents would respond by referring their children.

**Intervention characteristics and settings**

Only interventions that focused solely on the parents were included in the review for the technology appraisal. Included parent-training/education programmes had to have content that was documented and repeatable, and be run over a defined time period, but there were no restrictions regarding the theoretical basis of a programme, the length, setting or mode of delivery. Where programmes also involved children and/or teachers they were excluded because it was judged likely that their effectiveness might differ from that of programmes targeting parents only. Interventions where children attended sessions to give parents an opportunity to rehearse skills under therapist guidance, and non-structured parent-focused interventions such as a support groups or informal home visits, were also excluded.

The interventions included group-based therapist-led training, self- (parent-) administered programmes and individual one-to-one sessions. The person delivering the interventions varied between studies and included people educated to graduate, masters or PhD level as well as nurses and school
counsellors. Mothers were the primary focus of the trials, with only a small proportion of fathers also participating. The majority of included studies were conducted in the US but studies conducted in Australia, the UK, Canada and Ireland were also included.

**Evidence and interpretation**

Meta-analyses were undertaken for child behaviour outcome measures reported consistently across a high proportion of the included RCTs – the Child Behaviour Checklist (CBCL), the Eyberg Child Behaviour Inventory (ECBI), and the Dyadic Parent–Child Interaction Coding System (DPICS) child deviance total score. There was a consistent trend across studies for an improvement in all measures for parent-training/education compared with no-treatment controls. Meta analysis of the CBCL and ECBI outcome measures established that parent-training programmes were more effective than a waitlist control. For the DPICS there was a trend in favour of parent-training/education programmes. Longer-term follow-up data suggested that parent-training/education programmes had sustained effects up to 3 years later. The meta-analysis did not find a difference in the effects of group compared with individual interventions.

The results were regarded as clinically meaningful and it is suggested that the effect of the intervention on child behaviour might have been underestimated because the meta-analysis was conducted on the CBCL total score rather than the externalising score. Though the majority of trials were conducted outside the UK, the findings of the meta-analysis were considered to be generalisable to UK practice.

Parent participants who did not complete the studies were more likely to be significantly younger, come from a lower socioeconomic group, have less social support, have higher levels of life stress, be significantly less educated, be a mother with higher ratings on the Depression Anxiety Stress Scales (DASS), or have higher levels of parental dysfunction.

Qualitative work conducted by the SCIE and NICE project teams identified characteristics that appear to be essential components of effective programmes. Based on this work the appraisal committee proposed that parent training programmes should:

- be structured and have a curriculum informed by principles of social-learning theory. The content should incorporate learning opportunities that reflect social-learning approaches, such as skills rehearsal and role play, watching recorded vignettes as triggers for discussion of alternative parenting strategies, and preparation and review of homework
- include relationship-enhancing strategies such as play and praise, and effective discipline strategies
• offer sufficient sessions, with an optimum of 8–12, to maximise the possibility of participants deriving benefit
• not be didactic, but should enable parents to identify their own parenting objectives
• incorporate role-play during sessions, as well as homework to be undertaken between sessions, to achieve generalisation of newly rehearsed behaviours to the home situation
• be delivered by appropriately trained and skilled facilitators (accredited as meeting relevant standards such as the National Occupational Standards for Work with Parents) who are supervised, have access to necessary ongoing professional development and are to engage in a productive therapeutic alliance with parents
• adhere to the programme developer’s manual and employ all of the necessary materials to ensure consistent implementation of the programme.

The technology appraisal concluded that parent-training/education programmes that contained these essential elements were clinically effective. Group-based programmes containing these elements were recommended for the management of children with conduct disorders as they offered best value for money. Individual programmes containing the same elements were recommended only where there are particular difficulties in engaging with the parents and/or the complexities of the family’s needs cannot be met by group programmes. Examples of programmes that demonstrated the essential characteristics listed above included the Webster-Stratton Incredible Years Programme and the Triple P – Positive Parenting Programme.

As parents who might have the greatest needs could find it difficult to access these programmes it was considered important that programme providers should enable participation by providing accessible venues, helping with transport, and providing support for any caring responsibilities that might hinder participation.

7.2.10 Characteristics of effective psychological interventions for ADHD

In the review of psychological interventions for ADHD, six studies were identified that demonstrated that psychological interventions improved outcomes for children with ADHD (BOR2002; FEHLINGS 1991; LONG1993; PFIFNER1997; SONUGA-BARKE2001; TUTTY2003). Further information about each study can be found in Appendix 17. The studies suggest that slightly different approaches are necessary for pre-school children and for older children. None of the studies showing effectiveness involves significant numbers of adolescents but some inferences about suitable interventions can be obtained from those designed for younger age groups.

Psychological interventions for pre-school children
Parent training was found to be an effective intervention in two studies (BOR2002; SONUGA-BARKE2001), both of which involved parents with 3-year-old children. These studies add weight to the inference that the NICE technology appraisal guidance for children with conduct disorders is relevant to children with ADHD. The parent training intervention in one of the studies (BOR2002) was a generic programme (Triple P) that includes the essential components identified by the NICE TA (see above). In this study an enhanced version of the parent training intervention that included adjunctive interventions on partner support and coping skills was also investigated, but data from the group receiving the standard intervention were used in the analysis as the standard intervention had a larger effect on child outcomes.

The studies of Bor and colleagues (BOR2002) and Sonuga-Barke and colleagues (SONUGA-BARKE2001) suggest that parent training is effective when structured interventions are delivered on an individual participant basis. Equally, the findings of the NICE technology appraisal for parent training in conduct disordered populations for this age group show that both group and individual programmes are effective for children with conduct disorders and problem behaviours. Given the overlap between the population included in the technology appraisal and the ADHD population it is reasonable to extrapolate from the technology appraisal guidance that group parent training programmes would also be effective for children with ADHD.

The interventions in both studies (BOR2002; SONUGA-BARKE2001) employed structured interventions based on social learning and behavioural learning principles. Both approaches involved giving information on ADHD and involved active learning strategies such as role play, modelling and active feedback, individualised homework assignments, diaries and observation.

The study conducted by Bor and colleagues (BOR2002) suggests that involving fathers and partners may be an important element, at least for some families. Sessions were primarily clinic-based, although some home-based sessions were incorporated to allow for observation and feedback. The study conducted by Sonuga-Barke and colleagues (SONUGA-BARKE2001) predominately involved mothers, but children were also involved in the sessions, which were delivered in the home.

**Psychological interventions for older children – parent effectiveness training**

On the basis of the NICE technology appraisal (NICE, 2006) it appears that parent training is likely to be an effective intervention for older children and young adolescents (up to 12-13 years) with ADHD. No studies were found that used group parent training alone as an intervention for this age group. A small RCT study by Long and colleagues (1993) demonstrated the value of providing parents of children aged 6 to 11 with a manual on behavioural techniques as an adjunct to stimulant medication and there were positive
improvements in child behaviour in the children whose parents received the manual.

Psychological interventions for school-age children – CBT and social skills training

Four studies were found that demonstrated positive effects of psychological interventions on core ADHD symptoms together with ratings of conduct, social skills or self-efficacy (FEHLINGS 1991; LONG1993; PFIFNER1997; TUTTY2003). The interventions studied were either mixed CBT/social skills interventions delivered to groups (PFIFNER1997; TUTTY2003) or predominately CBT interventions (FEHLINGS1991; LONG1993).

In PFIFNER1997, social skills training was the main intervention but also had an element of parent training to support the skills acquisition of the child participants. Similarly, in Tutty and colleagues’ (TUTTY2003) study, children were engaged in a course of social skills training but parents, in separate group sessions, learned about parenting skills and behavioural management principles. It is difficult to ascertain if all, or just some, of these elements are effective but whether the target is social skills or behaviour generally, psychological intervention seems to have a positive effect on core ADHD symptoms.

FEHLINGS1991 involved teaching children CBT techniques to improve behaviour in home settings. Time was taken to teach problem solving techniques, which included identifying the problem, goal setting, generating problem-solving strategies, choosing a solution and evaluating the outcome. Active learning methods were used including modelling and role play. Homework assignments were set and related to individual problem situations at home. Learning gains were reinforced with reward strategies such as tokens and so on. As in TUTTY2003 and PFIFNER1997, separate parent sessions were also held. Parents received education about ADHD and training in CBT techniques that they were then encouraged to use to reinforce target behaviours in individual homework tasks given to each child participant.

The mixed social skills/CBT interventions (PFIFNER1997; TUTTY2003) were delivered in group sessions whereas the CBT intervention (FEHLINGS1991) was delivered in individual sessions. Conceptually, there is no reason why either group or individual approaches should not be considered but cost issues may be the determining factor.

It is noteworthy that in all three studies, separate child and parent groups were involved which may have contributed to outcome effectiveness. Perhaps supportive of this, are findings from three studies which met our methodological criteria and were included in our analyses, but for which statistically positive results were not found. In the HOOFDAKKER2007 and
HOATH2002 studies involving behavioural parent training, no child groups were incorporated. In the study of Social Skills Training (ANTSHEL2003), a parent training element was included but comprised only three sessions which comprised giving information about the programme and how to monitor homework assignments given to their child.

LONG1993 studied the effects of a CBT intervention that simply involved providing parents with a 4200-word manual on CBT strategies to use at home while children were receiving medication for ADHD. Significant improvements in child behaviour were achieved as a result of the addition of the manual. The manual comprised behavioural strategies including attending, rewarding, time out and behavioural charts, and so on. This intervention probably represents the simplest type of CBT but is a useful indicator of what is needed, especially since basic CBT principles are widely available as manuals, books and in visual media.

Psychological interventions for adolescents

None of the included studies yielded evidence on what might constitute an effective intervention for young people of 13 years and older; however it is likely that CBT/social skills therapy as described for older children above would be applicable to adolescents with ADHD.

Adapting parent training/education programmes for children with ADHD

The available evidence indicates that the essential elements for working with children who have ADHD are likely to be included in established parent training programmes that are effective where children have disordered conduct. It is important to add a component to provide information about ADHD and the behavioural and emotional sequelae that arise from the condition. There is no indication that existing programmes such as Triple P have to be significantly extended to achieve this, nor do they need to incorporate add-on elements such as partner support, communication between partners and other family functioning issues. This means that existing parent effectiveness training programmes need only a modest adaptation for working with parents who have children with ADHD.

7.2.11 Initiation and optimum duration of psychological interventions for children with ADHD

Initiation of therapy

There is no reliable evidence on the relationship between waiting time and outcome. It is likely, however, that for most parents this will be a key issue. It takes several weeks from referral to the child receiving a diagnosis of ADHD and parents will be naturally keen to have their child’s difficulties addressed in the shortest possible time. Drug treatment has the perceived advantage of providing symptomatic relief rapidly and optimum dosage can be achieved within 6 weeks. Psychological therapy, whether parent training, CBT or social
skills training, takes a minimum of 8-10 weeks if delivered on consecutive
weeks. Clearly this may be a disincentive for some parents to agree to
psychological therapy. The disincentive is even greater if there is a significant
waiting time before psychological treatment is commenced and may result in
an adverse effect on recruitment, adherence and skills acquisition.

**Optimum duration**

There is a surprising consistency across all successful psychological
intervention studies on the duration of treatment and this allows helpful
inferences to be drawn. For pre-school children, programmes in the BOR2002
and SONUGA-BARKE2001 parent training intervention studies were
delivered by specifically trained facilitators or therapists and involved
between eight and ten sessions lasting 1 to 1 and a half hours. For school-age
children, CBT/social skills training interventions consisted of between eight
and 12 sessions lasting 50 to 90 minutes for children and 8 sessions lasting 50
to 120 minutes for parents, and were delivered by specifically trained
facilitators. Where there is a large age range (for example, TUTTY2003) there
may be value in breaking participants into more homogenous age groups.

**7.2.12 Promoting adherence to psychological interventions for children
with ADHD**

The studies demonstrating the effectiveness of psychological interventions for
pre-school and older children up to early adolescence suggest that issues of
adherence may be important elements in intervention effectiveness. This is
true of most interventions but with group treatments it is more so. If
programmes are not appealing or seen as relevant, it can take several weeks
for sufficient numbers to be recruited to enable the programme to get
underway. During this time, the young person with ADHD may be deprived
of much needed help. Equally, if there are significant drop-outs during the
course of a programme, there may be adverse effects on the functioning of the
remaining group through, for example, loss of group cohesion, support and
friendships.

Participants are likely to have to be strongly convinced of the need for
involvement particularly in view of the time commitment and inconvenience
involved. Typically parents, and also children, may have to commit
themselves for between 1 and 1 and a half hours each week over a 2- to 3-
month period. Child care arrangements may be problematic for many parents
who have other children. Involving fathers/partners, although desirable, may
again pose problems for many families. Travel to treatment centres may also
be difficult for some families especially in rural areas. Some studies report
holding out-of-hours sessions and/or running them in local health or
community centres. The SONUGA-BARKE2001 parent training intervention
with the parents of pre-school children held individual sessions at home.
Theoretically, it would be possible to run interventions over the long summer school holiday period but there might be interruptions due to families and or staff taking vacations and this may leave insufficient time for learning tasks to be put into practice in the home setting within the duration of the intervention programme.

Successful programmes tend to use active learning methods such as role play, modelling, observation and feedback. They also involve individualised elements often with homework assignments and diary keeping. These methods contribute to effective learning but they may have the added advantage of improving adherence through maintaining interest and offering relevance.

A further characteristic of both studies of parent training interventions that demonstrated beneficial effects (BOR2002; SONUGA-BARKE2001) is that efforts were made to hold sessions at times and/or locations convenient for participants. The BOR2002 intervention was delivered at centres in local neighbourhoods and the SONUGA-BARKE2001 intervention was delivered in participants’ own homes. One study of a parent training intervention with the parents of pre-school children was not included in the analysis because of an unusually high subject attrition and other methodological issues (BARKLEY2000). The study illustrates the need for a careful approach to the design of interventions which maximise compliance.

7.2.13 Health economic evidence

Systematic literature review

No evidence on the cost effectiveness of psychological interventions versus a control condition (no intervention, waitlist control, standard care or a control intervention) for children with ADHD was identified by the systematic search of the economic literature. Details on the methods used for the systematic search of the economic literature are described in Chapter 3.

Economic analysis in the NICE guidance on parent training/education programmes for children with conduct disorders

The NICE technology appraisal on parent-training/education programmes in the management of children with conduct disorders (NICE, 2006) incorporated economic evidence from two de novo economic models assessing the cost effectiveness of parent training/education programmes relative to no active intervention for this population. The initial economic analysis (Dretzke et al., 2005) assessed the cost effectiveness of three parent training/education programmes differing in the mode of delivery and the setting: a group community-based programme, a group clinic-based programme, and an individually delivered, home-based programme. Costs included intervention costs only; no potential cost savings to the NHS following reduction of antisocial behaviour in treated children were
considered. Total costs of these three types of interventions were estimated based on a ‘bottom-up’ approach, using expert opinion alongside information from the literature in order to determine the healthcare resources required for providing such programmes. Meta-analysis of clinical data had demonstrated that there was no difference in clinical effectiveness between group-based and individually delivered programmes. Results were reported as cost per responder and cost per Quality Adjusted Life Year (QALY) gained, at various levels of response to treatment and various levels of improvement in children’s Health Related Quality of Life (HRQoL), respectively.

The analysis found that, at a 5% success (response) rate and an 80% uptake of such programmes, the cost per responder was £14,384, £10,060, and £61,429 for the community-based, the clinic-based, and the home-based programme, respectively. At a 50% success rate and with the same 80% uptake, the respective figures were £1,438, £1,006 and £6,143. In addition, the study reported that, at a 5% improvement in children’s HRQoL, the cost per QALY gained was £17,980, £12,575, and £76,785 for the community-based, the clinic-based, and the home-based programme, respectively, while at a 20% improvement in HRQoL the above ratios fell at £4,495, £3,144 and £19,196 respectively.

The initial economic analysis was based on hypothetical rates of response and percentages of improvement in HRQoL following provision of parent training/education programmes, as well as on a number of assumptions. Therefore, the results should be interpreted with caution, as acknowledged by its authors. Nevertheless, the analysis demonstrated that group-based parent training/education programmes for children with conduct disorders were, as expected, substantially more cost effective than individually delivered ones, because the two modes of delivery did not differ in terms of clinical effectiveness and the intervention costs of group-based programmes were spread to a large number of treated families. Moreover, the study findings suggest that individually delivered programmes meet the NICE criteria on cost effectiveness, that is, have a cost per QALY below £20,000 (The Guidelines Manual [NICE, 2006]), only when they result in significant improvement in children’s HRQoL (roughly 20%). In contrast, group-based programmes are cost effective even if they achieve small increases in children’s HRQoL (such as 5%). It must be noted, though, that the above estimated figures are conservative as they have not included any potential cost savings resulting from reduction in antisocial behaviour in treated children and associated costs of its management.

The additional economic analysis undertaken to support NICE guidance evaluated the cost effectiveness of the three parent training/education programmes described above, plus an individually delivered clinic-based programme, over a time horizon of 1 year. Costs included intervention costs as the initial analysis, but they also incorporated cost savings to the NHS,
education and social services following provision of parent training/education programmes to children with conduct disorders. The analysis modelled three different health states, that is, normal behaviour, conduct problems and conduct disorders. It was found that the mean net cost of a parent training/education programme in improving a child’s behaviour from conduct disorders to a better state (either conduct problems or normal behaviour) was £90, £1,380, and £2,400 for a group community-based programme, an individually delivered clinic-based programme, and an individually delivered home-based programme, respectively; the group clinic-based programme proved to be overall cost saving. These results further support the argument that group-delivered parent training/education programmes for children with conduct disorders are most likely to be cost effective, especially when long-term benefits and cost savings to healthcare, education and social services are considered.

Economic modelling

Objective

The objective of the analysis was to assess the cost effectiveness of parent training for children diagnosed with ADHD, since no economic evidence on this area was identified in the systematic search of the economic literature.

Interventions examined

The economic analysis compared parent training with no treatment. Parent training consisted of 10 hourly sessions provided by clinical psychologists to parents of children with ADHD over a 10-week period.

Methods

Model structure

An economic model in the form of a simple decision tree was developed to estimate costs and benefits associated with parent training for children with ADHD. According to the model structure, hypothetical cohorts of children with ADHD received therapy in the form of parent training or no treatment. The time horizon of the analysis was 1 year. Parents of children responding to parent training over 10 weeks attended three further booster sessions until the end of the year. Children responding to parent training or showing clinically significant improvement with no treatment were assumed to retain improved symptoms (that is, to remain responsive) for the remaining time of the analysis.

A schematic diagram of the Markov model is provided in Figure 3.

Figure 3. Schematic diagram of the structure of the economic model
Costs and health benefit measures included in the analysis

The analysis adopted the perspective of the NHS. Health service costs consisted of intervention costs of parent training. Costs of personal social services and education services were not included in the analysis owing to lack of relevant data. Other societal costs, such as social benefit payments and productivity losses of carers of children with ADHD, were not considered as they were beyond the scope of this analysis.

The measure of benefits was the number of QALYs gained. QALYs are considered to be the most appropriate generic measure of health benefit that incorporates both gains from reduced mortality, and improvements in HRQoL.

Total costs and health benefits over 1 year associated with each arm of the model were estimated and combined in an incremental cost-effectiveness ratio (ICER) expressing the additional cost required in order to achieve an additional unit of health benefit provided by parent training versus no treatment to children with ADHD.

Effectiveness data

Clinical-effectiveness data used in the economic model were derived from the meta-analysis of studies included in the guideline systematic literature review of clinical evidence. There was a considerable variation in the methods used to measure clinical effectiveness. Generally, the clinical studies can be divided into two main categories: those who reported outcomes as changes in scores on scales developed to measure ADHD symptoms, and those who reported outcomes as rates of clinically significant response to treatment, with response defined as a % improvement or a final score beyond/below a cut-off point on one of the scales measuring ADHD symptoms. Although outcomes expressed as changes in scores are useful in evaluating clinical effectiveness, they cannot
be easily translated into a measure of change in HRQoL (that is, a utility score), which is required in order to estimate QALYs gained by treatment. This is because the change in HRQoL depends not only on the overall change in a score (effect size), but also on the point on a scale where this change occurs. Moreover, no evidence exists to link changes in scores on scales measuring ADHD symptoms with utility scores. On the other hand, it is possible to convert response or no response to treatment into a utility score expressing HRQoL for responders and non-responders respectively. In fact, there is published literature linking response or no response to treatment for children with ADHD with respective utility scores. Therefore, for all economic analyses undertaken for this guideline, it was decided to utilise data only from clinical studies reporting outcomes as response rates, with response defined in a way that the GDG found both clinically meaningful and significant.

The guideline systematic review identified four studies evaluating parent-based psychological therapies versus no active treatment for children with ADHD that reported outcomes as response rates (BOR2002; HOATH2002; PFIFFNER1997; SONUGA-BARKE2001). Three of the studies examined enhanced and/or standard parent training (BOR2002; HOATH2002; SONUGA-BARKE2001), while PFIFFNER1997 evaluated a social skills training programme with parent-mediated generalisation. Therapies were provided individually or in groups. In two studies (HOATH2002; PFIFFNER1997) some children had been receiving medication during the intervention period. Response was determined in all studies by use of the Reliable Change Index, which was considered appropriate by the GDG. For the base-case analysis, it was decided to synthesise data from BOR2002, HOATH2002, SONUGA-BARKE2001; inclusion of data from PFIFFNER1997 in the meta-analysis of clinical studies was considered in a sensitivity analysis. Analysis of efficacy data was based on intention-to-treat. Details of the studies in terms of interventions examined, mode of delivery, medication status of children, and definition of response are presented in Table 8. Full details of the studies are provided in Appendix 17.

Utility data and estimation of QALYs
In order to express clinical outcomes in the form of QALYs, utility scores for health states of children with ADHD were required. Utility scores represent
the HRQoL associated with specific health states; they are estimated using preference-based measures capturing people’s preferences and perceptions on HRQoL characterising the health states under consideration. The systematic review of the literature identified four studies providing utility scores for health states of children with ADHD (Coghill et al., 2004; Gilmore & Milne, 2001; Matza et al., 2005; Secnik et al., 2005b).

Gilmore and Milne (2001) estimated utility scores for children with ADHD before and after treatment, using the Index of Health Related Quality of Life (IHRQL). This index measures three dimensions of HRQoL: pain, social or physical disability, and emotional distress. The authors estimated that, before treatment, children with ADHD experienced no pain, slight social disability, and moderate emotional distress; after treatment, responders experienced no pain, no physical or social disability, and slight emotional distress. These health states of the IHRQL translated into utility scores of 0.884 (before treatment) and 0.970 (after treatment - responders).

The study by Coghill and colleagues (2004) was available as a poster presentation; it reported utility scores for children with ADHD that either responded or did not respond to treatment, generated from Euro-Qol 5-Dimension (EQ-5D) scores. The study asked parents of 151 children with ADHD in the UK to fill in EQ-5D questionnaires, and then linked the responses with symptom severity or symptom improvement following treatment, as determined by physicians. EQ-5D is a generic measure of HRQoL, covering five dimensions of health: mobility, self-care, usual activities, pain/discomfort, and anxiety/depression. Health states defined by the five-dimensional descriptive system can be converted into utility scores by using existing value sets for EQ-5D health states, elicited from general population samples. Such value sets for the general UK population have been developed using the Visual Analogue Scale (Gudex et al., 1996) and the Time Trade-Off (TTO) method (Dolan, 1997). The utility values generated for children with ADHD as reported by Coghill and colleagues (2004) were 0.837 for responders (symptom improvement) and 0.773 for non-responders (no symptom improvement). However, the methodology used to obtain these values was not described in detail; therefore, it is not known whether the authors utilised any of the existing value sets produced from the general UK population, or followed a different methodology in order to convert EQ-5D scores into utility scores.

Matza and colleagues (2005) evaluated parent preferences for health states of children with ADHD in the US. Using the Standard Gamble (SG) technique, the authors asked 43 parents to value their child’s current health and 11 hypothetical health states, presented to parents as vignettes describing untreated ADHD, as well as ADHD treated with a stimulant or non-stimulant, covering aspects such as response to treatment and presence of intolerable side effects. The health states were defined according to parent...
and clinical opinion, supported by a literature review. The resulting utility scores, adjusted on a scale from 0 (death) to 1 (perfect health), ranged from 0.90 (severe untreated ADHD) to 0.98 (treatment with non-stimulant, response to treatment, tolerable side effects).

Secnik and colleagues (2005b), using a similar methodology to Matza and colleagues (2005), produced utility scores by interviewing 83 parents of children with ADHD in England. Parents were asked to value their child’s current health plus 14 hypothetical health states, also using the SG technique. The 14 health states were comparable with those described in Matza and colleagues (2005), but distinguished between stimulants of instant and extended release (IR and ER respectively). The utility scores resulting from this exercise, adjusted on a scale from 0 (death) to 1 (perfect health), ranged from 0.88 (treatment with IR or ER stimulant, no response, presence of side effects) to 0.95 (no medication, symptom improvement).

NICE recommends a standardised and validated generic instrument for the measurement of HRQoL in cost-utility analyses, with utility scores generated according to public preferences using a choice-based method, that is, TTO or SG technique. EQ-5D is suggested as the most appropriate choice in the UK; at the same time, it is acknowledged that under certain circumstances EQ-5D may not be suitable to use at estimation of QALYs (NICE, 2004). Following NICE guidance, the utility scores reported in Coghill and colleagues (2004), which were generated from EQ-5D, were used in the base-case analysis of all economic evaluations of interventions for children with ADHD in this guideline, also taking into account that they were used in the recent NICE guidance on the use of pharmacological treatments for the management of children and adolescents with ADHD (NICE, 2006). The GDG expressed concern that the EQ-5D, as a generic measure, was not sensitive enough to capture all aspects of HRQoL in children with ADHD. As an alternative option, the utility values reported by Secnik and colleagues (2005b), which were produced by SG technique using vignettes describing health states of children with ADHD in the UK, were tested in a sensitivity analysis; for the current analysis of parent training versus no treatment, utility scores for health states characterised by no medication/untreated ADHD described in Secnik and colleagues (2005b) were assumed to describe the HRQoL of all children in the model, despite the fact that in the clinical studies a number of children were reported to receive some medication during the intervention period. This was necessary as no details on the type of medication and the rate of side effects were reported for those children; however, this is unlikely to have affected the results of the analysis, as the overall use of medication was similar between the two arms of the model.

It was assumed that HRQoL in children initially responding to treatment improved linearly over 10 weeks starting from the utility score of non-responders and reaching the utility score for responders (10 weeks was the average duration of interventions in the clinical trials considered in the
economic analysis), and remained at this value for the remaining time of the
analysis.

Resource utilisation and cost data
Owing to lack of patient-level cost data, deterministic costing of all treatment
options assessed was undertaken. Relevant healthcare resource use was
estimated and subsequently combined with unit prices to provide total costs
associated with parent training or no treatment. Costs of children receiving
medication, as described in some clinical studies that provided the
effectiveness data, were not estimated, but these were likely to be similar in
the two arms of the model. Resource use estimates associated with parent
training were based on GDG expert opinion, reflecting UK clinical practice,
and were consistent with the average resource use described in the clinical
studies that provided effectiveness data. In addition, booster sessions for
responders were modelled according to optimal practice required to retain a
positive outcome (GDG expert opinion).

Parent training consisted of 10 weekly individual meetings between clinical
psychologists and parents of children with ADHD, of 1-hour duration each.
Following completion of the intervention, parents of children responding to
parent training attended three further booster sessions with psychologists,
lasting 30 minutes each, in order to maintain children’s response for the
remaining time of the analysis.

The unit cost of clinical psychologists was taken from the Unit Costs for
Health and Social Care 2006 (Curtis & Netten, 2006). Discounting was not
applied, as costs and benefits were measured over a period of 1 year.

All input parameters, including effectiveness data, utility scores and cost data
utilised in the base-case economic analysis of parent training versus no
treatment are presented in Table 9.

</tbody>
</table>
Sensitivity analysis was undertaken to investigate the robustness of the results under the uncertainty characterising input parameters of the model. The following scenarios were tested in a one-way sensitivity analysis:

1. Changes in response rates to treatment
   - Use of the upper and lower confidence intervals (CIs) of the relative risk (RR) of parent training to no treatment (mean RR = 2.48; 95% CIs = 1.46 to 4.23)
   - Inclusion of data from PFIFFNER1997 in the meta-analysis of clinical studies

2. Utility scores obtained from Secnik and colleagues (2005b) for the health state of no medication /untreated ADHD. The scores for responders and no responders were 0.95 and 0.90 respectively.

3. Changes in resource use estimates for parent training
   - Clinical psychologist replaced by health visitor (cost per clinic hour: £61 [Curtis & Netten, 2006] qualification costs excluded).
   - Group-based parent training for pre-school children, provided by clinical psychologists, consisting of 10 hourly sessions delivered to groups of 10 parents, including 1 extra hour for training and preparation (the later at a unit cost of £29, Curtis & Netten, 2006), reflecting effective, optimal routine practice for pre-school-age children (GDG expert opinion). The cost of this scenario was £69 per child (excluding booster sessions, which were assumed to be provided individually, as in the base-case analysis).
   - Group-based CBT for school-age children, provided by clinical psychologists, consisting of 10 hourly sessions with parents and 10 hourly sessions with children (10 parents and 10 children in each group, respectively), plus 2 extra hours for training and preparation; the cost of this intervention was £138 per child (excluding booster sessions, which were assumed to be provided individually, as in the base-case analysis).
   - Group-based CBT for school-age children as above, including two extra individual sessions with children’s teachers at school, lasting 30 minutes each; the cost of this intervention was £206 per child (excluding booster sessions, which were assumed to be provided individually, as in the base-case analysis).

In addition to the above scenarios, a threshold analysis was carried out to identify the number of hourly individual sessions of parent training that would reverse the conclusions of the economic analysis.

Results
Base-case analysis

Parent training incurred an incremental cost of £39,007 per QALY compared with no treatment. This value is beyond the cost-effectiveness threshold of £20,000 per QALY set by NICE (The Guidelines Manual [NICE, 2006]). This means that, according to the base-case results, individual parent training is not cost effective for children with ADHD. Full results of the base-case analysis are presented in Table 10.

Sensitivity analysis

The ICER of parent training versus no treatment remained above the NICE set cost-effectiveness threshold under most scenarios tested in the sensitivity analysis. The scenario that strongly affected conclusions in favour of parent training was the provision of parent training in groups rather than individually. Under this scenario, the ICER of parent training versus no treatment for pre-school-age children became £6,608 per QALY, while the ICER of CBT for school-age children was £14,144 and £10,384 per QALY with and without extra sessions with children’s teachers respectively. These values stand on the basis of equivalent efficacy between group-based and individually delivered programmes; although not established, clinical equivalence of group and individually delivered parent-based programmes for children with ADHD is not unlikely: although no direct evidence (that is, head-to-head comparisons) exists to support such an argument, HOATH2002, which described group-based parent training, reported in fact a larger effect size than that reported in BOR2002 and SONUGA-BARKE2001, both examining individually delivered interventions.

The above ICERS of group-based programmes also presuppose that treatment groups work to full capacity, that is, groups of 10 parents (and groups of 10 children in the case of behavioural family therapies) need to attend each programme session. If parents or children drop out of therapy without being replaced by other parents or children, respectively, in the group, then the cost-effectiveness of group-based parent training programmes will be reduced. A threshold analysis determined that group parent training for pre-school-age children needed to work at a minimum capacity of 30% in order to remain cost effective (that is, with an ICER below £20,000 per QALY). CBT programmes with or without extra sessions with children’s teachers were required to work at a 60% and 50% capacity respectively in order to remain below the cost-effectiveness threshold of £20,000 per QALY.

Full results of the one-way sensitivity analysis are shown in Table 11.

</tbody>
</table>

Threshold analysis showed that individual parent training was cost effective (with an ICER reaching £17,302/QALY), when it consisted of 4 hourly sessions only (instead of 10, as modelled in the base-case analysis). It is unlikely though that parent training can be as effective as demonstrated in the meta-analysis of clinical studies with 4 hours of contact only.

Limitations of the economic analysis

The results of the economic analysis were based on a simple decision-analytic model developed to estimate costs and health benefits associated with provision of parent training in children with ADHD over the period of 1 year. Clinical evidence was derived from three trials that reported outcomes in the form of response to treatment. The total number of participants in these trials was small (N=132). Additional evidence coming from studies reporting outcomes in the form of changes on scales measuring ADHD symptoms that were included in the guideline systematic review and meta-analysis suggested a moderate beneficial effect of parent training in children with ADHD.

Costs consisted of intervention costs only; potential cost savings to the healthcare, social and education services resulting from improvement in ADHD symptoms of children were not considered owing to lack of relevant data. It is therefore likely that the cost effectiveness of parent training programmes for children with ADHD is greater than that suggested by the results of the analysis.

Estimates on healthcare resource use were based on GDG expert opinion, reflecting, as closely as possible, resource use described in the clinical studies used in the economic analysis; however, these studies described only vaguely some aspects of resource use, and obviously they did not provide any relevant data for resource use beyond the duration of the trials (that is, beyond 10 weeks of treatment). It is unknown whether three booster sessions with parents are sufficient to retain a positive outcome in children with ADHD over 1 year (as assumed in the economic model), as no relevant follow-up data are available. Likewise, the long-term effectiveness of parent
training programmes in children with ADHD is unknown. Therefore, it is not possible to estimate the cost-effectiveness of parent training programmes beyond 1 year.

Utility scores used in the base-case analysis were based on EQ-5D questionnaires filled in by parents of children with ADHD in England. EQ-5D is a generic measure of HRQoL and, as such, it has been recommended by NICE for use in economic evaluation. However, the full methods used to convert EQ-5D scores into utility scores were not reported in the study that provided the utility data for this economic analysis. In addition, the GDG expressed concerns about the appropriateness of using a generic measure to capture aspects of quality of life in children with ADHD. For this reason, utility scores developed using vignettes describing health states specific to ADHD were used in the sensitivity analysis. Utility scores used both in the base-case and sensitivity analysis were generated using parents of children with ADHD as proxy reporters of their children’s perceptions of their own HRQoL. There are concerns about using parents’ ratings as proxies to children’s experience; still, for some groups of children who are unable to reliably report their own perceptions and preferences, parent proxies may be appropriate (Wallander et al., 2001; De Civita et al., 2005). In the area of ADHD, no data on HRQoL preferences directly reported by children rather than by their parents are currently available.

The findings of the analysis regarding group-based programmes rely on the hypothesis of equivalent efficacy between group-based and individually delivered programmes; such equivalence has not been established, but existing clinical evidence suggests that the mode of delivery does not affect the clinical effectiveness of parent training programmes. In fact, one of the studies included in the meta-analysis of clinical data (HOATH2002) has evaluated a group-based parent training programme.

**Overall conclusions from the economic analysis**

The results of the economic analysis indicate that group-based parent training programmes (or CBT for children of school age) are likely to be cost-effective for children with ADHD, if the mode of delivery of such programmes does not affect their clinical effectiveness. Further research is needed to explore the long-term benefits and cost savings associated with parent training programmes for children with ADHD, as well as to investigate in depth the perceptions of children and their carers on aspects of HRQoL associated with ADHD. Moreover, future research needs to confirm the equivalence of efficacy between group-based and individually delivered parent training programmes, so that the cost effectiveness of group-based parent training can be effectively established.
7.2.14 From evidence to recommendations: Psychological interventions for children and young people with ADHD

Overall, the evidence indicates that psychological interventions for children with ADHD have moderate beneficial effects on parent ratings of ADHD symptoms and conduct problems, both for children not on medication and as an adjunct to continued routine medication for ADHD. However, the evidence suggests that slightly different approaches are necessary for pre-school and older children.

For the pre-school group there is good evidence that individual parent training is helpful for core ADHD symptoms and conduct problems. Effective interventions were structured, based on social learning and behavioural learning principles, involved giving information on ADHD, and involved active learning strategies such as role play, modelling and active feedback, individualised homework assignments, diaries and observation.

Further evidence on the use of parent training programmes as an intervention for ADHD comes from the findings of the NICE technology appraisal of parent training as an intervention for children up to 12 with conduct disorders (NICE, 2006). The GDG concluded that the technology appraisal was broadly generalisable to children with ADHD given the overlap between the population included in the technology appraisal and the population with ADHD. The technology appraisal indicates that both group and individual programmes are likely to be effective.

Taken as a whole the available evidence indicates that referring parents of children with ADHD to established parent training programmes, such as Triple P, is likely to result in beneficial effects for the child. However, it may be important to incorporate information about ADHD and the behavioural and emotional sequelae that arise from the condition into a generic programme attended by parents of children with ADHD.

For school-age children the available evidence indicates that interventions offering mixed CBT and social skills training group sessions for children along with parallel group sessions for parents are beneficial. Effective interventions all followed a structured curriculum. Areas that effective interventions addressed include: challenging and oppositional behaviour in the home; problem solving; listening skills; recognising, dealing with and expressing feelings; anger management, self-control and ignoring provocation; accepting consequences; assertiveness and conflict resolution; friendship skills; self-esteem and good sportsmanship. Successful programmes tended to use active learning methods such as role play, modelling, observation and feedback along with reward systems such as star boards and token rewards, with similar rewards for home based objectives. They also involved individualised elements, often with homework assignments and diary keeping. The evidence indicates that parent sessions

ADHD: full guideline DRAFT (January 2008)
should be designed to reinforce and support child learning while also
incorporating training in parenting skills and behavioural management
principles.

There is also some evidence that providing parents of school-age children
written manuals on behavioural strategies to use at home may result in
positive improvements in child behaviour. While not a substitute for parent
training this is an intervention that can be delivered immediately.

No RCT evidence on interventions for young people of 13 years and older
was identified but it is likely that CBT/social skills therapy interventions as
described for older children would be applicable to young people with
ADHD.

In summary, the psychological interventions for ADHD that were evaluated
are well established and constitute a repertoire of interventions in current
clinical practice that are based on CBT principles and have beneficial effects
for children with ADHD: parent training, cognitive and behavioural therapy
approaches, social skills training, and self-instructional manuals. Generally
therapist led psychological interventions were delivered in courses of
between eight and 12 sessions lasting 1 to 2 hours. Individual parent training
that involves working with the child and parent together may be favoured for
pre-school children. However, the NICE technology appraisal of parent
training as an intervention for children with conduct disorders indicates that
group interventions are also likely to be effective for both pre-school and
school age children with ADHD. For school-age children interventions that
involve separate group sessions for parents and children appear favoured.
Given the concerns about the use of medication for ADHD, psychological
interventions therefore appear to present a deliverable and potentially
effective alternative therapeutic approach for children and young people with
ADHD. The economic analysis indicates that both group-based parent
training programmes and group CBT for children of school age are likely to
be cost-effective interventions for children with ADHD.

7.3 Psychological interventions for adults with ADHD

7.3.1 Databases searched and inclusion/exclusion criteria
Information about the databases searched and the inclusion/ exclusion
criteria used for this section of the guideline can be found in Table 12.

10 Here and elsewhere in the guideline, each study considered for review is referred to by a study ID in capital letters (primary author and date of study publication, except where a study is in press or only submitted for publication, then a date is not used).
7.3.4 Review of clinical evidence for psychological interventions for adults with ADHD

Psychological treatment may be required at different points in time and/or stages in youth and adult development. This may commence with ‘de novo’ diagnosis in adulthood in order to help the individual undergo a process of understanding and acceptance of their diagnosis and to cognitively reframe their past (Young et al., in press a; Young et al., in press b). The few studies that have investigated the psychological treatment of adults with ADHD have all used a cognitive-behavioural paradigm, either applied on an individual or group basis. This reflects the broad consensus that individual needs will be best met by this approach (Young, 2007; Young & Bramham, 2007).

Furthermore, CBT has a strong evidence base for many of the comorbid problems associated with ADHD.

Evidence on psychological interventions to treat ADHD in adults is very sparse, nevertheless there is consensus from clinicians working with these populations that psychological interventions adapted for ADHD may have a therapeutic role in its treatment (Ramsay & Rostain, 2003; Weiss & Murray, 2003; Wilens et al., 1999; Young & Bramham, 2007). Only one small RCT of a psychological intervention for adults with ADHD met inclusion criteria (SAFREN2005).

The search identified two other trials of psychological interventions for adults with ADHD (Stevenson et al., 2002; Stevenson et al., 2003), however, these studies were excluded because although they appear to report two different studies (one of a modified version of the intervention used in the other) and appear to have different sample sizes, the main outcome data tables report identical means and standard deviations. These two studies were by the same authors and efforts were made to seek clarification from the authors regarding what data could be included, but no response was received and it was concluded that the data as published could not be cited.

The one RCT of a psychological intervention for adults with ADHD was a small study comparing 16 participants receiving CBT plus continued medication for ADHD with 15 participants receiving continued medication for ADHD alone (Safren et al., 2005). Analysis of the data conducted for this guideline indicates that for adults with ADHD on continuing medication CBT delivers a positive impact on anxiety as rated by both the individual and an independent evaluator blind to treatment assignment. The analysis also indicates that there is a trend for beneficial effects of CBT on ADHD symptoms. Although not statistically significant, the effect size for ADHD symptoms rated at end of treatment by an independent evaluator was moderate. The intervention was provided on an individual basis and seems to have varied in duration according the participants’ needs up to a maximum of 15 weeks. The CBT intervention comprised three core modules providing psychoeducation; developing skills to attend, organise and plan; and
cognitive restructuring and learning adaptive thinking skills; there were also three optional modules for participants showing clinically significant difficulties in procrastination, anger/frustration and/or communication.

While the available RCT evidence therefore suggests that CBT interventions might provide some benefits for adults with ADHD, the findings from only one small study should be only be regarded as tentative. RCTs of CBT, coaching and other approaches currently used with adults with ADHD are needed in order to clarify whether psychological interventions are effective for adults with ADHD.

Given the lack of RCT evidence, consideration of the potential value of psychological therapies for adults with ADHD may also be informed by a recent non-randomised controlled study of a group CBT workshop-style brief intervention for adults with ADHD (Bramham et al., in press). Forty-one completers receiving CBT plus treatment as usual were compared with 37 participants receiving treatment-as-usual who were on a waiting list for CBT (the majority of participants were taking medication for ADHD). The objectives of the brief intervention were to provide psychoeducation and to teach techniques and develop psychological skills with the aim of improving the confidence, self-esteem and self-efficacy of participants. The workshops included sessions about inattention and memory, impulsivity, frustration and anger, anxiety, depression, social relationships, time management, problem solving, and preparing for the future. Compared with baseline there were significant improvements in measures of anxiety and depression for both groups, but the CBT plus usual care group had significantly greater improvements in measures of knowledge about ADHD, self-efficacy and self-esteem than the usual care group. Participants’ evaluations of the sessions suggested that sharing personal experiences with other adults with ADHD was an important aspect of the intervention. These findings suggest that CBT group treatments, even when delivered in a brief intense design, may be an acceptable and beneficial intervention for adults with ADHD.

The studies by Safren and colleagues (2005) and Bramham and colleagues (in press) both provided treatment based on a CBT paradigm, however there are some key differences between these two studies. Bramham and colleagues (in press) provided a group treatment delivered as three 1-day workshops using a non-randomised waitlist control design while Safren and colleagues (2005) evaluated a randomly allocated course of individual CBT sessions. Furthermore, Safren and colleagues (2005) titrated the treatment according to the clients’ needs and thus evaluated specific changes in interpersonal functioning while Bramham and colleagues (in press) provided a more generalised treatment and evaluated more global change. Nevertheless, taken together these two studies indicate that psychological interventions may have a beneficial impact for adults with ADHD, whether provided on an individual or group basis.
The use of coaching interventions for people with ADHD is growing. These are supportive interventions that have strong parallels with brief solution-focused therapies, but in practice what is provided varies greatly and no studies investigating the effectiveness of coaching interventions were identified.

The addition of psychological interventions may be especially important in the treatment of older adolescents and adults with ADHD and comorbid antisocial behaviour. Along with interventions to treat the symptoms and problems associated with ADHD, this subgroup of ADHD individuals may benefit from interventions that aim to develop specific skills in prosocial competence, emotional control, problem solving and conflict resolution. Longer and more intensive treatment programmes may be required to address these issues, and while the overall cost of treatment is therefore likely to be relatively high, this has to be balanced against the financial burden these individuals place on social, health, educational and criminal justice services, as well as wider potential costs to society.

7.3.5 Clinical evidence summary

Psychological treatment may be required at different points in time and/or stages in youth and adult development. There is some evidence from both service users and carers to support the need for psychological treatment to be provided following de novo diagnosis of ADHD in adulthood. There is little research evidence about the psychological treatment of adults with ADHD, however strong clinical consensus exists that cognitive behavioural treatments are the most appropriate. Two studies, drawing on different methodologies, indicate that both group and individual CBT interventions may have beneficial effects for adults with ADHD. However, the inference that CBT might be a useful intervention for adults with ADHD should only be regarded as tentative as it is based on one small RCT and a non-randomised controlled trial. Group treatments that provide the opportunity to meet others and share experiences may be the preferred approach to the psychological treatment of ADHD for adults.

7.3.6 Health economic evidence

Systematic literature review

No evidence on the cost effectiveness of psychological interventions versus a control condition (no intervention, waitlist control, standard care or a control intervention) for adults with ADHD was identified by the systematic search of the economic literature. Details on the methods used for the systematic search of the economic literature are described in Chapter 3.

Economic modelling
Objective
The objective of the analysis was to assess the cost effectiveness of psychological treatments for adults with ADHD, given that no economic evidence relating to this issue was identified in the systematic search of the economic literature.

Interventions examined
The treatment options examined were CBT added to standard medication versus standard medication alone. CBT was defined as 1-day sessions with a clinical psychologist, addressing different issues such as psychoeducation about ADHD, learning skills to reduce distractibility, cognitive restructuring, and so on, lasting in total 15 hours over a 15-week period. Standard medication was defined as provision of a variety of pharmacological treatments for adults with ADHD. The treatment options examined in the analysis were determined by the availability of clinical data.

Methods
Model structure
An economic model in the form of a simple decision tree was developed to estimate costs and benefits associated with provision of CBT on top of standard medication in adults with ADHD. According to the model structure, hypothetical cohorts of adults with ADHD received CBT in addition to their usual medication, or were given their usual medication alone. The time horizon of the analysis was 1 year. Adults responding to CBT over 15 weeks received two further booster sessions until the end of the year. All adults in both arms continued their usual medication for the whole duration of the analysis. Adults showing response to either treatment option retained improved symptoms (that is, remained responsive) for the remaining time of the analysis.

A schematic diagram of the Markov model is provided in Figure 4.

Figure 4. Schematic diagram of the structure of the economic model
Costs and health benefit measures included in the analysis

The analysis adopted the perspective of the NHS. Health service costs consisted solely of intervention costs. The cost of CBT was the only intervention cost estimated, since standard medication costs were assumed to be equal in the two groups. These included drug acquisition costs, costs of visits to healthcare professionals and other monitoring costs, as well as costs of treating side effects. Costs of personal social services were not included in the analysis owing to lack of relevant data. Other societal costs, such as social benefit payments and productivity losses, were not considered, as they were beyond the scope of this analysis. The measure of benefit was the number of QALYs gained. Results are reported in the form of ICERs.

Effectiveness data

Only one study providing evidence on the effectiveness of psychological interventions in adults with ADHD was identified by the systematic literature search for clinical evidence (SAFREN2005). The study compared CBT added to usual medication versus usual medication alone. The study population consisted of 31 adults stabilised on medication for a minimum of 2 months, who continued to show clinically significant symptoms. Medication involved mainly use of stimulants and/or bupropion or velanfaxine. Outcomes were reported as response rates, as well as changes in scores on the ADHD rating scale. No discontinuations from treatment were reported. Response was defined as a 2-point change in the Clinical Global Impression Instrument, which was considered clinically meaningful and significant by the GDG. Therefore, response rates reported in this study were used to inform an economic analysis. More details on the study characteristics can be found in Appendix 17.

Utility data and estimation of QALYs
The systematic review of the literature identified one poster presentation providing utility weights for health states in adults with ADHD (Laing & Aristides, 2005). The study was based on an RCT comparing atomoxetine 40 mg versus atomoxetine 80 mg in 218 adults with ADHD. The original study measured the HRQoL in the study population at baseline and endpoint of the trial using the SF-36, and then linked these outcomes with response or no response to treatment, determined by severity of ADHD symptoms as measured on the Conners’ Adult ADHD Rating Scale (CAARS) (Adler et al., 2006). SF-36 is a generic measure of HRQoL, consisting of eight health domains: physical functioning, bodily pain, role limitations due to physical problems, role limitations due to emotional problems, general health perceptions, mental health, social functioning, and vitality. SF-36 scores for responders and non-responders were converted into SF-6D scores (SF-6D is a shorter version of SF-36), and subsequently into utility scores reflecting preferences of the UK population, using published algorithms based on the SG technique (Brazier et al., 1998; Brazier & Roberts, 2004). The resulting utility weights are in accordance with NICE recommendations on methods for measuring HRQoL in cost-utility analysis (NICE, 2004) and were therefore utilised in this economic model.

The utility scores reported by Laing and Aristides (2005) were 0.678 for adults with ADHD responding to treatment, 0.634 for non-responders at beginning of observation, and 0.630 for non-responders at end of observation. For this analysis, it was decided to use the score for non-responders at beginning of observation, as the utility score for non-responders at the end of observation in Laing and Aristides (2005) probably reflected decrement in HRQoL coming from the presence of newly developed side effects. However, the study population in this analysis consisted of adults that were already on drugs for at least 2 months, and continued drugs over the whole time of the analysis, and therefore side effects were likely to be already present at the beginning of the analysis.

It was assumed that HRQoL in adults responding to treatment improved linearly over 15 weeks, starting from the utility score of non-responders and reaching the utility score for responders (15 weeks was the duration of the trial in SAFREN2005), and remained at this value for the remaining time of the analysis. Decrement in quality of life owing to presence of side effects was assumed to be the same in both groups and therefore was not considered in the analysis.

Resource utilisation and cost data
Owing to lack of patient-level cost data, deterministic costing of all treatment options assessed was undertaken. Relevant healthcare resource use was estimated and subsequently combined with unit prices to provide total costs associated with CBT. Costs of medication were not estimated, as these were assumed to be equal in the two treatment arms. Resource use estimates
associated with CBT were based on GDG expert opinion, reflecting UK clinical practice, and were consistent with resource use described in SAFREN2005. In addition, booster sessions for responders were modelled according to optimal practice required to retain a positive outcome (GDG expert opinion).

CBT consisted of 1-day sessions with a clinical psychologist lasting in total 15 hours over a 15-week period. Following completion of the intervention, responders attended two more booster sessions lasting 1 hour each, in order to remain responsive to treatment for the remaining time of the analysis.

The unit cost of clinical psychologists was taken from the Unit Costs for Health and Social Care 2006 (Curtis & Netten, 2006). Discounting was not applied, as costs and benefits were measured over a period of 1 year.

All input parameters, including effectiveness data, utility scores and cost data utilised in the base-case economic analysis of psychological interventions for adults with ADHD are presented in Table 14.

Sensitivity analysis
Sensitivity analysis was undertaken to investigate the robustness of the results under the uncertainty characterising input parameters of the model. The following scenarios were tested in one-way sensitivity analysis:

1. Use of the upper and lower confidence intervals (CIs) of the relative risk (RR) of CBT on top of standard medication to standard medication alone (mean RR = 4.22; 95% CIs = 1.08 to 16.45).
2. Use of utility scores generated for disease-specific health states for children with ADHD (Secnik et al., 2005b), given the lack of any other utility data for adults with ADHD. Utility scores for the health states characterised by use of ER stimulants were used. The scores for responders and non-responders were 0.93 and 0.90 respectively, when no side effects occurred; and 0.91 and 0.88 respectively, when side effects were present. In both cases the difference in utility between responders and non-responders was 0.03, which meant that use of any pair of scores (referring to presence or absence of side effects) would give the same results.

3. Replacing individually delivered CBT resource-use estimates by group-based CBT, consisting of 15 hours in total, delivered to groups of 10 adults by two clinical psychologists (reflecting optimal routine practice for adults with ADHD – GDG expert opinion). The cost of 15 hours of CBT under this scenario was £198 per adult (excluding booster sessions, which were assumed to be provided individually, as in the base-case analysis).

In addition to the above scenarios, threshold analyses were carried out to identify the values of selected parameters at which the conclusions of the cost-effectiveness analysis would be reversed. The following parameters were tested:

- Total number of hours of (individual) sessions of CBT
- Minimum difference in utility between responders and non-responders.

Results

Base-case analysis

CBT added to standard medication was more effective and more expensive than standard medication alone, at an additional cost of £65,279/QALY. This value is beyond the cost-effectiveness threshold of £20,000/QALY set by NICE (The Guidelines Manual (NICE, 2006)). This means that, according to the base-case results, CBT is not cost effective when it is added to standard medication in adults with ADHD. Full results of the base-case analysis are presented in Table 15.

Sensitivity analysis
The ICER of CBT on top of standard medication versus standard medication alone remained above the NICE-set cost-effectiveness threshold under the vast majority of scenarios tested in sensitivity analysis. The only scenario that strongly affected conclusions in favour of CBT was the delivery of CBT in groups rather than individually. Under this scenario, the ICER of CBT added to standard medication versus standard medication alone became £16,699/QALY. This value is based on the hypothesis that group-based CBT is as effective as individually delivered CBT; moreover, therapy groups must be working to full capacity, that is, 10 adults need to attend each CBT session facilitated by two psychologists. If adults with ADHD drop out of therapy without being replaced by other service users in the group, then the relative cost effectiveness of group-based CBT will be reduced. A threshold analysis determined that group CBT was required to work at a minimum 80% capacity in order to remain cost effective (that is, with an ICER below £20,000/QALY).

Full results of one-way sensitivity analysis are shown in Table 16.

</table>

As shown in the threshold analysis, individual CBT was cost effective (with an ICER reaching £16,699/QALY), when it lasted 3 hours in total (instead of 15, as modelled in the base-case analysis). It is extremely unlikely though that CBT can be as effective as described in SAFREN2005 with 3 hours of contact only. Another threshold analysis showed that a minimum improvement of 0.15 in the utility score (from the health state of no response to that of response) was required in order for individually provided CBT to become cost effective.

Limitations of the economic analysis

The results of the economic analysis were based on a simple decision-analytic model developed to estimate additional costs and health benefits associated with provision of CBT in adults with ADHD already taking medication, over the period of 1 year. Clinical evidence was derived from the only available trial evaluating the effectiveness of psychological therapies in adults with ADHD. The total number of participants in this trial was very small (N=31). CBT was shown to have a significant effect when response rates were used as the measure of outcome. However, changes in score on the ADHD rating scale, while favouring CBT, were nevertheless not significantly different between the two arms of the trial. The study population consisted of adults
who continued to show clinically significant ADHD symptoms, despite
having received medication for at least 2 months before CBT was started. It is
uncertain whether the results of the clinical study (and, subsequently, of the
economic analysis) would be the same on a population of adults less resistant
to medication.

Costs consisted of intervention costs only; potential cost savings to the
healthcare and social services resulting from improvement in ADHD
symptoms of adults were not considered owing to lack of relevant data. It is
therefore likely that the cost effectiveness of CBT added to standard
medication in adults with ADHD is greater than that suggested by the results
of the analysis.

Estimates on healthcare resource use were based on GDG expert opinion,
reflecting resource use described in SAFREN2005, which was the only source
of clinical-effectiveness data for this economic analysis; however, this study
only roughly described some aspects of resource use relating to CBT, and did
not provide any data on resource use beyond the duration of the trial. It is
unknown whether two booster sessions are sufficient to retain a positive
outcome in adults with ADHD (as assumed in the economic model), as no
relevant follow-up studies are available. Likewise, the long-term effectiveness
of CBT if added to standard medication in this population is unknown.
Therefore, it is not possible to estimate the cost effectiveness of CBT in the
longer term.

Utility scores used in the economic model, taken from a poster presentation,
were based on SF-36 scores obtained from an RCT comparing two different
doses of atomoxetine in adults with ADHD. These were the only utility scores
available for adults with ADHD. The study population in this trial consisted
of adults under medication, mainly stimulants. It is possible that the resulting
utility scores are not fully representative of the HRQoL of the study
population in the economic analysis. Nevertheless, they were derived from a
generic, validated instrument, which is in accordance with NICE
recommendations (NICE, 2004).

A key assumption used in the sensitivity analysis, was that individual-based
and group-based CBT are equally effective. Group-based CBT was proven to
be cost effective in a sensitivity analysis, assuming that its effectiveness was
equal to that of individual CBT. The clinical effectiveness data used in the
economic analysis were taken from SAFREN2005, which examined
individually delivered CBT. According to GDG expert opinion, it is likely that
group-based CBT has similar effectiveness with individually delivered CBT.
However, at the moment there is no evidence to support this theory.

Overall conclusions from the economic analysis
The results of the economic analysis indicate that individually delivered CBT is not a cost-effective option for adults with ADHD who have already taken stimulants but still have clinically significant ADHD symptoms. However, if group-based CBT has similar effectiveness to individual CBT in this population, then group-based CBT is a cost-effective option from the perspective of the NHS.

Further research is needed to explore the long-term benefits and potential cost savings associated with provision of CBT to adults with ADHD, and to further investigate the HRQoL of this population. More importantly, future research is required to examine the effectiveness of group-based CBT versus individually delivered CBT, so that the cost effectiveness of group-based CBT can be determined.

7.3.7 From evidence to recommendations: Psychological interventions for adults with ADHD

Psychological treatment may be required at different points in time and/or stages in youth and adult development, including when there is a ‘de novo’ diagnosis in adulthood, and may help the adult with ADHD to undergo a process of understanding and acceptance of their diagnosis and to cognitively reframe their past. The sparse evidence available indicates that CBT interventions deliver therapeutic benefits for adults with ADHD, whether provided on an individual or group basis. CBT may be particularly relevant to adults on medication who have persisting functional impairments associated with ADHD.

Areas that it may be important for CBT interventions to address include: psychoeducation; developing skills to attend, organise and plan; and cognitive restructuring and learning adaptive thinking skills. Where there are clinically significant difficulties in procrastination, anger/frustration and/or communication it may also be useful to address these areas.

Brief workshop style group CBT interventions that aim to improve confidence, self-esteem and self-efficacy may deliver therapeutic benefits for adults with ADHD and appear to be an acceptable way of providing CBT to this population. Such interventions can provide psychoeducation and teach techniques and psychological skills to address inattention and memory, impulsivity, frustration and anger, anxiety, depression, social relationships, time management, problem solving, and preparing for the future. In group interventions participants may value the opportunity to share personal experiences with other adults with ADHD.

Economic analysis supports the use of group-based CBT for adults with ADHD, if this has similar effectiveness to individual CBT in this population. Future research is required so that the effectiveness and cost effectiveness of group-based CBT can be confirmed.
7.4 Other non-pharmacological approaches

A number of non-pharmacological approaches have been used as therapies for ADHD, including biofeedback, relaxation training and environmental manipulation and management.

7.4.1 Environmental manipulation and recreational interventions

It is not unusual to find suggestions in the therapy literature of interventions involving making changes to the environment to address core ADHD symptoms. Keeping distracting stimuli to a minimum in home and school settings is supported by research showing that distractions in the environment result in decreases in time on task (Whalen et al., 1979) and that ADHD may be associated with neuropsychological impairments characterised by deficits in executive functioning and/or an aversion to waiting for rewards (Thorell, 2007; Sonuga-Barke, 2003). Children with ADHD seem to seek stimulation when low levels of it are present (Antrop et al., 2000), and this finding would support strategies that ensure that sufficient stimulation is available. This may mean keeping ‘idle’ time to a minimum while at other times making it possible for children to engage in a psychologically stimulating activity.

It is difficult to judge how important the concept of environmental manipulation is in practice. It is likely that teachers in employing usual classroom management techniques will tend to reduce the amount of distracting stimulation a child with ADHD is exposed to, for example by seating them at the front of the class. Parents too may naturally ensure that their children have sufficient appropriate recreational and leisure activities so as to reduce the likelihood of inappropriate behaviour occurring. However, it is not known whether this type of intervention is employed in a systematic way by clinicians and teachers, despite the possible theoretical underpinnings.

Related to environmental manipulation are strategies designed to stimulate through recreation parts of the brain that may confer some control over disinhibition, executive functioning and inattentiveness (Rabinowitz, 2004). It is not known how extensively such approaches are used and the evidence base is poor. Nevertheless, it is likely that at least on an intuitive level some parents and therapists develop and use such techniques.

Somewhat more widespread, but again with a weak evidence base, are recreational and leisure strategies designed to appeal to the needs of children for stimulus and activity but to do so through engaging in socially acceptable activities. There is no systematic research on the efficacy of this approach, but anecdotally it seems that it may be in widespread informal use. Competitive...
contact sports such as football, rugby and hockey are obvious choices as are
individual contact sports such as the many forms of martial arts including
boxing. Recreational pursuits involving bikes, skateboards and roller blades
are also popular. The actual choice may to a large extent depend upon local
amenities and family finances. Parents and therapists may see such
recreational and leisure pursuits as not only an opportunity for youngsters to
‘let off steam’, but also a way of providing opportunities for them to develop
social skills and self-control.

7.4.2 Biofeedback

Biofeedback has been employed as a non-invasive treatment for children with
ADHD since the 1970s but is probably not used as a significant intervention in
UK clinical practice. A wide range of feedback presentations that are suitable
for children are available and its rationale lies in theories of brain plasticity
and cortical self-regulation that suggest it may be possible to countermand
deficits of cortical activation (see Heinrich et al., 2006). The use of electro-
encephalography (EEG) biofeedback derived from the initial hypothesis of
Satterfield and colleagues (Satterfield & Dawson, 1971; Satterfield et al., 1973)
that attentional deficits result from dysfunction of the central nervous system
and that children with ADHD exhibit behaviours consistent with ‘low
arousal’. It is assumed that variations in alertness and behavioural control are
directly related to specific thalamocortical generator mechanisms and that
such variations are evident in distinctive EEG frequency rhythms that emerge
over specific topographic regions of the brain (Sterman, 1996). It is proposed
that ADHD neuropathology could alter these rhythms and that EEG
biofeedback training directed at normalising these rhythms might therefore
yield sustained clinical benefits.

Biofeedback techniques thus involve training individuals to exercise a certain
amount of control over their brainwaves (as recorded by EEG) through
bioelectrical neuroregulation. The mechanism by which it is proposed that
this can be achieved is based on the assumption that the central nervous
system can regulate a series of physiological functions in addition to its own
activity. Intentional modulation of cortical self-regulation is achieved through
a process of operant learning through the provision of training aimed to
decrease excessive theta or slow wave activity (which is associated with
feeling drowsy) and increase beta activity (which is associated with ‘alertness’
and attentional and memory processes). Biofeedback training involves the
clinician setting desired thresholds on the biofeedback equipment. These
thresholds are based on treatment goals, for example to decrease theta rhythm
and increase beta rhythm. As the individual’s physiological changes approach
and surpass the set thresholds, the equipment provides either auditory or
visual feedback, which serves as positive reinforcement for the desired
changes. Thus, as an individual decreases theta and increases beta waves
during EEG biofeedback, reinforcement is provided to encourage them to
become more aware of what they are doing to achieve this desired state and
to continue in the same manner. In children a focus has been on the training
of slow cortical potentials as well as theta and beta waves, and the use of a
computer-based delivery seems to assist with the acceptability of the method.

7.4.3 Relaxation training and other physical therapies
Relaxation training involves the systematic tensing and relaxing of specific
muscle groups. These techniques can be used to help children and young
people in situations where they feel anxious and tense and to gain a sense of
self-control. Other physical therapies that have similar aims include yoga and
massage.
7.5 Recommendations

7.5.1 Identification, pre-diagnostic intervention and referral in children and young people

7.5.1.1 Group-based parent-training/education programmes are recommended in the management of children with conduct disorders [NICE 2006]. This should include all children with suspected ADHD.

7.5.2 Treatment for preschool children

7.5.2.1 The parents of pre-school children with a diagnosis of ADHD should be offered a referral to a parent-training programme as the first-line treatment. [Key priority]

7.5.2.2 Group-based parent-training/education programmes are recommended in the management of children with conduct disorders [NICE 2006], and this should include all children with ADHD.

7.5.2.3 Individual-based parent-training/education programmes are recommended in the management of children with conduct disorders only in situations where there are particular difficulties in engaging with the parents or a family’s needs are too complex to be met by group-based parent-training/education programmes. [NICE 2006], and this should include all children with ADHD as parent-training programmes are effective in reducing problem behaviours and disordered conduct that are often associated with ADHD.

7.5.2.4 Individual parent-training programmes for parents of children diagnosed with ADHD may also be considered as an alternative when viable group interventions are difficult to achieve because of low participant numbers.

7.5.2.5 When individual parent-training programmes for pre-school children with ADHD are undertaken, the skills training stages should include working with the parents and the child together.

7.5.2.6 It is recommended that all parent-training/education programmes, whether group- or individual-based, should:

- be structured and have a curriculum informed by principles of social-learning theory
- include relationship-enhancing strategies
- offer a sufficient number of sessions, with an optimum of 8-12, to maximise the possible benefits for participants
• enable parents to identify their own parenting objectives

• incorporate role-play during sessions, as well as homework to be undertaken between sessions, to achieve generalisation of newly rehearsed behaviours to the home situation

• be delivered by appropriately trained and skilled facilitators who are supervised, have access to necessary ongoing professional development, and are able to engage in a productive therapeutic alliance with parents

• adhere to the programme developer’s manual and employ all of the necessary materials to ensure consistent implementation of the programme. [NICE 2006]

• In addition, consideration should be given to including both parents in parent-training programmes wherever this is feasible.

7.5.2.7 Programme providers should also ensure that support is available to enable the participation of parents who might otherwise find it difficult to access these programmes. [NICE 2006]

7.5.2.8 If overall treatment, including parent-training programmes, has not been effective in managing ADHD symptoms and any resulting impairment for pre-school children, healthcare professionals should consider a referral to tertiary services for further care.

7.5.2.9 If overall treatment, including parent-training programmes, has been effective in managing ADHD symptoms and any resulting impairment for pre-school children, healthcare professionals should carry out an assessment to ascertain the extent of any residual comorbidities. They should also monitor for the recurrence of ADHD symptoms and impairment that may occur following the child's entry to school.

7.5.3 Treatment for school-aged children with moderate ADHD

7.5.3.1 If the child or young person diagnosed with ADHD has moderate symptoms and impairment, the parents should be offered referral to a group parent-training programme, either alone or as part of a combined intervention including a group treatment programme for the child or young person. [Key priority]

7.5.3.2 When using group treatment for the child or young person in conjunction with a parent-training programme, particular emphasis may be given in the group treatment on targeting a range of areas in functioning, including social skills with peers, problem solving, self-
control, listening skills, and dealing with and expressing feelings; active learning strategies should be used and rewards included for achieving key elements of learning.

7.5.3.3 For older adolescents with moderate ADHD symptoms and impairment, individual psychological interventions should be considered as these are more likely to be effective and acceptable than parent training.

7.5.3.4 For children and young people (including older age groups) with ADHD and a learning disability, a parent-training programme should be offered to parents on either a group or individual basis, whichever is preferred following discussion with the parents and child.

7.5.3.5 Following successful treatment with a parent-training programme and prior to considering discharge, the child and family should be reviewed for any other remaining problems such as anxiety, aggression and learning difficulties.

7.5.4 Treatment for school-age children with severe ADHD (hyperkinetic disorder)

7.5.4.1 If a group parent-training programme is effective for children and young people with severe symptoms of ADHD who have refused drug treatment, healthcare professionals should assess for possible comorbidity and develop a longer-term care plan.

7.5.5 Treatment for all children with ADHD

7.5.5.1 Healthcare professionals working with children and young people with ADHD should anticipate major life changes, ensure adequate personal and social support during times of increased need, and consider the possible need for psychological treatment at those times.

7.5.6 Treatment of adults with ADHD

7.5.6.1 For adults with ADHD stabilised on medication who have persisting functional impairments associated with ADHD, a course of either group or individual CBT to address their functional impairment should be considered. [Key priority]

7.5.6.2 For adults with ADHD, CBT may be considered when:

- the individual has made an informed choice not to have drug treatment
- stimulant medication has proved to be ineffective or the person is intolerant to medication
• engagement with services or acceptance of the diagnosis has
proved problematic, and engagement with other treatments needs
to be enhanced.

7.5.3 Psychological interventions may be considered as the first choice for
treatment of ADHD in people where there may be concern about
prescribing and/or potential for misuse, such as in prison services.

7 Research recommendations

7.6.1.1 Effectiveness of group-based parent training

• Are group-based behavioural parent-training methods more
effective than medication in the treatment of school-age children
(including young people) with ADHD in terms of symptom counts,
quality of life assessment, and health economic evaluation? (This
would be best evaluated by a head-to-head randomised controlled
trial.)

• Why this is important: The evidence for the effect of group-based
parent training is largely based on studies of younger children yet
they such training are is an important part of the regime that is
provided and their its cost effectiveness is not clear for older
children and adolescents.

7.6.1.2 Effectiveness of non-pharmacological approaches used with adults
with ADHD

• Are non-pharmacological treatments (including focused
psychological treatments and supportive approaches such as
coaching), more effective than the use of drug treatment
(methylphenidate) in terms of symptom counts, quality of life, and
health economic evaluation, drug misuse and other comorbidites,
and use of health, forensic and criminal justice services, in the
treatments of adults with ADHD? (This would be best conducted as
a randomised controlled trial.)

• Why this is important: Currently there is good evidence of the
effectiveness of methylphenidate on symptoms and their associated
impairments. However, there is insufficient evidence as to whether
non-pharmacological approaches could have specific advantages in
some important aspects of the life of a person with ADHD. Given
the strong association of ADHD in adults with drug misuse,
personality disorder and involvement in the criminal justice system,
a health economic approach would be essential.
8 Interventions for children with ADHD in educational settings

8.1 Introduction

This chapter reviews the literature and makes recommendations for interventions for children with ADHD within educational settings, while recognising that such interventions need to be considered as one component within the overall service provision.

Children with ADHD fall behind their peers academically (Barbaresi et al., 2007; Barkley et al., 1990; Frazier et al., 2007; Lahey et al., 1994, Marshall et al., 1999; Nussbaum et al., 1990; Willcutt et al., 2001; Zentall, 1993). It has been shown that this trend extends to children who are severely inattentive, hyperactive and impulsive in the classroom, even if they do not have a formal diagnosis of ADHD (De Shazo-Barry et al., 2002; Gaub & Carlson, 1997; McGee et al., 2002; Merrell & Tymms, 2001; Merrell & Tymms, 2005). The studies by Merrell and Tymms, which are based upon a large sample of English school children aged between 5 and 7 years, showed that the inattentive factor was particularly related to academic underachievement, and that the greater the number of symptoms, the greater the impairment (Merrell & Tymms, 2005). Further, children who had been identified by their teachers in the first (reception) year of school as having severe ADHD symptoms were shown to fall behind their peers academically at least until the end of primary schooling at age 11 years.

There can be little doubt that when a child has symptoms of ADHD his or her behaviour varies across different situations. Rutter and colleagues (1979) showed clear differences in behaviour across secondary schools using observation and self-report. Similar differences were noted by Mortimore and colleagues (1988) across primary schools, although they relied on teachers’ questionnaires. In reviewing the evidence, Galloway (1995) proposed that ‘differences between teachers are substantially greater than differences between schools’, suggesting that the teacher was the dominant influence on behaviour in the classroom. Gray and Sime (1988) suggested that 60% of the variance in behaviour lay within schools. In the Elton report (1988) it is stated that ‘a teacher's general competence has a strong influence on his or her pupils' behaviour.’

Although the ordinary experience of teachers and anecdotal evidence suggests that the behaviour of children with ADHD is influenced by school and teachers, there is no formal evidence to support this. Clearly, there would be many advantages if the behaviour of children with ADHD could be modified with school-based interventions. Although evidence is lacking, the
desired outcomes for children with ADHD are, nevertheless, improvements in their behaviour within the school setting, academic achievement, attitude to school, self-esteem, peer relationships, social inclusion and post-education opportunities. Another desired outcome, which extends beyond the clinical question (see Appendix 6) but is important to bear in mind, is an improvement in the quality of life for teachers of children with ADHD (Barbaresi & Olson, 1998).

8.2 Databases searched and inclusion criteria

Information about the databases searched and the inclusion/exclusion criteria used for this section of the guideline can be found in Table 17.

8.3 Studies considered

The review team conducted a new systematic search for RCTs that assessed the efficacy and/or safety of interventions delivered by teachers in educational settings for children and adolescents with ADHD.

Six trials met the eligibility criteria set by the GDG, providing data on 26117 children. Three of the trials were cluster randomised controlled trials. All trials were published in peer-reviewed journals between 1989 and 2006. In addition, four studies were excluded from the analysis. The most common reason for exclusion was that they were not RCTs (further information about both included and excluded studies can be found in Appendix 17).

---

11 Here and elsewhere in the guideline, each study considered for review is referred to by a study ID in capital letters (primary author and date of study publication, except where a study is in press or only submitted for publication, then a date is not used).
8.4 Clinical evidence for screening for ADHD in educational settings

8.4.1 Introduction

Key behaviours related to ADHD are readily observable in children at school and it might be advantageous for teachers to be able to recognise those pupils who may have ADHD. In the US, clinical practice guidelines recommend that teachers should be involved in the process of diagnosing ADHD by completing rating scales and providing information about possible symptoms and impairment in the school setting (American Academy of Child and Adolescent Psychiatry, 2007). Teachers thus have a crucial role in assisting with accurate clinical case identification.

A screening programme for ADHD has attractions: the early identification of problems, early intervention, and, if repeated regularly throughout primary and secondary school, recognising cases that ‘slipped through the net’ or have a late onset. However, the potential downsides of screening are the identification of false positive/false negative cases, as well as the economic costs involved.

Current practice

To the best of the knowledge of the GDG and the review team, no screening intervention for children with ADHD is carried out in schools in the UK.

Definition and aim of intervention/service system/topic of review

Two types of screening have been defined. One, a ‘case identification’ approach may be seen as screening, but it is distinct from a universal programme of screening which collects data across all children in schools and selects possible cases of ADHD for further assessment or referral. This section considers the latter possibility.

8.4.2 Clinical evidence for screening versus no intervention

There was only one study from the six included trials that involved a comparison of screening of children with ADHD as an intervention compared with no intervention in a school setting (TYMMS2006) (see Table 18 for further details). This study also involved advice to teachers in a factorial design and that is dealt with in the next section (TYMMS2006). The class teachers of 2040 participating English primary schools completed a rating scale at the end of children’s first year at school. The rating scale was based on the DSM-IV diagnostic criteria. The intervention involved identifying children who, at the end of the first year of school, exhibited severe ADHD symptoms, based on the cut-off points for the number of criteria deemed to represent severe ADHD symptoms as suggested in DSM-IV. The names of these pupils in half of the schools in the sample were forwarded to the new class teachers. The schools were randomly selected. Outcome measures were collected 18 months later, half-way through school year 2 when pupils were
aged 6 to 7 years. The identification of children with severe ADHD symptoms had no detectable impact on ADHD symptoms, reading or mathematics.

Study information and evidence from the important outcomes and overall quality of evidence are presented in Table 18. The full evidence profiles and associated forest plots can be found in Appendix 19 and Appendix 18, respectively.

**8.4.3 Clinical evidence summary**

From the original search only one study (2006) was identified that assessed the efficacy of screening in educational settings. The quality of the evidence was moderate given that only one study was included. Evidence suggests that
there is little to no effect of introducing a screening programme on children’s ADHD symptoms or academic achievement.

8.5 Clinical evidence for advice to teachers about ADHD, effective classroom interventions, and teacher training

8.5.1 Introduction
This section reviews the effect of advising teachers about ADHD in general, and of providing classroom management techniques for children with ADHD. It then considers the issue of teacher training.

8.5.2 Advice to teachers about classroom strategies for children with ADHD

Introduction
Some parents conceptualise ADHD as more of an educational rather than a health problem and request educational input and services (Poduska 2000). In the UK two-thirds of parents of children with ADHD have consulted and discussed their concerns with teachers (Sayal et al., 2006a). Therefore, improving teachers’ knowledge of ADHD alongside providing advice on how to work with children who might have ADHD may improve outcomes. To achieve this, teachers need to be equipped with information about the behavioural problems that children with ADHD are likely to exhibit in the classroom, possible reasons for that behaviour, suggestions for its management and information about seeking further help with particular children.

Current practice
The review team was unable to find any recent UK-based surveys of teachers’ knowledge of ADHD. At the present time, it is highly likely that teachers’ knowledge of the disorder varies according to the training that they have received and whether they have direct experience of children with ADHD. A recent study set in one Local Education Authority (LEA) found that over half the teachers had experience of teaching a child with a clinical diagnosis of ADHD (Sayal et al., 2006b), and the provision of a brief educational intervention for teachers has been found to raise awareness and improve recognition of children with possible ADHD (Barbaresi & Olson, 1998; Sayal et al., 2006b). Beyond the recognition of children with ADHD, providing advice to teachers about ADHD and how to help children with the disorder within mainstream classrooms has, in some studies, also been combined with other related approaches such as screening and parent training.

Definition and aim of intervention
In the context of this section, the advice for teachers is not part of their pre- or in-service training, delivered in person. The kind of advice that is considered is communicated in the form of written information about the underlying causes of ADHD, and strategies for helping children with the disorder in the classroom setting. The strategies generally involve making adjustments to the classroom environment, groupings with other pupils and interactions with the teacher. Advice can also be more specific; for example, updating a teacher on the treatment of a particular child given by other professionals with suggestions about how the teacher might build upon that work.

8.5.3 Clinical evidence for advice given to teachers as an education intervention

Of the six included trials, three involved advice given to teachers as an intervention (see Table 19 for further details). In one study (TYMMS2006), the intervention consisted of sending an advice booklet to half of the schools (randomly selected). This booklet contained general information about ADHD as well as teaching and classroom management strategies that had been previously shown to help children with ADHD, such as those evaluated in the meta-analyses published by DuPaul and Eckert (1997) and Purdie and colleagues (2002). In this same study (TYMMS2006) the effectiveness of this advice booklet was assessed in conjunction with screening (mentioned previously in section 8.4). The third teacher advice intervention (CORKUM2005) consisted of providing teachers with a general information package about ADHD including the CHADD Educators’ Manual (Fowler et al., 1995) at the start of the intervention period and then sending them weekly brief updates about what the parents had learned that week in a concurrent parent training programme, and suggestions on how to use similar strategies in the classroom.

Study information and evidence from critical outcomes and overall quality of evidence are presented in Table 19. Full evidence profiles and associated forest plots can be found in Appendix 19 and Appendix 18, respectively.

Clinical evidence summary

Advice given to teachers versus no intervention

The quality of the evidence was moderate given that only one study (TYMMS2006) addressed the comparison of advice given to teachers and no intervention. The evidence suggests that there is little to no effect in providing advice to teachers in relation to children’s ADHD symptoms or academic achievement. The authors of the study, however, state that the advice booklet was read by a small percentage of the teachers, which could account for the lack of positive results.

Advice given to teachers + screening versus no intervention

There is limited evidence from one study (TYMMS2006) of the combined effect of advice given to teachers and screening. The results indicate little to no effect in children’s ADHD symptoms or academic achievement. The intervention had a negative effect on some of the academic outcome measures.

Advice given to teachers as an added intervention to parent training

A further study (CORKUM2005) examined the added efficacy of giving advice to teachers to a parent training programme in improving the behaviour of children with ADHD. The general quality of the evidence was moderate reflecting the paucity of the data in this area.

The effectiveness of adding teacher advice to a parent training programme was large (SMD 1.15) in reducing children’s ADHD core symptoms as rated by both parents and teachers. However, there was little to no effect (SMD 0.08) of this intervention when added to parent training in improving children’s conduct problems.

In summary, there is evidence that teacher advice as an added intervention to parent training is effective in reducing children’s ADHD core symptoms.

8.5.4 Clinical evidence for teacher-led educational interventions for children with ADHD

Introduction

As discussed in the introduction to the guideline and to this chapter, children with ADHD are at risk academically and socially, and they can be difficult to manage in the classroom. Interventions to improve those difficulties are desirable and since teachers work with these children for several hours each day, they are in a position to be able to implement strategies in the context of the school environment. Additionally, all children and young people, including those with ADHD, have the right to a school experience that provides a broad, balanced and relevant curriculum, including the National Curriculum, which is appropriately differentiated according to their needs.
Teacher-led educational interventions mainly consist of managing academic activities or adapting the physical environment. A description of a wide range of strategies for use with children with ADHD is given by Cooper and Ideus (1996). They suggest techniques such as seating the child in a place that is relatively free from distraction (for example, doors and windows) in a position where the teacher can easily intervene if the child is not attending, having a designated quiet area for a child to work in, providing stimulating activities, giving concise, clear instructions, following a defined, regular timetable, avoiding repetitive tasks, breaking down tasks into a series of small steps, giving frequent positive feedback, working in a pair rather than a group, isolating the child from the class for a short time when they are misbehaving, giving points or tokens as rewards to be exchanged at a later time for a favourite activity or treat, and taking away points or tokens if the child misbehaves.

**Current practice**

According to the Special Needs Code of Practice, the LEA will need to consider, on an individual basis, whether these interventions can be provided through *School Action Plus* or whether the LEA needs to undertake a statutory assessment. Although there is a statutory requirement to provide appropriate education to all children, including those with ADHD, local practice varies.

**Definition and aims of interventions**

Teacher led interventions are defined as programmes and/or techniques delivered by teachers within the classroom such as those described in the introduction above.

**Teacher-led interventions versus no intervention**

From the six included trials, there was one comparison involving a teacher-led intervention named ‘giving effective commands’ (Barkley, 1997), which consists of the teacher giving the child a command once and, if necessary, proceeding to a warning where the child is informed of the consequences of not carrying out the command; in cases where the child does not comply, the warning is carried out (KAPALKA2005) (see Table 20 for further details).

Study information and evidence from critical outcomes and overall quality of evidence are presented in Table 20. Full evidence profiles and associated forest plots can be found in Appendix 19 and Appendix 18, respectively.

</tbody>
</table>

**Benefits**

| Conduct problems (teacher-rated) | School Situations Questionnaire: SMD -1.47 (-1.94 to -0.99) Quality: moderate K = 1, N = 86 |

**Clinical evidence summary**

The only reported relevant outcome was conduct problems (teacher-rated) and the quality of the evidence was moderate, reflecting the paucity of the data.

There is evidence from KAPALKA2005 indicating a large effect (SMD -1.47) of teacher-led behaviour interventions compared with a control group in reducing conduct problems as rated by teachers.

**8.5.5 Clinical evidence for teacher training on the identification of ADHD and school-based interventions**

**Introduction**

The Special Educational Needs Code of Practice published by the DfES (2001) states that for mainstream schools:

‘Provision for pupils with special educational needs is a matter for the school as a whole. In addition to the governing body, the school’s head teacher, the SENCO or SEN [Special Educational Needs] team and all other members of staff have important responsibilities. In practice the division of day-to-day responsibilities is a matter for individual schools, to be decided in the light of a school’s circumstances and size, priorities and ethos.’
The National Service Framework for Children (2004) highlights the need for support and training of front-line professionals who have daily contact with children. Despite this, teachers receive limited training about child mental health problems (Gowers et al., 2004) or special needs in general (Aubrey et al., 2007).

As discussed earlier, in England teachers’ knowledge about ADHD and experience of teaching a child with a diagnosis of ADHD is variable. In the US, where over 90% of teachers have reported experience of teaching a child with ADHD (Bussing et al., 2002; Power et al., 1995), the following topics have been highlighted as important for in-service education: ADHD, adapting lessons for pupils with ADHD, managing stress caused by children with ADHD in the classroom, behavioural management and implementation of behaviour plans (Barbaresi & Olson 1998; Bussing et al., 2002; Walter et al., 2006).

The provision of in-service training, peer observation and coaching by professionals can be effective (Adey et al., 2004; Dreyfus & Dreyfus, 1986; Dall’Alba & Sandberg, 2006; Joyce & Showers, 1980; Sparks, 1986), but the process takes time, and Adey and colleagues (2004) suggested that 30 hours of in-service provision are required for sustained changes to teachers’ classroom practice.

Since teachers have to deal with children with ADHD on a daily basis and since schools and their staff have responsibilities for such children and since the knowledge basis is variable it makes sense to consider enhancing the training of teachers in the area at the pre-service and in-service stages.

Current practice
Anecdotally, parents report that they need to be proactive in terms of educating teachers about ADHD and consistent teacher education approaches (for example, in-service education or training for the special educational needs coordinators) are desirable.

Teacher-training versus no intervention
From the six included trials only two involved a comparison of teacher training with control. One study (BLOOMQUIST1991) consisted of one 2-hour inservice and six 45- to 60-minute consultation sessions over a 10-week period. Teachers were given educative and restructuring exercises to help modify potential dysfunctional opinions they might have held toward pupils with ADHD in mainstream classes. Teachers were trained in behavioural child management methods and encouraged to actively participate with their students in ‘collaborative problem-solving’. A second study (BARKLEY2000) consisted of a teacher-training programme where teachers were trained by a master teacher and child psychologist in behavioural treatments. During the
training, teachers were given information about defiant behaviour and
behavioural interventions such as rewarding children for nondisruptive
behaviour, setting up a home token system, time out, response cost and
managing children in public places with ‘think aloud-think ahead’ strategies.
Teachers implemented these behavioural treatments in special treatment
classes.

Multicomponent teacher training versus no intervention

Three studies were identified that compared multicomponent teacher training
with control. The former consisted of teacher training much like that
described above together with other components such as parent interventions
and, at times, child interventions.

In the multicomponent intervention in BARKLEY2000, teachers participated
in a teacher training programme described previously (BARKLEY2000). As a
second component of the intervention, parents were trained in the same way
as teachers by a child psychologist.

In BLOOMQUIST1991, teachers were trained as described above (see
BLOOMQUIST1991). In addition, parents were given seven 90-minute
sessions by a therapist, the aim of which was to provide a comprehensive
educational programme of ADHD, establish a supportive atmosphere among
parents, and present parents with an intensive cognitive-behavioural training
programme similar to the one imparted to teachers. Children were also
trained by school psychologists in a step-by-step framework to guide
problem-solving efforts, which included: problem recognition, generation of
alternative solutions, thinking of consequences for potential solutions,
anticipation of obstacles, and execution of specific behaviours to solve
problems.

In BRASWELL1997, the teacher training component involved a 2-hour in-
service session and five 45-minute in-building sessions. Teachers were trained
via didactic instruction, live and videotaped modelling, and role play.
Teachers were given information regarding ADHD, methods of increasing
compliance and the use of problem-solving methods and self-monitoring
techniques. The multicomponent intervention also consisted of giving parents
information about ADHD in fifteen group sessions of 2 hours’ duration each.
Each session involved didactic presentation, modelling, role-play exercises,
and videotaped examples. Parents received a manual with information and
were given homework assignments for using the trained skills with their
children. The child element of this multicomponent intervention consisted in
children participating in eighteen 45- to 60-minute peer training group
sessions with coleaders (school psychologists trained for this specific role).
Children were also taught skills via didactic instruction, modelling, and role-
play exercises.
Multicomponent teacher training versus teacher training

Two studies were identified that compared the effectiveness of a multicomponent teacher training with teacher training only. BLOOMQUIST 1991 compared multicomponent teacher training involving teacher training, parent and child involvement (see description of BLOOMQUIST 1991) with teacher training only (see description of BLOOMQUIST 1991). BARKLEY 2000 compared the multicomponent teacher training described previously (see description of BARKLEY 2000) with teacher training alone (see description of BARKLEY 2000).

Study information and evidence from critical outcomes and overall quality of evidence are presented in Table 21. Full evidence profiles and associated forest plots can be found in Appendix 19 and Appendix 18, respectively.

Clinical evidence summary

**Teacher-training versus no intervention**

There were two studies that compared teacher-training with no intervention: BLOOMQUIST1991 was conducted in mainstream classes while BARKLEY2000 was carried out in two special treatment classrooms. The quality of the evidence was moderate. There was a small effect (SMD -0.33) of teacher training in mainstream classes on improving children’s conduct problems as rated by teachers. There was little to no effect of teacher training in mainstream classes on children’s ADHD core symptoms when compared with no intervention. However, when looking at teacher training in special treatment classrooms there was a small effect in reducing both children’s ADHD symptoms and conduct problems (SMD range -0.20 to -0.34).

**Multicomponent teacher training versus no intervention**

The quality of the evidence of multicomponent teacher training versus no intervention was low to moderate. The effectiveness of multicomponent teacher training in mainstream classes compared with no intervention in improving children’s conduct problems (teacher-rated) was small to medium (SMD -0.49). There was little to no effect of this intervention on reducing children’s ADHD core symptoms when compared with no intervention. Multicomponent teacher training carried out in special treatment classes had a small effect in reducing teacher’s reports of children’s ADHD core symptoms (SMD -0.27) and conduct problems (SMD -0.34). There was little to no effect of this intervention on improving parents’ ratings of their children’s ADHD symptoms or conduct problems. As mentioned previously, the authors of BARKLEY2000 point out that parent’s attendance to the training programme was poor and this might explain the lack of effectiveness in their ratings.

**Multicomponent teacher training versus teacher training**

The overall quality of the evidence of multicomponent teacher training versus teacher training alone was moderate. This is mainly due to only one study being found that addressed this comparison in mainstream classes and only one study in special treatment classes. There is evidence of a medium effect of multicomponent teacher training in mainstream classes over teacher training alone in reducing children’s ADHD core symptoms as rated by teachers (SMD -0.51). There was little to no effect of this comparison in relation to conduct problems. However, when comparing multicomponent teacher training in special treatment classes versus teacher training alone the evidence favoured teacher training alone in improving children’s ADHD symptoms and conduct problems as rated by parents (SMD 0.31, 0.22, respectively). Poor attendance by parents to parent training programme was reported by authors and could account for the results.
To summarise, there is some evidence that teacher-training and multicomponent teacher-training involving parent training and child interventions have a small effect in improving the behaviour of children with ADHD.

8.5.6 Children with suspected ADHD in the context of disordered conduct.

The Technology Appraisal on Conduct Disorder (NICE, 2006) examined the impact of parent training on children with various conduct problems. Given the large percentage of children with ADHD symptoms and hyperactivity in conduct disordered populations, the GDG decided it would be appropriate that children suspect of ADHD in the context of conduct disorder in the educational setting their parents should have access to parent training (for a detailed discussion of the TA refer to NICE 2006).

8.6 Recommendations

8.6.1.1 The Department for Children, Schools and Families should consider enhancing the education of trainee teachers in the area of ADHD.

8.6.1.2 When children with disordered conduct and possible ADHD are referred to the school SENCO, they should assess the child and contact the parents; consideration should be given to referring the parents to a local parent-training programme.

8.6.1.3 Following diagnosis of a school-age child with ADHD, healthcare professionals should, with the parents' or carers' consent, contact the child's school, and advise on:

- the diagnosis and severity of symptoms and impairment
- the treatment plan
- any special educational needs.

They should offer information on classroom strategies on learning and behaviour.

8.6.1.4 Teachers who have received some training about ADHD and its management should provide behavioural interventions within the classroom to help children with ADHD. [Key priority]

8.6.1.5 When parents with children diagnosed with ADHD undertake parent-training programmes, the professional delivering the sessions should consider contacting the school and providing the child's teacher with written information on the areas of behavioural
management of ADHD covered in these sessions. This should only be done with parental consent.

8.6.1.6 Universal screening for ADHD in primary and secondary educational settings should not be undertaken.

8.7 Research recommendations

8.7.1.1 Effect of providing training in behavioural management of ADHD for teachers

- Does the training of teachers to undertake behavioural management of children with ADHD in the classroom in primary and secondary schools improve their ADHD symptoms and academic attainment, the teacher’s experience of stress in the classroom, and the impact of ADHD on other pupils in the classroom when compared with education as usual? (This would be best conducted as a randomised trial.)

- Why this is important: Secondary school is typically a different environment from primary in matters concerning the organisation of the daily timetable and expectations for increasing independence of pupils. These may impact harshly on young people with ADHD, but the effect of understanding and modifying the impact has not yet been researched. The potential for teachers taking a more active role in behavioural management of primary and secondary school children with ADHD shows some significant promise in at least one trial. The benefits of examining primary and secondary education, both compared with education as usual, and examining the broader impact on the child, the teacher, and the wider classroom would significantly improve future versions of this guideline.

8.7.1.2 Given that inattention is particularly associated with academic underachievement, it is recommended that research be conducted into the effectiveness of interventions for each subtype of ADHD.

8.7.1.3 It is recommended that research is conducted into the ways in which children with problems related to ADHD are currently identified and referred for assessment in schools.
9 Dietary interventions

9.1 Introduction

Dietary interventions in the treatment of ADHD have been widely used and take the form of supplementation with substances thought to be deficient or exclusion of substances thought to be harmful. Research, however, has encountered many difficulties of methodology and feasibility: changes in food and drink are subject to many confounding influences, are difficult to disguise in controlled trials, and may be hard to comply with. Trials often fail to meet the usual criteria of quality for these reasons, or because of poor reporting of methodological details, because of very small numbers, or because most of the studies are based on non-ADHD samples. Furthermore, most of the trial evidence is based on crossover studies that do not lend themselves to a quantitative methodology, especially when pre-crossover scores are not provided. Therefore a narrative, rather than a systematic, approach has been taken for this topic, and any conclusions are correspondingly tentative.

9.2 Elimination diets

Elimination diets were introduced with the ‘Feingold theory’ that implicated artificial colourings, preservatives and cross-reacting natural salicylates in a variety of illnesses including ADHD. Public concern led to several trials being conducted. At present the Feingold diet is not part of conventional management of ADHD.

Multiple idiosyncratic reactions to food and drink have been alleged to lead to hyperactive behaviour (McCann et al., 2007). The notion is that susceptible children can each be affected by one or more substances triggering adverse reactions. Therefore the intervention aims to discover and eliminate from the diet the substances individually implicated for each child.

9.2.1 Elimination of tartrazine and other artificial colourants and preservatives

Several trials have addressed multiple idiosyncratic reactions to food, focusing either on tartrazine, or on mixed additives, or on a range of potentially harmful substances that can vary from child to child. Conners and colleagues (1976) found a significant difference between a ‘Feingold diet’ (excluding artificial additives and natural salicylates) and a ‘placebo’ diet; but the generalisability was limited by unexplained order effects and by doubts over whether there was adequate disguise of the treatment allocation. Harley and colleagues (1978) reported a similar comparison, with enhanced measures...
to preserve the disguise, and found no consistent effects. Williams and colleagues (1978) used a crossover design to compare the administration of additives, methylphenidate, and placebo in a group of 26 children who were known to be responders to stimulant medication. They found that the diet was superior to ‘placebo’ but inferior to medication. By contrast, Levy and colleagues (1978) and Mattes and Gittelman (1981) found no differences between additives and placebo in double-blind crossover designs in small groups of hyperactive children.

9.2.2 Elimination of individually identified food substances

Four published studies have used randomised trial designs to examine the possibility that individual children with ADHD may be adversely affected by foodstuffs that would not influence the behaviour of most children with ADHD.

Two studies (Egger et al., 1985, Carter et al., 1993) have used open trials to identify the foods that affected individual children, and then introduce those identified substances in double-blind crossover design. The incriminated foods varied substantially between children, and included natural foods (for example, cows’ milk, wheat flour, citrus fruit, eggs) as well as artificial colourings and preservatives. Both studies indicated that the results of the open trial could be replicated in a double-blind design: some children were helped by individually designed elimination diets, at least in the short term. One of the studies suggested that children’s responsiveness to incriminated foods was predicted by parents’ informal observations (Carter et al., 1993).

Two studies (Kaplan et al 1989; Schmidt et al 1997) have randomly allocated young people to a diet excluding the commonest provoking substances or a ‘normal’ diet. Both are limited by small numbers, and one (Schmidt et al 1997) by an inpatient sample; but both have reported the superiority of the elimination diet.

There are also potential adverse effects to consider in elimination regimes. They are potentially difficult for families to manage, and might lead to unbalanced diets and nutritional problems; the issue has not been satisfactorily addressed by trials. Good clinical practice suggests that such diets should be embarked on with professional advice and subject to clinical assessment of the child’s needs.

9.3 Supplementation diets

After a preliminary review of studies on supplementation diets, those using fatty acids and zinc were selected as the most promising.
9.3.1 Fatty acids

Long-chain polyunsaturated fatty acids (PUFA) are used for many purposes, including the development of nerve cells and their membranes (see Chapter 2). A deficiency could result either from a restricted diet or from an increased metabolic need. Omega-3 and omega-6 PUFA differ in their chemical structure and potentially in their physiological effects. Different commercial preparations have different proportions of PUFAs.

A few comparisons of fatty acid supplementation have been reported, but for the most part have not met the quality criteria for systematic review. One exception comes from Stevens and colleagues (2003) who randomized 47 children to receive either a proprietary preparation of PUFA or an olive oil placebo. The analysis suggested a small or absent effect: out of ten primary outcome measures, just one (teacher-rated attention) showed a statistically significant difference between PUFA and placebo, and the finding would not have reached significance had allowance not been made for the number of comparisons.

Earlier RCTs did not find benefit from evening primrose oil (providing omega-6 rather than omega-3 PUFA) (Aman et al., 1987). Their generalisability, however, was limited by short treatment period (one month only), which might not have allowed time for the effects of the supplement on brain function.

More recent investigations have considered omega-3 PUFA more specifically. Randomised trials in the US (Voigt et al., 2001) and Japan (Hirayama et al., 2004) have found, respectively, no difference compared with placebo, or differences only in a small number of a wide variety of outcome measures.

Some trials have described behavioural improvements with PUFA supplements in children with other learning difficulties (Richardson & Puri 2002) or developmental coordination disorder (Richardson & Montgomery 2005), but are not considered further here as they were not carried out on children with diagnosed ADHD. Other trials on ADHD have not yet reported their results.

9.3.2 Clinical Evidence Summary

The quality of the evidence for dietary interventions is generally poor, reflecting the paucity of the data.

The evidence that elimination or supplementation diets when compared to placebo may reduce ADHD symptoms is inconclusive.
9.4 Recommendations

9.4.1.1 Healthcare professionals should stress the value of a good and balanced diet, nutrition, and exercise.

9.4.1.2 The elimination of artificial colouring and additives from the diet is not recommended as a generally applicable treatment for ADHD. [Key priority]

9.4.1.3 Clinical assessment for ADHD should include enquiry about foods or drinks that have been noted to influence an individual child’s hyperactive behaviour. If there is a clear link, healthcare professionals should:

- advise that a food diary should be kept
- if the diary supports a relationship between specific foods and behaviour then offer referral to a dietician.

Further management, such as specific dietary elimination should be jointly undertaken by the dietician, mental health specialist or paediatrician, parent, and child. Dieticians should be competent to advise families on how elimination of the suspected foods should be achieved.

9.4.1.4 Dietary zinc and fatty acid supplementation regimens are not recommended for the treatment of ADHD.
10 Pharmacological treatment

10.1 Introduction

The aim of this chapter is to produce evidence-based recommendations to guide the pharmacological management of children, young people and adults with ADHD.

It is over 70 years since the serendipitous observation that stimulant drugs can improve hyperactive behaviour in children (Bradley, 1937). The immediate release stimulant medications methylphenidate and dexamfetamine have been available since the 1960s. From the mid-1990s the level of drug prescribing for ADHD has increased markedly in the UK, coinciding initially with changes in the regulatory framework and more recently with the introduction of modified release (once-daily) methylphenidate preparations (Concerta XL ®, Equasym XL ®, Medikinet XL ®) and the non-stimulant atomoxetine (Strattera ®). Other drugs used less commonly to treat ADHD include clonidine, bupropion, modafinil, imipramine, risperidone and nicotine patches.

Despite a large literature supporting the short-term benefits of stimulant medication in children with ADHD (Spencer et al., 1996), uncertainty still surrounds the balance of risks and benefits of long-term drug treatment (Poulton, 2006). Little empirical evidence is available to guide clinicians on questions such as the optimum duration of treatment, when it is appropriate to consider drug discontinuation and how and when to combine pharmacological and psychological treatments. Furthermore, the increasing use of stimulants in clinical practice has raised concerns about the potential for stimulant drug misuse and diversion. Finally, important clinical questions also relate to the balance of risks and benefits of ADHD drug treatment in less well-studied groups including pre-school children, adults and those with comorbid mental health conditions or learning disabilities.

10.2 Prescribing for children, young people and adults

In the UK, methylphenidate and atomoxetine are licensed for the treatment of ADHD (hyperkinetic disorders) in children aged 6 and over while dexamfetamine is licensed for children from age 4. Methylphenidate and dexamfetamine are not currently licensed for treatment of ADHD in adults, although dexamfetamine is licensed for the treatment of narcolepsy. Atomoxetine is licensed for continued treatment of ADHD in adults when treating was initiated in childhood.
Other less frequently used drugs such as clonidine, bupropion, modafinil, imipramine, risperidone and nicotine patches are not licensed for the treatment of ADHD. However there is some clinical experience of their use in young people with ADHD, particularly those with comorbidities.

In 2000, the Royal College of Paediatrics and Child Health issued a policy statement on the use of unlicensed medicines, or the use of licensed medicines for unlicensed applications, in children and young people. This stated clearly that such use is necessary in paediatric practice and that doctors are legally allowed to prescribe unlicensed medicines where there are no suitable alternatives and where the use is justified by a responsible body of professional opinion (Joint Royal College of Paediatrics and Child Health/Neonatal and Paediatric Pharmacists Group Standing Committee on Medicines, 2000). Similar considerations apply in licensed use of medicines in adults.

10.3 The regulatory framework

Methylphenidate has been used for over 50 years for the treatment of ADHD. Ritalin ® (Novartis Pharmaceuticals UK), an immediate release form of methylphenidate was only available in the UK on a named-patient basis until April 1995 when it was licensed under the trade name Ritalin as a Class B Schedule 2 Prescription-Only Medicine (POM). Subsequently, other immediate release preparations such as Equasym and generic methylphenidate have been made available. These immediate release preparations are licensed as part of a comprehensive treatment programme for ADHD in children aged 6 years and above.

In 1999, the Committee on Safety of Medicines (CSM) were informed that concern had been raised about a recent increase in prescribing of methylphenidate, which may increase the potential for misuse of this drug. The Committee noted the increase in prescribing but were informed that there was a real increase in the diagnosis of ADHD and so a corresponding increase in prescribing was expected. The Subcommittee on Pharmacovigilance proposed that the patient information leaflet might also include the advice that methylphenidate should only be used under the supervision of a specialist.

In 2005 the US Food and Drug Administration (FDA) reviewed data from the FDA’s Adverse Event Reporting System database and identified 12 cases of sudden death in paediatric patients who were being treated with Adderall and Adderall XR (mixed amphetamine salts). Of these cases, five occurred in patients with underlying structural heart defects (abnormal arteries or valves, abnormally thickened walls, and so on), which are all conditions that increase the risk for sudden death. Several of the remaining cases presented problems of interpretation, including a family history of ventricular tachycardia,
association of death with heat exhaustion, dehydration and near-drowning, very rigorous exercise, fatty liver, heart attack, and type 1 diabetes mellitus. One case was reported 3 to 4 years after the event and another had above-toxic blood levels of amphetamine. The duration of treatment varied from one day to 8 years. The number of cases of sudden death reported for Adderall is only slightly greater per million prescriptions than the number reported for methylphenidate products, which are also commonly used to treat paediatric patients with ADHD in the US. When the FDA considered the rate of sudden death in paediatric patients treated with Adderall products based on the approximately 30 million prescriptions written between 1999 and 2003 (the period of time in which these deaths occurred), it did not appear that the number of deaths reported was greater than the number of sudden deaths that would be expected to occur in this population without treatment. For this reason, the FDA did not take any further regulatory action at that time. (FDA Alert for Healthcare Professionals Adderall and Adderall XR [amphetamine]). These results cannot be generalised to dexamfetamine as licensed in the UK (http://www.fda.gov/cder/drug/InfoSheets/HCP/AdderallHCPSheet.pdf).

Subsequently, the FDA reviewed reports of serious cardiovascular adverse events in patients taking usual doses of ADHD products (stimulants plus atomoxetine) that revealed 17 sudden death cases (16 with Adderall, 1 with dexamfetamine) including some patients with underlying serious heart problems or defects, and reports of stroke and heart attack in adults with certain risk factors. Furthermore, the FDA review of ADHD medicines revealed a slight increased risk (about 1 per 1,000) for drug-related psychiatric adverse events, such as hearing voices, becoming suspicious for no reason, or becoming manic, even in patients who did not have previous psychiatric problems. In February 2007, the FDA directed the manufacturers of all drug products approved for the treatment of ADHD to develop ‘Patient Medication Guides’\footnote{Patient Medication Guides are handouts given to patients, families and caregivers when a medicine is dispensed. The guides contain FDA-approved patient information that could help prevent serious adverse events.} to alert patients to possible cardiovascular risks and risks of adverse psychiatric symptoms associated with the medicines, and to advise them of precautions that can be taken (http://www.fda.gov/cder/drug/information/adhd/default.htm).

Subsequent analysis did not suggest that the sudden death rate associated with stimulants was higher than the base rate in the population; however, the FDA was unable to draw firm conclusions due to the deficiency of the spontaneous reporting system data and inaccurate estimation of the exposure data. Consequently, the FDA has initiated a large-scale study to investigate the association of sudden death and ADHD treatment, which was still ongoing when this guideline was being prepared in 2007.
Atomoxetine

On 15 September 2005 the Medicines and Healthcare Products Regulatory Agency (MHRA) was informed by the marketing authorisation holder for atomoxetine (Eli Lilly) that clinical trial data had identified a statistically significant increased risk of suicidal thoughts with atomoxetine compared with placebo in children with ADHD. On discussion with the CSM it was agreed that these new data warranted a full risk–benefit evaluation of atomoxetine in its licensed indications, particularly in light of previous concerns about its safety profile including serious hepatic reactions and seizures.

The Pharmacovigilance Working Party of the Committee for Medicinal Products for Human Use (CHMP) considered safety of atomoxetine in January 2006 and advised that the overall balance of risks and benefits of atomoxetine remained positive in its licensed indication but recommended that the amendments to the product information included the potential risk of seizures and QT prolongation.

10.4 Databases searched and inclusion/exclusion criteria for clinical evidence

Information about the databases searched and the inclusion/exclusion criteria used for this section of the guideline can be found in Table 22.

10.5 Studies considered in the systematic review of clinical evidence\textsuperscript{13}

The review team conducted a new systematic search for RCTs that assessed the efficacy and/or safety of pharmacological treatments for children, adolescents and adults with ADHD.

A total of 49 trials relating to clinical evidence met the eligibility criteria set by the GDG, providing data on 7500 participants. All trials were published in peer-reviewed journals between 1976 and 2007. In addition, 537 studies were excluded from the analysis, the most common reason for exclusion was the lack of validated outcome measures (as agreed to by the GDG group) (further information about both included and excluded studies can be found in Appendix 17).

10.6 Methylphenidate (stimulant)

10.6.1 Pharmacology and prescribing

Methylphenidate is a CNS stimulant. The mechanism by which it reduces symptoms in ADHD is not completely clear; however it believed that it increases intrasynaptic concentrations of dopamine and noradrenaline in the frontal cortex as well as subcortical brain regions associated with motivation and reward (Volkov \textit{et al.}, 2004). Methylphenidate blocks the presynaptic membrane dopamine transporter (DAT) and thereby inhibits the reuptake of dopamine and noradrenaline into the presynaptic neuron.

Methylphenidate is rapidly and almost completely absorbed. Owing to its pronounced first-pass metabolism the absolute bioavailability is low at only 30\% (11-51\%) of the dose. Maximum plasma concentrations are reached on average 1-2 hours after administration of 10 mg immediate release (IR) preparation. The maximum plasma concentrations vary considerably between individuals. The relatively short half-life correlates well with the duration of action of 1 to 4 hours for IR preparations. Therefore a twice or three times daily dose is needed. Modified-released preparations have been developed to give longer duration of action: Concerta \textsuperscript{®} (approximately 12 hours), Medikinet XL \textsuperscript{®} and Equasym XL \textsuperscript{®} (approximately 8 hours). The immediate release formulation is normally started at a dose of 5 mg twice, or three times, daily (every 4 hours) at breakfast, lunchtime and late afternoon/early evening. Dosage and frequency can be titrated according to symptom response to a maximum recommended daily dose of 60 mg.\textsuperscript{13}

\textsuperscript{13} Here and elsewhere in the guideline, each study considered for review is referred to by a study ID (primary author and date of study publication, except where a study is \textit{in press} or only submitted for publication, then a date is not used).
With a short duration of action of approximately 4 hours, some patients find the effects of the dose diminish in the evening requiring an additional smaller dose, although a balance needs to be achieved as methylphenidate can cause insomnia.

This multiple dosage regimen also brings with it other difficulties such as the administration of medication at school, which causes problems such as storage of a controlled drug, timing of doses and stigmatisation of the child having to take medication in front of peers. These considerations led to the development of sustained or modified release (MR) preparations of methylphenidate: Concerta XL® (Janssen-Cilag Ltd), Equasym XL® (UCB Pharma Limited) and Medikinet XL®. These medications are taken once daily in the morning (although clinical need may require twice daily dosing) resulting in an initial release of medication similar to the IR formulation followed by a gradual release over 8 to 12 hours.  

10.6.2 Safety and adverse effects

The common adverse effects of methylphenidate include decreased appetite, sleep disturbance, headaches, stomach aches, drowsiness, irritability, tearfulness, mildly increased blood pressure and pulse (Wolraich et al., 2007). Rare but more severe adverse events can include psychotic symptoms and sensitivity reactions requiring discontinuation of the medication.

Weight and growth

While there remains some conflicting evidence regarding weight and growth in children receiving methylphenidate (Bereket et al., 2004; Poulton, 2005), a significant decrease in appetite can lead to a decrease in expected growth during the active period of drug treatment (MTA study, 2004). It is unclear whether final adult height is affected (Poulton, 2005).

Tics

There remains controversy regarding the association of methylphenidate and tics. In a study of children with Tourette syndrome, tics increased only with high doses of stimulant medication and were observed to diminish over time in some of those treated with methylphenidate (Castellanos, 1997). Other studies have found no association between methylphenidate and exacerbations of tics (Gadow et al., 1999).

Pulse and blood pressure

Research regarding the effect of methylphenidate on blood pressure has indicated a small but clinically non-significant effect (average increase <5mmHg) from methylphenidate on blood pressure in short-term use (Findling et al., 2001) with a slight increase in pulse rate (average <5bpm) (Brown et al., 1984). The research on ambulatory blood pressure monitoring of boys who had been receiving the medication for at least 2 months (Stowe et
al., 2002) indicated statistically significant increases in systolic and diastolic blood pressure when the child was awake and a decrease in sleep.

Seizures

The possibility of methylphenidate lowering the seizure threshold for those with epilepsy has been investigated in recent studies in those patients whose seizures were under control. These studies did not find an increase in seizures (Feldman et al., 1989, Gross-Tsur et al., 1997). It is noted in the literature that patients with seizures are generally excluded from the majority of studies regarding treatment for ADHD (Hemmer et al., 2001).

10.6.3 Clinical evidence for methylphenidate

Of the 49 included trials, there were 18 involving a comparison of methylphenidate with placebo or waitlist control. Of these, one trial involved preschool children, 14 involved school-aged children, and three were of an adult population. In all trials, the participants had been diagnosed with ADHD (common comorbidities in school-aged children population included conduct disorder and oppositional defiant disorder and mood, anxiety and psychiatric disorders in the adult population; see Table 23 for the full list or comorbidities) and one trial (KUPIETZ1998) recruited children with ADHD and comorbid developmental reading disorder. One study of school-aged children (BROWN1985) compared methylphenidate with a waitlist control while the other trials used placebo as a comparator (see Table 23).

For methylphenidate statistically significant adverse events and/or with a relative risk greater than 5% are displayed in Figure X. For a full list of adverse events refer to Appendix 18 (forest plot).

Study information and evidence from the important outcomes and overall quality of evidence are presented in Table 23. The full evidence profiles and associated forest plots can be found in Appendix 19 and Appendix 18, respectively.

10.6.4 Long-term evidence review – efficacy

Evidence included

The Multimodal Treatment Study of Children with ADHD (MTA) (MTA Cooperative Group 1999; 2004; 2007) began as a large (n=579) randomised trial where children were assigned to one of the following groups: medication management, intensive behavioural treatment, combination treatment or community care (which included medication for approximately two thirds of the sample). Medication management began with a 28-day, double-blind, daily-switch titration of methylphenidate using five randomly ordered repeats each of placebo or different doses of methylphenidate (5 mg, 10 mg, 15 mg or 20 mg). Clinicians agreed the child’s initial dose. For those not responding adequately to methylphenidate during titration, alternative medications were titrated openly until a satisfactory one was found. Of the 289 subjects assigned to medication management (n=144) and combined treatment (n=145), 256 successfully completed titration. Of these, 198 (68.5%) were assigned to methylphenidate. The remaining titration completers were either openly titrated to dextroamphetamine (n=26) or to no medication (n=32) because of robust placebo response. The children were followed up and results of the MTA study have been reported at 14, 24 and 36 months.

Key findings

At 14 months (MTA, 1999) the outcome strongly favoured careful medication (whether or not in combination with behaviour therapy); at that point the randomisation ended, families were free to choose treatment or not, and the intensive interventions (medication monitoring and behavioural work) were discontinued.

Subsequent reports have provided details of naturalistic follow-up of the groups at 24 (MTA, 2007) and 36 months after randomisation, and conference presentations have outlined preliminary findings at the 8-year point. By the 3-year mark, the outcome was similar for all four groups.

These results have been widely interpreted as showing no long-term impact of medication or behaviour therapy. While this is one possible reading, it is not demonstrated by the study and other explanations need to be considered.

First, the end of randomisation entails that patients and families select which intervention is best for them. This may lead to a situation in which each individual gets whatever combination suits them best, so all interventions would have reasonably good outcomes.
Second, the end of intensive therapy could mean that any effects additional to those of usual good treatment wane when the intensity is reduced: therefore all treatment arms become similar to community treatment.

Third, the absence of an untreated control group makes it impossible to know whether the treatments were better than not intervening. Outcome scores at 36 months remained considerably better than the levels before treatment; the conclusion may be that all treatments work rather than that none do.

Fourth, the MTA investigators did not report that the treatments had no effect. They agreed that there was some evidence of medication benefit when the results were analysed by growth mixture modelling, which divides the sample into latent classes based on their trajectory over time. The best fit was three classes. One of the classes (34% of the sample) showed gradual improvement with continuing benefit from medication over the entire 3 years. The second class (52% of the sample) had an initial large response, maintained for 3 years; in another 14% a large initial response was followed by deterioration. In the second group who responded well, there was a significant preponderance of children who had been assigned to the intense MTA medication algorithm in the first 14 months, whether or not they continued medication.

Adverse events at the 24- and 36-month points after randomisation included influences on growth in height and weight—an effect of 0.75 inches at the 2-year mark, with no further loss at the 3-year point and (in conference reports) catch-up growth by the 8-year point, suggesting no growth suppression in that time scale.

It would therefore not be correct to regard behaviour therapy or stimulant medication as short-term treatments only.

10.6.5 Long-term evidence review – harm

Evidence included

The safety of the use of methylphenidate was further assessed by examining long-term data. Nine sources of long-term use of methylphenidate met the eligibility criteria set by the GDG: a cross-sectional study involving hyperactive children receiving the drug for at least 4 months but not longer than 18 months and where data was obtained after 5 years of initial assessment (Weiss et al., 1975); a 4-year follow-up study of children with ADHD receiving methylphenidate (Spencer et al., 1996); a 3-year follow-up of the MTA study of 370 children with ADHD of which 70 had received consistent medication management, 88 were newly medicated, and 147 had been inconsistently medicated (Swanson et al., 2007); a 2-year RCT observational follow-up of 34 children with ADHD and either chronic motor
tic disorder or Tourette syndrome taking methylphenidate (Gadow et al., 1999); a 2-year cohort study of 61 young adults who were treated with methylphenidate hydrochloride in childhood for at least 6 months (Gittelman-Klein et al., 1988); a review of three short-term RCTs (1 to 4 weeks) and two open-label studies lasting 2 years (only the two long-term studies are reported on within this section; the short-term data is summarised in following section) (Palumbo et al., 2004); a 4-month RCT of children with ADHD assigned to either methylphenidate or placebo (Schachar et al., 1997); a safety review assessing sudden deaths associated with the use of central nervous stimulants (Villalba et al., 2006); and a safety review by the FDA (FDA, 2004).

Key findings

It was not possible to pool the data of these studies given the different outcome measures used and, in some, the lack of variability measures reported. There is some indication that children’s height (Swanson et al., 2007) and weight (Swanson et al., 2007; Schachar et al., 1997) is affected by the use of methylphenidate. However, in some studies this difference failed to reach statistical significance (Spencer et al., 1996; Gadow et al., 1999; Gittelman-Klein, 1988) or the growth curve increased after methylphenidate was discontinued (Weiss et al., 1975).

There is evidence of tics in children taking methylphenidate (Gadow et al., 1999; Palumbo et al., 2004). In terms of emotional factors, one study (Weiss et al., 1975) found no significant differences between children taking methylphenidate and those taking placebo with respect to emotional adjustment, delinquency or the mother-child relationship. In a follow-up study of children with ADHD treated with methylphenidate (Gadow et al., 1999) condition effects were evident for systolic blood pressure and heart rate, but not diastolic blood pressure.

In 2006 the US FDA conducted a review on reports of sudden death in patients treated with ADHD medications using data from their Adverse Event Reporting System (AERS). The review identified 14 paediatric and four adult sudden death cases reported with methylphenidate between January 1992 and February 2005. The review reported that none of them appears solely or directly related to methylphenidate. Six of the 14 paediatric sudden deaths occurred in children with structural cardiovascular abnormalities that likely preceded the use of methylphenidate.

The review concluded that the rate of sudden death with methylphenidate and atomoxetine was below background rates available. However, no definitive conclusions can be drawn from the analyses of AERS cases due to

---

34 The review also investigated Adderall and Adderall XR (amphetamine/dextroamphetamine) which were not marketed in the UK at the time of this guidance was being prepared.
the inherent limitations of the AERS and uncertainty regarding information on drug utilisation and background incidence of sudden death. Further studies are being conducted by the FDA at the time this guideline was being prepared (January 2008).

10.6.6 Drug misuse and diversion
The available research is primarily with open trials with few RCTs to indicate the most efficacious treatment approaches. The open trials have indicated improvement in ADHD symptoms and no worsening of substance misuse (Wilens et al., 2005).

Bukstein (2006) found that there is a risk of drug diversion, misuse (intravenous use causes euphoria, or cognitive enhancement), psychiatric comorbidity and adherence issues with adolescents and adults with ADHD requiring detailed assessment and consideration of treatment options prior to decisions being made regarding treatment for ADHD.

There is no evidence of significant interactions and no contraindication to stimulant prescribing in the presence of alcohol and cannabis consumption. Concomitant cannabis and stimulant use in those with a family history or past history of psychosis should be closely monitored.

Stimulants are controlled drugs and have the potential for misuse and diversion. However, in UK clinical practice, the reported rate of misuse by patients is very low and confined to methylphenidate immediate release preparations and dexamfetamine and to patients with known conduct disorder or substance misuse problems. A meta-analysis suggests that treatment (usually including stimulants) for ADHD reduces the risk of the misuse of drugs other than those used to treat ADHD by two fold (Wilens et al., 2003). However, results from the MTA suggest that behaviour therapy may be the key treatment component. Reasons for a reduced risk of substance misuse with stimulant treatment may include reduced impulsivity and conduct disorder symptoms and improved academic performance and family relations.

10.6.7 Clinical evidence summary
For individual outcomes, the quality of the evidence was generally moderate to high.

Methylphenidate in preschool children
Only one study (KOLLINS2006) evaluated the effect of methylphenidate in preschool children. There is small clinical improvement (RR 1.61) in preschool children taking methylphenidate when compared with placebo. However,
this result is not statistically significant and therefore the evidence is inconclusive.

Methylphenidate in school-aged children
In school-aged children, there is evidence that methylphenidate when compared with placebo or waiting list produced a medium to large effect in reducing children’s ADHD symptoms and conduct problems.

There is some indication that there is improvement in outcomes when increasing the dose.

Methylphenidate (high dose) is more likely than placebo to cause the following side effects: insomnia, anorexia, increased irritability, moodiness, thirst, itching, diarrhoea, palpitations, stuttering, negativism, reddened eyes, incoherent speech, and decrease in bodyweight.

The long-term studies of methylphenidate indicate an increased risk of side effects, systolic blood pressure and heart rate problems. The association between the use of methylphenidate and sudden death is not clear given the lack of background rates.

Special circumstances – ADHD comorbid with developmental reading disorder
Only one study, KUPIETZ1988, compared methylphenidate with placebo in an ADHD population comorbid with developmental reading disorder. Methylphenidate in low, medium and high doses is effective in reducing children’s ADHD core symptoms. The evidence suggests that methylphenidate when compared with placebo may reduce the risk of discontinuation.

Conclusion (methylphenidate in children)
Methylphenidate is effective in reducing ADHD core symptoms and conduct problems in children with ADHD. There is evidence suggesting that methylphenidate may increase side effects.

Methylphenidate in adults
In adults with ADHD, methylphenidate (high dose) showed evidence of a reduction in ADHD symptoms as rated by an investigator but a small effect of improvement in medium doses as measured from self-reports. There was also evidence of global clinical improvement when compared with placebo.
Only one RCT (BIEDERMAN2006A) assessed side effects and indicated that methylphenidate (high dose) is more likely than placebo to cause the following side effects: decreased appetite, gastrointestinal problems, tension, cardiovascular complaints, depression, dizziness, anxiety, autonomic symptoms, increased energy, tics, skin problems, bruising, and sexual problems. Methylphenidate may reduce the risk of discontinuation when compared with placebo.

Long-term studies of side effects in adults are scarce but the safety reviews indicated an association between the use of methylphenidate and sudden death, however the evidence is inconclusive given the lack of background rates.

**Conclusion (methylphenidate in adults)**

Methylphenidate is effective in reducing ADHD core symptoms and in producing clinical improvement as rated by investigators in adults with ADHD. There is evidence suggesting that methylphenidate may increase side effects.

**10.7 Dexamfetamine (stimulant)**

**10.7.1 Pharmacology and prescribing**

Dexamfetamine is a more potent stimulant than methylphenidate. In addition to blocking the reuptake of dopamine and noradrenaline via the dopamine transporter (DAT) it also releases dopamine and noradrenaline into the extraneuronal space by blocking the intraneuronal vesicular monoamine transporter (VMAT).

Dexamfetamine is readily absorbed from the gastrointestinal tract. It is resistant to metabolism by monoamine oxidase. It is excreted in the urine as an unchanged parent drug together with some hydroxylated metabolites. Elimination is increased in acidic urine. After high doses, elimination in the urine may take several days. The apparent elimination half-life of dexamfetamine in children is 6.8 hours, which suggests that once or twice daily dosing is sufficient (Brown *et al.*, 1979).

In children for the treatment of hyperkinetic states, the usual starting dosage for 3 to 5 year-olds is 2.5 mg a day, increased if necessary by 2.5 mg a day at weekly intervals; for 6 year-olds and over, the usual starting dose is 5-10 mg a day increasing if necessary by 5 mg at weekly intervals. The usual upper limit is 20 mg a day though some older children have needed 40 mg or more for optimal response (Summary of Product Characteristics for Dexedrine Tablets 5 mg).
### 10.7.2 Clinical evidence for dexamfetamine

There was only one study that involved a comparison of dexamfetamine with placebo in adults with ADHD (PATERSON1999), which involved 45 adults.

Study information and evidence from the important outcomes and overall quality of evidence are presented in Table 24. The full evidence profiles and associated forest plots can be found in Appendix 19 and Appendix 18, respectively.

10.7.3 Evidence from the Technology Appraisal

No efficacy studies were available for meta-analysis meeting basic quality criteria. In children, adverse effects are unknown (mixed amphetamine salts were not included in the analysis).

10.7.4 Long-term clinical evidence review

Evidence included

Long-term data of the use of dexamfetamine was also assessed. There was only one study found that met the criteria set by the GDG: an 8-week RCT of 61 hyperactive boys (Greenberg et al., 1972).

Key findings

Children receiving dexamfetamine complained of decreased appetite and had stomach aches more often than the control groups (hydroxyzine and placebo). Of the dexamfetamine group, two manifested marked regressive, dependent behaviour, and one became overtly psychotic. The intensity of all side effects improved with a decrease in dosage.

10.7.5 Clinical evidence summary

For individual outcomes, the quality of the evidence was moderate reflecting the paucity of the data.

Dexamfetamine in adults

There is some evidence of global clinical improvement in adults taking dexamfetamine when compared with placebo.

There is evidence that dexamfetamine when compared with placebo increases the risk of the following side effects: sleep disturbance, dry mouth, thirst and weight loss. The long-term study indicates the risk of side effects such as decreased appetite, stomach aches and the risk of regressive, dependent behaviour and psychosis.

Conclusion from clinical evidence

There is some evidence of the effectiveness of dexamfetamine in producing global improvement in adults with ADHD. Dexamfetamine may increase the risk of side effects and regressive, dependent behaviour as well as psychosis.

10.8 Atomoxetine

10.8.1 Pharmacology and prescribing

Atomoxetine is a non-stimulant drug licensed for use in children of 6 years and over and adolescents for the treatment of ADHD. Its precise mechanism...
of action in the treatment of ADHD is not clear but it is thought that it works by selectively inhibiting the pre-synaptic noradrenaline transporter thus inhibiting noradrenaline reuptake. While both atomoxetine and stimulants both increase intrasynaptic concentrations of dopamine and noradrenaline in the cortex, it is thought that atomoxetine differs from a stimulant in having less effect on subcortical brain regions associated with motivation and reward.

As it is neither a stimulant medication nor a controlled substance, atomoxetine has less potential for misuse and does not require the same strict prescribing and storage conditions as methylphenidate and dexamfetamine. Atomoxetine is taken as a once-daily dose in the morning, though some patients may benefit from dividing the daily dose and taking it twice daily in the morning and late afternoon or early evening. Atomoxetine is rapidly and almost completely absorbed after oral administration, reaching mean maximal observed plasma concentration (Cmax) approximately 1 to 2 hours after dosing. The absolute bioavailability of atomoxetine following oral administration ranges from 63 to 94%, depending upon inter-individual differences in the modest first pass metabolism. The mean elimination half-life of atomoxetine after oral administration is 3.6 hours in extensive metabolisers and 21 hours in poor metabolisers. Approximately 7% of Caucasians have a genotype corresponding to a non-functional CYP2D6 enzyme (CYP2D6 poor metabolisers). Patients with this genotype have a several-fold higher exposure to atomoxetine when compared with patients with a functional enzyme. Poor metabolisers may be at higher risk of adverse events. For patients with a known poor metaboliser genotype, a lower starting dose and slower up titration of the dose may be considered. However, given that 2D6 status is rarely known for an individual patient, a low starting dose and slow titration will reduce the risk of adverse events.

10.8.2 Safety and adverse effects
Common adverse effects associated with atomoxetine include abdominal pain, nausea and vomiting, decreased appetite with associated weight loss, dizziness and slight increases in heart rate and blood pressure (Wolraich et al., 2007). These effects are normally transient and may not require discontinuation of treatment. Very rarely, liver toxicity, manifested by elevated hepatic enzymes and bilirubin with jaundice, has been reported. Seizures are a potential risk for atomoxetine (Summary of Product Characteristics for Eli Lilly, 2007). Suicide-related behaviour (suicide attempts and suicidal ideation) has been reported in patients treated with atomoxetine. In double-blind clinical trials, suicide-related behaviours occurred at a frequency of 0.44% in atomoxetine-treated patients (6 out of 1,357 patients treated, one case of attempted suicide and five of suicidal ideation). The age range of children experiencing these events was 7 to 12 years. There were no events in the placebo group (n = 851). It should be noted that the number of
adolescent patients included in the clinical trials was low (Summary of

10.8.3 Clinical evidence for atomoxetine

Of the 49 included trials 14 included a comparison of atomoxetine with
placebo. Of these, 11 were of school-aged children and 3 were of adults. In all
trials, participants had been diagnosed with ADHD (common comorbidities
included Oppositional Defiant Disorder and Conduct Disorder). One study
(ALLEN2005) recruited school-aged children with ADHD and comorbid Tic
Disorders. One study (WANG2007) involved a comparison of atomoxetine
with methylphenidate.

One trial (NEWCORN2006) included a comparison of atomoxetine low dose
(0.5mg/kg/day) with atomoxetine high dose (1.8mg/kg/day) in children
with ADHD. Another trial (ADLER2006), included a comparison of
atomoxetine once daily with atomoxetine twice daily in adults with ADHD.

For atomoxetine statistically significant adverse events and/or with a relative
risk greater than 5% are displayed in Figure X. For a full list of adverse events
refer to Appendix 18 (forest plot).

Study information and evidence from the important outcomes and overall
quality of evidence are presented in Table 25. The full evidence profiles and
associated forest plots can be found in Appendix 19 and Appendix 18,
respectively.

10.8.4 Long-term clinical evidence review

Evidence included

Long-term data of the use of atomoxetine was examined. There was only one study (a review of three 1-year follow-up studies of children and adolescents with ADHD taking atomoxetine; Wernicke et al., 2003) found that met the criteria set by the GDG as well as one safety review mentioned previously (Villalba et al., 2006).

Key findings

The evidence is inconclusive regarding the increase of heart rate and blood pressure with the use of atomoxetine.

The safety review found seven cases of sudden death (three children and four adults) of which one had lymphocytic myocarditis and two had toxic levels of olanzapine or a possible seizure preceding death; none of these patients had prior history of cardiovascular problems or cardiovascular structural abnormalities. The review reported that none of the cases appears solely or directly attributable to atomoxetine at therapeutic doses. The cases were highly confounded. None of the patients had structural cardiovascular abnormalities. However, the extent of the role of atomoxetine in these deaths is difficult to establish. Further studies are being conducted by the FDA at the time this guideline was being prepared (January 2008).

10.8.5 Clinical evidence summary: atomoxetine

For individual outcomes, the quality of the evidence was generally moderate to high.

Atomoxetine in school-aged children

There is evidence that atomoxetine has a small to medium effect in reducing ADHD core symptoms in children with ADHD, as rated by both parents and teachers. In one outcome measure (ADHD core symptoms as rated by teachers) the effect was large when children were given a high dose of atomoxetine. With respect to conduct problems, there was a small effect in the reduction of these as reported by parents and no effect when reported by teachers, although this data was only from one study (MICHELSON2004).

There is some evidence of global clinical improvement (RR 1.46) in children taking a high dose of atomoxetine when compared with placebo groups.

The evidence suggests there is a slight improvement in reducing children’s conduct problems when the dose of atomoxetine is reduced.
There is evidence that atomoxetine in children with ADHD causes the following side effects: nausea, cough, decreased appetite, dyspepsia, vomiting, asthenia, dizziness, pruritus, somnolence, fatigue, rash, infection, nervousness, and emotional lability. And there is an increase of risk of decreased appetite, dyspepsia and vomiting when dosage is augmented. The evidence suggests there is an increase of risk of discontinuation of atomoxetine when compared with placebo but this risk is not present when children are given high doses of atomoxetine. The safety reviews report sudden deaths in children taking atomoxetine, however given the lack of background rates, no conclusions can be drawn from this data.

Atomoxetine versus methylphenidate

The evidence from one study (WANG2007) indicates that there is little to no difference in efficacy between methylphenidate and atomoxetine in reducing ADHD core symptoms or general clinical improvement. In terms of leaving study early due to adverse events, the evidence suggests that there is an increased risk in adverse events in children taking atomoxetine when compared to methylphenidate.

Conclusion (school-aged children)

Atomoxetine is effective in reducing ADHD core symptoms and clinical improvement in children with ADHD. There is no effect of atomoxetine on children’s conduct problems as rated by teachers. There is evidence suggesting that atomoxetine may increase side effects.

Special circumstances – ADHD comorbid with tic disorder

Only one study (ALLEN2005) compared the effect of atomoxetine with placebo in a population of children with ADHD comorbid with tic disorder. The results indicate that there is a medium effect (SMD -0.56) in the reduction of ADHD core symptoms as rated by parents. The ALLEN2005 study also suggests that there is increased nausea, decreased appetite and risk of discontinuation in children taking atomoxetine.

Atomoxetine in adults

There is evidence of the effectiveness of atomoxetine in reducing ADHD core symptoms in adults with ADHD alone.

There is evidence that atomoxetine increases the risk of side effects in adults with comorbid and non-comorbid ADHD when compared with placebo. Atomoxetine is more likely than placebo to increase the risk of
discontinuation. The safety reviews report cases of sudden death in adults taking atomoxetine. Once again, due to the lack of background rates the evidence is inconclusive.

**Conclusion (adults)**

Atomoxetine is effective in reducing ADHD core symptoms in adults with ADHD. The association between sudden death and the use of atomoxetine in adults is difficult to establish.

### 10.9 Clonidine

**10.9.1 Pharmacology and prescribing**

Clonidine is an alpha2 noradrenergic agonist which is thought to work in ADHD by affecting noradrenaline transmission in the frontal cortex. Clonidine is licensed for the treatment of hypertension, migraine (from age 12) and menopausal flushing. Unlicensed uses of clonidine include the treatment of tics, Tourette syndrome and ADHD.

**10.9.2 Safety and adverse effects**

Common adverse effects of clonidine include sedation and reduction in heart rate.

**10.9.3 Clinical evidence for clonidine**

Two trials were found that included a comparison of clonidine with placebo. One trial (HAZELL2003) was done with a sample of school-aged children with ADHD (common comorbidities included oppositional defiant disorder and/or conduct disorder). The second study (KURLAN2002) involved adults with ADHD and comorbid Tourette syndrome, chronic motor tic disorder or chronic vocal tic disorder. This same study (KURLAN2002) also included a comparison of clonidine with methylphenidate.

For clonidine, statistically significant adverse events and/or with a relative risk greater than 5% are displayed in Table 26. For a full list of adverse events refer to Appendix 18 (forest plot).

Study information and evidence from the important outcomes and overall quality of evidence are presented in Table 26. The full evidence profiles and associated forest plots can be found in Appendix 19 and Appendix 18, respectively.

10.9.4  Clinical evidence summary: clonidine

For individual outcomes, the quality of the evidence was moderate reflecting
the paucity of the data.

Clonidine in school-aged children
There is evidence that clonidine reduces children’s ADHD core symptoms
and conduct problems as well as produces general clinical improvement.
When outcomes were measured by teachers the effect sizes were medium and
small to no effect when outcomes were taken from parent reports.
Clonidine is more likely than placebo to decrease the risk of discontinuation.

Special circumstances – ADHD comorbid with Tourette syndrome, chronic
motor tic or chronic vocal tic disorder
In children with ADHD and comorbid Tourette syndrome, chronic motor tic
or chronic vocal tic disorder, clonidine produced a large effect in reducing
ADHD core symptoms and conduct problems. However, these results are
based on only one study [KURLAN2002].
As in the mixed comorbid ADHD population, clonidine is more likely than
placebo to decrease the risk of discontinuation.

10.9.5  Clinical evidence summary: clonidine versus methylphenidate

In one study of ADHD with comorbid tics (KURLAN2002) there was a small
preference for methylphenidate over clonidine in reducing ADHD symptoms
and conduct problems.

10.10  Bupropion

10.10.1 Pharmacology and prescribing
Bupropion is a selective inhibitor of the neuronal reuptake of noradrenaline
and dopamine. It is licensed as an aid to smoking cessation in combination
with motivational support in nicotine-dependent patients; it is currently not
licensed for patients under 18 years or for the treatment of ADHD (Summary
of Product Characteristics for Zyban, 2007). The mechanism by which
bupropion enhances the ability of patients to abstain from smoking is
unknown. However, it is presumed that this action is mediated by
noradrenergic and/or dopaminergic mechanisms (Summary of Product
Characteristics for Zyban).

10.10.2 Safety and adverse effects
Many adverse events have been reported: dry mouth, gastro-intestinal
disturbances, taste disturbance; insomnia (reduced by avoiding dose at
bedtime), tremor, impaired concentration, headache, dizziness, depression,
agitation, anxiety; fever; rash, pruritus, sweating; less commonly chest pain,
tachycardia, hypertension, flushing, confusion, tinnitus, asthenia, and visual
disturbances; rarely jaundice, hepatitis, palpitation, postural hypotension,
hallucinations, depersonalisation dystonia, ataxia, abnormal dreams, memory
impairment, paraesthesia, blood-glucose disturbances, urinary retention,
urinary frequency, Stevens-Johnson syndrome, and exacerbation of psoriasis;
very rarely delusions and aggression (BNF 2007; Zyban Summary of Product
Characteristics 2007). However, many of these adverse events could also
caused by smoking cessation (Summary of Product Characteristics for Zyban,
2007).

Bupropion is associated with a dose-related risk of seizure with an estimated
incidence of approximately 0.1%. There have been 184 reports in the UK of
seizures suspected as being associated with the use of bupropion (July 2002).
In approximately one half of the reports, patients had either a past history of
seizure(s) and/or risk factors for their occurrence. To reduce the risk of
seizures, bupropion is contraindicated in patients with a current seizure
disorder or any history of seizures, with current or previous diagnosis of
bulimia or anorexia nervosa, with a known central nervous system tumour,
and those experiencing abrupt withdrawal from alcohol or benzodiazepines

10.10.3 Clinical evidence for bupropion

Of the 49 trials, 5 included a comparison of bupropion with placebo. Two of
these studies recruited school-aged children with ADHD (common
comorbidity was conduct disorder). Three trials involved adults with ADHD
(common comorbidities included major depression, anxiety disorders, and
antisocial personality disorder).

Study information and evidence from the important outcomes and overall
quality of evidence are presented in Table 27. The full evidence profiles and
associated forest plots can be found in Appendix 19 and Appendix 18,
respectively.

### 10.10.4 Clinical evidence summary

For individual outcomes, the quality of the evidence was generally moderate to high.

**Bupropion in school-aged children**

There is evidence that bupropion reduces ADHD core symptoms in children with ADHD alone. There is limited evidence that bupropion improves children’s conduct problems as rated by teachers. The evidence is inconclusive whether bupropion improves children’s conduct problems as rated by parents.

One study reports an increase of rash in children taking bupropion when compared with placebo. When compared with placebo, bupropion may increase the risk of discontinuation.

**Conclusion (school-aged children)**

There is some evidence that bupropion is effective in reducing ADHD core symptoms and limited evidence of a reduction in conduct problems in
children with ADHD. There is limited evidence that bupropion may increase the risk of rash.

**Bupropion in adults**

There is some evidence that bupropion when compared with placebo reduces ADHD core symptoms and produces clinical improvement in adults with comorbid and non-comorbid ADHD.

Bupropion is more likely than placebo to produce the following side effects: dry mouth, insomnia, and chest pain as well as increasing the risk of discontinuation.

**Conclusion (adults)**

There is some evidence that bupropion is effective in reducing ADHD core symptoms and producing clinical improvement in adults with ADHD. There is also evidence that bupropion may increase the risk of side effects.

### 10.11 Modafinil

**10.11.1 Pharmacology and prescribing**

Modafinil is an antinarcoleptic and mood-enhancing drug; the pharmacological mechanism by which it acts as both is still under investigation. It has been proposed that modafinil acts on the GABAergic inhibitory network of the thalamic-cortical system, in agreement with the previously described effect on GABAergic networks in sleep and non-sleep-related areas (Urbano et al., 2007).

Modafinil is licensed for the symptomatic relief of excessive sleepiness associated with narcolepsy, obstructive sleep apnoea/hypopnoea syndrome and moderate to severe chronic shift work sleep disorder (Summary of Product Characteristics for Provigil, 2007).

**10.11.2 Safety and adverse effects**

Reported side effects are: dry mouth, appetite changes, gastro-intestinal disturbances (including nausea, diarrhoea, constipation and dyspepsia), abdominal pain; tachycardia, vasodilation, chest pain, palpitation; headache (uncommonly migraine), anxiety, sleep disturbances, dizziness, depression, confusion, abnormal thinking, paraesthesia, agitation, asthma; visual disturbances; less commonly mouth ulcers, glossitis, pharyngitis, dysphagia, taste disturbance, hypertension, hypotension, bradycardia, arrhythmia, peripheral oedema, hypercholesterolaemia, rhinitis, dyspnoea, dyskinesia, amnesia, emotional lability, abnormal dreams, tremor, decreased libido, weight changes, hyperglycaemia, urinary frequency, menstrual disturbances, eosinophilia, leucopenia, myasthenia, muscle cramps, dry eye, sinusitis,
epistaxis, myalgia, arthralgia, acne, sweating, rash, and pruritus (BNF 2007; Summary of Product Characteristics for Modafinil, 2007).

For modafinil, statistically significant adverse events and/or with a relative risk greater than 5% are displayed in Table 28. For a full list of adverse events refer to Appendix 18 (forest plot).

10.11.3 Clinical evidence for modafinil

Of the 49 studies included only 5 involved a comparison of modafinil with placebo. All trials were of school-aged children with ADHD (common comorbidities included oppositional defiant disorder, conduct disorder, learning disorder, phobias and separation anxiety).

Study information and evidence from the important outcomes and overall quality of evidence are presented in Table 28. The full evidence profiles and associated forest plots can be found in Appendix 19 and Appendix 18, respectively.

10.11.4 Clinical evidence summary

For individual outcomes, the quality of the evidence was generally moderate to high.

Overall, the evidence shows that modafinil when compared with placebo has a medium effect in reducing ADHD symptoms, conduct problems as well as producing general clinical improvement. Adverse effects include an increased risk of insomnia, decreased appetite, pain, vomiting, stomach ache, headache, tearfulness, irritability, tonsillitis, and pharyngitis.

Modafinil reduced the risk of discontinuation in children with ADHD.

No data were available for modafinil in adults.

10.12 Antidepressants

10.12.1 Pharmacology and prescribing

Tricyclic antidepressants (TCAs) are thought to block the synaptic reuptake of monoamines including 5-hydroxytryptamine (5HT or serotonin), noradrenaline and dopamine. TCAs have gradually been replaced in clinical practice by SSRIs and SNRIs which block the uptake of 5HT and noradrenaline respectively.

10.12.2 Safety and adverse effects

TCAs have significant side effects and high toxicity in overdose. Concerns regarding potential cardiotoxicity of desipramine have led to its withdrawal in the UK. There is limited evidence that SSRIs and SNRIs may increase the risk of suicidal ideation and/or behaviour.

10.12.3 Clinical evidence summary

There is no evidence that TCAs, SSRIs or SNRIs are of value in the treatment of the symptoms of ADHD.
10.13  Atypical antipsychotics

10.13.1 Pharmacology and prescribing
Atypical antipsychotic drugs such as risperidone are most often used to treat psychoses (including schizophrenia). Atypical antipsychotic are also used to treat some forms of bipolar disorder, psychotic depression, obsessive-compulsive disorder, Tourette syndrome, and autistic spectrum disorders. The atypical antipsychotics have found favour among clinicians and are gradually replacing the typical antipsychotics. The mechanism of action of these agents is unclear but it is thought that these drugs are D2 receptor antagonist and 5-HT2A receptor antagonist. The receptor binding profile of the atypical antipsychotics varies substantially, and this variability may be responsible for clinical differences.

10.13.2 Safety and adverse effects
The side effect profile of atypical antipsychotics includes increased appetite, weight gain and metabolic disturbances.

10.13.3 Clinical evidence summary
There is no evidence that atypical antipsychotics are of value in treatment of the symptoms of ADHD.

10.14  Efficacy/ harms in special circumstances
Pharmacological treatment may need to be more cautious in special circumstances such as specific comorbid conditions due to the possible increase of risk of medicat issues.

The search for randomised controlled trials identified studies of pharmacological treatment of children with ADHD and comorbid developmental reading disorder (see section 10.7.6), tic disorder (see section 10.8.5), Tourette syndrome, chronic motor tic or chronic vocal tic disorder (see section 10.9.4). However, there were no studies identified that met the quality assessment criteria for children with ADHD and comorbid learning disability and/or developmental disorders.

The GDG identified relevant literature, discussed and consensus agreement was reached about possible risks and/or benefits of drug treatment.

Treatment of ADHD in individuals with autism or learning disabilities should follow the guidelines as described however there needs to be careful assessment prior to the decision to use medication due to the increased risk of medical issues. Treatment may need to be more cautious if there are significant neurological problems due to the increased risk of side effects. In
those individuals who have difficulty communicating careful consideration needs to be given to enable them to take part in discussions about their medication and to monitor the effects of the medication. Carers will also have a pivotal role in carefully monitoring and looking for any evidence of side effects in those patients unable to engage with discussion about their medication.

While the pharmacological treatment of ADHD in the context of autism can be effective in reducing the core features of ADHD, careful monitoring is required due to the possibility of exacerbating the ritualistic behaviours and stereotypies.

10.14.1 Quality of evidence reviewed

The quality of the evidence reviewed was generally moderate to low. Efficacy studies were typically of short duration only (median, range?) and authors were usually not explicit regarding the inclusion or exclusion of ADHD comorbidities. Most studies compared a single active drug with placebo. There are few direct ‘head-to-head’ comparisons of active drugs.

Interpretation of harm-related outcomes was limited to a small number of short-term clinical trials that reported harm data. Overall, adverse events have been reported infrequently and poorly, and further research is recommended.

10.15 Conclusion from clinical evidence

Methylphenidate and atomoxetine are the only drugs where clear evidence exists for clinical effectiveness in reducing ADHD symptoms in school-age children, adolescents and adults. When compared with placebo, the size of clinical effect is largest for methylphenidate. Only one study involved a head-to-head comparison between the two drugs and the results indicated that there are no significant differences in terms of its effectiveness in children with ADHD.

Methylphenidate and atomoxetine have a similar adverse event profile with respect to effects on appetite, growth, pulse and blood pressure requiring similar monitoring. Rarer harm events associated with atomoxetine include increased risk of suicidal behaviour and hepatic damage. There is no evidence from high-quality controlled trials for the efficacy of dexamfetamine in children and only one trial supporting improvement in adults.

There is some limited evidence that the off-label use of modafinil, clonidine and bupropion reduces symptoms of ADHD in children (and adults for bupropion) while these drugs all produce more adverse effects than placebo.
### 10.16 Health economics evidence

#### 10.16.1 Pharmacological treatment in children and adolescents with ADHD

The systematic literature search identified 5 economic studies that assessed the cost-effectiveness of specific pharmacological treatments compared to placebo or other pharmacological treatments for children with ADHD, including the economic analysis undertaken to support NICE guidance on the use of methylphenidate, atomoxetine and dexamfetamine in this population (Donelly et al., 2004; Gilmore & Milne, 2001; King et al., 2006; Narayan & Hay, 2004; Zupancic et al., 1998). Of the identified studies, one was conducted in the US, one in Canada, one in Australia, and two in the UK. Details on the methods used for the systematic search of the economic literature are described in chapter 3. Information on the methods used and the results reported in all economic studies included in the systematic literature review are presented in the form of evidence tables in Appendix 14.

Gilmore and Milne (2001) performed a cost-utility analysis to assess the cost-effectiveness of methylphenidate compared to no treatment, in children aged 6-12 years with hyperkinetic disorder in the UK. The study was based on decision-analytic modelling, using a time horizon of one year. The perspective of the analysis was that of the NHS; costs included drug acquisition costs and outpatient clinic costs. The measure of outcome was the number of Quality Adjusted Life Years (QALYs) gained by use of methylphenidate compared to no treatment. Clinical effectiveness was based on a systematic review of the literature; no meta-analysis of the clinical studies was undertaken. QALYs were generated using the Index of Health Related Quality of Life (IHRQL) and a number of assumptions regarding the Health-Related Quality of Life (HRQoL) of children with hyperkinetic disorder responding or not responding to treatment. Resource use data were based on expert opinion. The ICER of MPH compared to no treatment was found to be £9,177 per QALY gained (1997 prices). In sensitivity analysis, this ratio ranged from £5,782 to £29,049 per QALY gained. The authors concluded that short-term treatment of hyperkinetic children with methylphenidate was a cost-effective option from the point of view of the NHS. The major limitations of the analysis were the lack of systematic search of the literature for evidence on the clinical effectiveness of methylphenidate, the use of IHRQL for the measurement of HRQoL in the study population, which was considered quite insensitive by the authors, and the further assumptions made in order to estimate the number of QALYs gained with therapy.

Donelly and colleagues (2004) evaluated the use of methylphenidate and dexamfetamine compared to standard care, which included contacts with health professionals but no medication, in children with ADHD in Australia. The study was based on decision-analytic modelling. Clinical effectiveness data were derived from meta-analysis of studies identified in a systematic literature review. Data on the severity of ADHD in Australia and the usage of...
health services by the study population were taken from a national survey. The study adopted the Australian health services perspective, including costs to the health care sector and to the children’s families. The measure of outcome was the number of Disability Adjusted Life Years (DALYs) averted by use of medication compared to standard care. The time horizon of the analysis was one year. The Incremental Cost Effectiveness Ratio (ICER) of methylphenidate versus standard care was found to equal approximately Aus$15,000 per DALY averted (95% CI: Aus$9,100 to Aus$22,000 per DALY averted), while the ICER of dexamfetamine versus standard care was Aus$4,100 per DALY averted (95% CI: dexamfetamine dominant to $14,000 per DALY averted). The cost year was 2000. In the comparison between the two medications, dexamfetamine was the dominant option, as its effectiveness was similar to that of methylphenidate but its cost was significantly lower. The authors concluded that both medications were cost-effective compared to standard care; given that dexamfetamine, but not methylphenidate, was partially subsidised by the government, methylphenidate might be more attractive financially for the government while dexamfetamine was more cost-effective from the perspective of the family.

Potential limitations of the study, as acknowledged by the authors, were the difficulty in determining the change in disability weights resulting from pharmacological treatment, as well as possible publication bias affecting the clinical effectiveness data used in the analysis. In addition, the study did not consider the treatment of frequently coexisting comorbidities, the long term side effects of medication, and also the long term educational, occupational, criminal and social outcomes and the resulting cost-savings associated with provision of medication in children with ADHD. The authors estimated that had they considered all the above factors, medications might prove to be overall more cost-effective than demonstrated.

Narayan and Hay (2004) assessed the cost-effectiveness of methylphenidate, amphetamine/dexamfetamine mixed salts (AMP/DEX), and no treatment in children with ADHD in the US. The study was based on decision-analytic modelling. Clinical and cost data were derived from a literature review. The perspective of analysis was stated to be societal, but indirect costs (i.e. productivity losses) were not taken into account at the estimation of costs. Costs included healthcare costs (costs of drugs, outpatient visits, and laboratory tests), school administration costs, as well as out-of-pocket expenses. Outcome was expressed in QALYs, generated using the IHRQL. The time horizon of the analysis was one year. The study demonstrated that methylphenidate was dominated by AMP/DEX (meaning that methylphenidate was more expensive and less effective than AMP/DEX). The ICER of AMP/DEX versus no treatment was US$21,957 per QALY gained in 2003 prices (the ICER of methylphenidate versus no treatment was roughly US$50,000 per QALY gained). Results were robust under most scenarios examined in sensitivity analysis. The major driver of cost effectiveness results was the relative compliance of the two medications; utility weights were also
important factors affecting the cost effectiveness of medications compared to no treatment. The authors’ conclusion was that both medications were cost-effective compared to no treatment and that it was difficult to make strong conclusions about the relative cost effectiveness between medications, given their essentially equal efficacy and similar side effect profiles. The limitations of the analysis were the lack of systematic review and meta-analysis of clinical studies of the assessed interventions, and the short time horizon that didn’t allow long term benefits and harms of medication to be considered.

Zupancic and colleagues (1998) assessed the cost effectiveness of methylphenidate, dexamfetamine, pemoline, psychological/behavioural therapy and combination therapy (consisting of psychological/behavioural therapy and methylphenidate) in comparison to no treatment from the perspective of a 3rd party payer in Canada. A decision-analytic model with a time horizon of one year was developed for this purpose. The clinical effectiveness data were derived from meta-analysis of studies included in a systematic literature review. Resource estimates were based on expert opinion and a published survey. Costs of medications included acquisition costs, costs of contacts with health professionals, laboratory testing costs, as well as hospitalisation costs associated with management of toxic hepatitis associated with use of pemoline. Costs of psychological/behavioural therapy included contacts with psychologists, alongside with parent and teacher training. The outcome of the analysis was the change in the Conners Teacher Rating Scale (CTRS) score. The meta-analysis of the clinical studies concluded that the efficacy of methylphenidate, dexamfetamine and pemoline was comparable. In the economic analysis, methylphenidate was found to dominate dexamfetamine. This result was robust under the majority of scenarios explored in sensitivity analysis. The ICER of methylphenidate versus no treatment was Can$64 per point change in the CTRS score, or Can$384 per 6-point change in the CTRS score, which was considered as a clinically significant difference. The ICER of pemoline versus methylphenidate was Can$246 per point change, or Can$1,476 per 6-point change in the CTRS score (1997 prices). However, there were concerns about the drug’s safety, as pemoline is associated with potentially fatal hepatic failure. The results of the analysis relating to other treatments (psychological/behavioural and combination therapy) are provided in chapter 11. The authors reported as a general limitation of the analysis the heterogeneity characterising the treatments assessed and the outcome measures across published trials, which did not allow for a comprehensive synthesis of data and a robust comparison across the treatment options evaluated. More specifically, the number of trials for each treatment strategy was small, resulting in wide 95% CIs of the efficacy data. Also, the meta-analysis was limited to effects of treatment measured by changes in CTRS score, as no dichotomous measures, indicating a clinically significant improvement, were available for all options. Subsequently, in order to interpret the results of the economic analysis, it was assumed that treatment efficacy was constant across different levels of ADHD.
severity. Additional concerns were expressed regarding the harms of pemoline, and the fact that mortality from hepatic failure was not captured in the measure of outcome used. Considering also the last point, methylphenidate was probably the most cost-effective among the medications assessed in the analysis.

10.16.2 NICE guidance on the use of methylphenidate, atomoxetine and dexamfetamine for children and adolescents with ADHD.

King and colleagues (2006) conducted an economic analysis to assess the cost-effectiveness of methylphenidate, atomoxetine, and dexamfetamine in children and adolescents with ADHD. As this evidence was used to support the recent NICE guidance on this area (NICE 2006), it is discussed in more detail.

The analysis was based on decision-analytic modelling. The medications assessed were instant-release methylphenidate, 2 forms of extended-release methylphenidate with 8 and 12 hours action respectively, atomoxetine, and dexamfetamine. The analysis evaluated the use of these medications alone, as well as in combination with behavioural therapy. The economic model considered alternative sequences of treatments in a hypothetical cohort of children with ADHD aged 6 years. The time horizon of the analysis was one year. Children not responding to one treatment or withdrawing treatment owing to the presence of intolerable side effects were assumed to move to the next treatment in line, until they reached no treatment at the end of the sequence. Children responding to treatment remained on therapy and continued being responsive for the remaining of the year. It was assumed that no intolerable side effects developed after the titration period, and, therefore, any side effects experienced after titration were relatively minor and tolerable and did not lead to discontinuation of treatment. A secondary analysis extended the time horizon of the analysis until children reached 18 years of age.

Preliminary analysis showed that strategies consisting of 3 lines of active treatment were cost-effective compared to strategies containing only one or 2 lines of treatment. For this reason, the results presented for the base-case and sensitivity analyses included strategies consisting of 3 lines of active treatment plus no treatment at the end of the sequence. In total, the analysis examined 18 strategies consisting of all possible 3-line sequences of the medications assessed, and a strategy of no treatment. A secondary analysis considered another 18 strategies of 3-line sequences of combined treatment, making the total number of strategies assessed 37.

The analysis adopted the perspective of the NHS and Personal Social Services (PSS). Costs included medications, contacts with health professionals (GPs, psychiatrists, paediatricians), and laboratory testing. Resource use estimates were based on expert opinion. The price year was 2003. The measure of
outcome was expressed in QALYs. Clinical effectiveness data were taken
from a systematic review of the literature and meta-analysis of RCTs. Only
studies reporting outcomes as response rates to treatment were considered;
first because this type of outcome expressed a clinically meaningful change on
a rating scale, and second because such data would allow a cost-utility
analysis to be conducted (that is, an economic analysis where the outcome is
expressed in QALYs), given that the literature review had identified studies
providing utility data for children with ADHD responding or not to
treatment. The base-case analysis included only clinical studies that defined
response as a score of 0-2 (from completely well to improved) on the Clinical
Global Impression Improvement subscale (CGI-I). Sensitivity analyses relaxed
the criteria of definition of response, and incorporated trials that used other
definitions, such as a 25% or greater reduction in the ADHD-RS score, a score
0 or 1 on the SNAP-IV scale, etc. It needs to be noted, though, that studies
defining response using scales other than the CGI-I were not available for all
interventions under assessment. In order to pool clinical data from all trials
considered in the economic analysis, a mixed treatment comparison model
was developed. Utility weights were based on Coghill and colleagues (2004);
the study generated utility weights for children with ADHD by asking
parents of 142 children with ADHD in the UK to fill in EQ-5D questionnaires
(more details of this study are provided in the economic sections of Chapter
7).

The base-case analysis demonstrated that all treatment strategies consisting of
drug monotherapies followed by no treatment were similar in terms of
QALYs gained. This was expected given the uncertainty surrounding the
relative clinical effectiveness of all pharmacological interventions examined.
Nevertheless, one dominant strategy was identified, which was associated
with the lowest costs and the highest QALYs gained compared with the rest
18 strategies. This strategy was a sequence of 1st line dexamfetamine, 2nd line
instant-release methylphenidate, and 3rd line atomoxetine, followed by no
treatment. Table 29 shows the total costs and benefits associated with the 18
strategies of 3-line drug sequences plus the strategy of no treatment. It can be
seen that strategy 13 incurs the lowest costs and results in maximum health
benefits.

Table 29. Results of the base-case analysis of the economic model developed to support NICE
guidance on the use of methylphenidate, atomoxetine and dexamfetamine for children and
adolescents with ADHD (taken from the NICE assessment report15)

ADHD: full guideline DRAFT (January 2008)
Probabilistic analysis showed that strategy 13 had the highest expected net benefit for willingness-to-pay between 0 and £60,000 per QALY. Sensitivity analysis showed that this strategy remained optimal when additional costs of comorbid conditions were included, when the model was extrapolated until children reached 18 years of age, and when alternative estimates on resource use were tested. In contrast, this result was sensitive to utility weights used. When alternative utility weights were employed (taken from a manufacturer’s submission), then strategy 11 was the optimal strategy. However, the authors acknowledged that this result should be interpreted with caution, owing to limitations characterising the alternative utility data tested. The authors concluded that strategy 13 was clearly an optimal treatment strategy, but acknowledged the limitations of the analysis, such as the use of a subset of the clinical evidence available owing to the need to utilise outcomes reported as response rates, the assumptions required in the model structure owing to lack of data, and the lack of evidence on long term outcomes associated with the evaluated treatments; hence, they highlighted the possibility of a significant change in the results as new data on long term outcomes emerge. Results of the sub-analysis that incorporated combination strategies are reported in chapter 11.

Overall, the review of the economic evidence demonstrated that pharmacological treatments are cost-effective compared to no treatment in children with ADHD. The relative cost-effectiveness of different medications cannot be established with confidence according to this literature, because of the uncertainty characterising their relative clinical effectiveness, the heterogeneity of outcome measures used in the clinical literature that makes synthesis of available evidence problematic, the lack of evidence on long-term benefits and harms of medication, alongside with the lack of comprehensive data on the HRQoL of children with ADHD.

10.16.3 Medication management – economic analysis of the MTA study

The MTA study (MTA Cooperative Group 1999; 2004; 2007), undertaken on children aged 7 to 9.9 years with ADHD combined type in the US,
incorporated an economic analysis that aimed at determining the cost
effectiveness of the interventions assessed in the trial, that is, medication
management, intensive behavioural treatment, a combination of the two, and
routine community care. The economic assessment referred to a follow up
period of 14 months. Two publications provided results of this economic
analysis (Jensen et al., 2005; Foster et al., 2007). Details of these studies are
presented in the form of evidence tables in Appendix 14. The two studies
selected a different measure of outcome as the primary outcome of the
economic analysis. Jensen and colleagues (2005) chose the proportion of
“normalised” children, with normalisation defined by a score 0 or 1 on the
SNAP scale; Foster and colleagues (2007) chose the change on Columbia
Impairment Scale (CIS) effect size (ES). The perspective adopted by both
studies was that of a 3rd party payer, including any costs paid by a patient, an
insurer, or other 3rd parties. Estimated costs included all real treatment costs
of the MTA study, such as drug acquisition costs, costs associated with
healthcare professional contacts (psychiatrists, psychologists, paediatricians
etc), teacher and teacher aides’ costs, but excluded any costs associated with
the research component of the study. Prices referred to year 2000. Results
were reported for four sub-groups of children according to their comorbidity
status: children with ADHD only (32%), children with ADHD and
internalising comorbidities, that is, anxiety or depression (14%), children with
ADHD and externalising comorbidities, that is, conduct or oppositional
defiant disorder (30%), and children with ADHD and both comorbidities
(24%). This section describes the results from the comparison between
medication management and routine community care. Full results of the MTA
economic analysis are provided in chapter 11.

Jensen and colleagues (2005) reported that medication management was more
effective than routine community care in terms of proportion of children
normalised in the total population of children with ADHD as well as in any of
the sub-groups with/without comorbidities. The costs associated with
medication management were higher than costs of routine community care in
all sub-populations, with the exception of children with pure ADHD, in
which medication management was slightly cheaper than routine community
care (US$1,079 versus US$1,131 per child with pure ADHD treated,
respectively). Therefore, in children with pure ADHD, medication
management was dominant over routine community care (more effective and
less costly). The ICER of medication management versus routine community
care for the total population of children with ADHD combined was US$360
per child normalised. The respective ICERs for the sub-groups of children
with comorbidities ranged from US$140 (ADHD plus internalising disorder)
to US$988 (ADHD plus both internalising and externalising disorders) per
child normalised. It was reported that, for the total population of children
with ADHD combined type, the difference in costs and outcomes between
medication management and routine community care were statistically
significant. The authors estimated that the additional costs of medication
strategy over routine community care were modest compared to the large respective gains in the number of children effectively treated, and therefore concluded that, compared to routine community care available in the US, medication management was a cost-effective intervention for children with ADHD, with or without comorbidities.

Foster and colleagues (2007) reported that medication management was more effective than routine community care also when the outcome was measured as a change in functioning, expressed in CIS ES, in all sub-groups of children examined. The authors presented their findings in the form of cost effectiveness acceptability curves (CEACs), which demonstrate the probability of an intervention being the most cost effective among all the interventions assessed at different levels of willingness-to-pay for one unit of outcome gained (in this case one standard deviation of the CIS). CEACs showed that medication management had higher probability of being cost-effective compared to routine community care at any level of willingness-to-pay.

The results of the above studies indicate that medication management is likely to be a cost-effective intervention from the perspective of a 3rd party payer in the US. The authors acknowledged as limitation of their analyses the fact that they did not address potential longer term costs and benefits associated with treatment, as well as broader societal costs, such as parental absence from work and related productivity losses, costs of special education services, and costs of other social services, including the juvenile justice system. Another limitation of the analysis, as stated in Foster et al. (2007), was the inability to generalise the results in other settings, as routine community care may vary considerably across different sites. It must be noted that routine community care described in the study included quite intensive psychosocial therapy (as indicated by high respective costs associated with routine community care), as well as provision of medication, mainly stimulants, in two thirds of the study population; hence, the intervention described in the MTA study may have been more intensive than community care received routinely in the UK.

Schlander and colleagues (2006a, 2006b, 2006c) evaluated the relative cost effectiveness of the interventions examined in the MTA study in the context of 4 European countries, including the UK. Resource use estimates still reflected US practice (taken from the MTA trial), but country-specific unit costs were employed. The perspective of the analysis referring to the UK was that of the NHS (direct medical expenditures). Costs for all countries were calculated in local currencies and then converted to 2005 Euros (€). In addition to previous sub-group distinctions, the authors provided results for children with ADHD combined type (according to DSM-IV), Hyperkinetic/Conduct Disorder (HKD/HKCD) (according to ICD-10), pure ADHD (without comorbidities), and pure HKD (without comorbidities). The measures of outcome used in the economic analyses were the number of children with ADHD normalised, the
CIS ES, and also the QALYs gained by treatment. This section provides the results from the comparison between medication management and routine community care. Results from the comparisons across medication management, intensive behavioural therapy and combination therapy are presented in chapter 11.

The ICER of medication management versus routine community care per normalised child in the UK was found to be approximately €3,720 for ADHD combined type, €3,540 for pure ADHD, €4,000 for HCD/HKCD, and €1,520 for pure HKD (or £2,565, £2,440, £2,760, and £1,050 respectively, using a conversion rate of 1UK£ = 1.45€). When the measure of outcome was the CIS ES, then the ICER of medication management versus routine community care was estimated at roughly €3,000 for ADHD combined type, €2,775 for pure ADHD, €6,730 for HCD/HKCD, and €160 for pure HKD (or £2,070, £1,915, £4,655, and £110 respectively, at a conversion rate of 1UK£ = 1.45€). CEACs demonstrated that for the majority of sub-populations examined, medication management had higher probability of being cost-effective compared to routine community care at any level of willingness-to-pay. However, for children with HKD/HKCD routine community care was likely to be more cost-effective than medication management for low levels of willingness-to-pay, that is, for up to roughly €6,000 (£4,100) per CIS ES. It was also found that for children with externalising comorbidities routine community care was likely more cost-effective than medication management up to a willingness-to-pay of approximately €4,000 (£2,700) per child normalised.

Schlander and colleagues (2006a) provided also a range of ICERs across the 4 European countries considered, with outcomes expressed in QALYs. However, no outcomes specific to the UK were available in the poster presentation. Using the reported costs per child treated in the UK context, the proportions of children normalised in the MTA study in the various sub-populations, and utility weights reported in Coghill et al. (2004), it was possible to estimate the incremental cost per QALY of medication management versus routine community care in the UK context. The estimated ICERs were £33,490 per QALY for ADHD combined type, £32,150 per QALY for pure ADHD, £36,590 per QALY for HCD/HKCD, and £13,990 per QALY for pure HKD. In order to estimate QALYs associated with any treatment option it was assumed that improvement in HRQoL occurred at time zero for responders. It must be noted that decrement in HRQoL from medication was not considered.

The above results suggest that medication management may actually not be a cost-effective option for children with ADHD in the UK, according to the NICE set cost effectiveness threshold (NICE, 2006), apart from the sub-population of children with pure HKD. However, this analysis is characterised by important limitations, as resource use estimates in both medication management and routine community care arms reflect clinical
practice in the US setting, and may not be representative of UK practice.
Therefore, the results of all economic analyses related to the MTA study, even
those referring to the UK context in terms of unit costs used, need to be
interpreted with caution.

10.16.4 Pharmacological treatment in adults with ADHD
The systematic search of the economic literature identified no studies
evaluating the cost effectiveness of pharmacological interventions for adults
with ADHD. Therefore, it was decided to develop an economic model in
order to assess the relative cost-effectiveness of potential first-line medications
in this population. The GDG considered the comparison between
methylphenidate and atomoxetine as most relevant, given the existing clinical
evidence in adults with ADHD. As discussed in chapter 7, clinical
effectiveness data in the form of dichotomous outcomes, such as response
rates to treatment, are the most appropriate to utilise in a cost-utility analysis,
where the measure of outcome is expressed in QALYs. However, no clinical
studies of atomoxetine reporting dichotomous outcomes were identified in
the systematic search of the literature for adults with ADHD. Subsequently, it
was attempted to undertake an economic analysis between methylphenidate
and atomoxetine based on studies reporting outcomes as changes in scores on
scales measuring ADHD symptoms. Again, the clinical data were sparse and
heterogeneous, and did not allow for the development of a decision-analytic
model. More specifically, there were no head-to-head comparisons between
methylphenidate and atomoxetine for adults with ADHD. The economic
analysis would need to be based on indirect comparisons between the two
drugs, with placebo being the common comparator in the available clinical
studies. Two studies assessed the clinical effectiveness of methylphenidate
versus placebo. SPENCER2005 expressed outcome as mean score of AISRS at
endpoint of analysis; KOOIJ2004 expressed outcome as mean score of the
ADHD-RS at endpoint of analysis. On the other hand, the three trials
comparing atomoxetine to placebo in adults with ADHD
(MICHELSON2003a, MICHELSON2003b, and WERNICKE2004b) measured
the mean change in CAARS from baseline to endpoint of analysis. It is evident
that the scales used and the time points of measuring outcome were different
between the studies of methylphenidate and those of atomoxetine. Using
these studies in an economic analysis would introduce bias, would require a
number of assumptions and would, consequently, result in conclusions with
high uncertainty.

Nevertheless, economic considerations are important at the formulation of
clinical practice recommendations. For this reason, a rough cost analysis was
attempted to measure the costs associated with provision of methylphenidate
and atomoxetine in adults with ADHD. Assuming that the health professional
costs for titration and monitoring are similar, the drug acquisition costs over a
year were estimated for the two medications. Provision of generic, instant
release methylphenidate at a daily dose of 60mg costs £30 per month or £360
per year (BNF 54). Extended release methylphenidate at a daily dose of 72mg costs £81 per month or £972 per year (BNF 54 - Concerta XL®). Atomoxetine at a dose of 80mg daily costs £129 per month or £1,548 per year (BNF 54 - Strattera®). Atomoxetine is therefore more expensive than methylphenidate in terms of drug acquisition costs.

The interpretation of all available clinical evidence indicated that methylphenidate is likely to be more effective than atomoxetine in adults with ADHD. Consequently, methylphenidate is possibly a dominant option over atomoxetine as a first line pharmacological treatment in adults with ADHD. However, other factors, such as the presence of intolerable side effects that leads to discontinuation of treatment and initiation of second-line therapy, the management of other side effects, the acceptability of a drug that affects continuation rates, and compliance, are additional factors that need to be assessed, as they may affect the relative cost effectiveness between methylphenidate and atomoxetine.

10.17 Recommendations

10.17.1 Treatment for pre-school children

Drug treatment is not recommended as first-line treatment of pre-school children with ADHD.

10.17.2 Treatment for school-age children with moderate ADHD

Drug treatment is not indicated for all school-age children. It should be reserved for those with moderate ADHD symptoms and impairment who have refused, or whose symptoms have not responded sufficiently to, parent-training programmes or individual psychological treatment, if this has been provided.

Following treatment with a parent-training programme, children with persistent ADHD combined with significant impairment should be offered drug treatment.

10.17.3 Treatment for school-age children with severe ADHD (hyperkinetic disorder)

In children with severe symptoms of ADHD (hyperkinetic disorder) and severe impairment, medication should be offered as the first-line treatment. Families should also be offered a group-based behavioural training programme. [Key priority]

Drug treatment should only be initiated by an appropriately qualified healthcare professional with expertise in ADHD and should be based on a comprehensive assessment and diagnosis. Continued
prescribing and monitoring of drug therapy may be performed by
general practitioners, under shared care arrangements (NICE 2006).

10.17.3.3 If medication is not accepted as a treatment option by the child
or young person with severe symptoms of ADHD, or their parents,
healthcare professionals should advise parents about the benefits and
superiority of drug treatment for this group. If medication is still not
accepted then a group parent-training programme should be offered.

10.17.3.4 If a group parent-training programme was not effective for a
child or young person with severe symptoms of ADHD and
impairment, and if drug treatment has not been accepted, re-discuss
the possibility of drug treatment or other psychological treatment,
highlighting the clear benefits and superiority of drug treatment in
this context.

10.17.4 Baseline pre-drug assessment for children and young people

10.17.4.1 Prior to initiating drug treatment, children and young people
should have a full physical and psychiatric baseline pre-treatment
assessment. This should include:

- standard symptom and side-effect rating scales,
- inquiry about family history of cardiac disease
- full history and physical examination, including assessment of
  exercise syncope, undue breathlessness and other cardiovascular
  symptoms
- ECG if there is past medical or family history of serious cardiac
disease or sudden death in young family members, or an abnormal
  cardiac examination
- height and weight plotted on a growth chart
- full psychiatric assessment
- identification of risk for substance misuse and drug diversion.

10.17.4.2 Drug treatment for children and young people should always
form part of a comprehensive treatment plan that includes
psychological/behavioural and educational advice and interventions.
[Key priority]

10.17.5 Choice of drug for children and young people with ADHD

10.17.5.1 Where drug treatment is considered appropriate,
methylphenidate, atomoxetine and dexamfetamine are
recommended, within their licensed indications, as options for the
management of ADHD in children and adolescents (NICE, 2006).

10.17.5.2 The decision regarding which drug to use should be based on
the following:

- the presence of comorbid conditions (for example, tic disorders,
  Tourette’s syndrome, epilepsy)
- the different adverse effects of the drugs
- specific issues regarding compliance identified for the individual
  child or adolescent, for example problems created by the need to
  administer a mid-day treatment dose at school
- the potential for drug diversion (where the medication is forwarded
  on to others for non-prescription uses) and/or misuse
- the preferences of the child/adolescent and/or his or her parent or
  guardian (NICE 2006).

If there is a choice of more than one appropriate drug, the product with
the lowest cost (taking into account the cost per dose and number of
daily doses) should be prescribed (NICE 06).

10.17.5.3 When a decision to treat children or young people with
medication has been made, methylphenidate should normally be
used as the first-line drug treatment. [Key priority]

10.17.5.4 When prescribing methylphenidate for the treatment of children
or young people, modified release (MR) preparations should be
considered for convenience, improving adherence, reducing stigma
(because the child does not need to take medication at school),
reducing the problems schools have in storing and dispensing a
controlled drug, and because of its smoother pharmacokinetic profile.
Alternatively, immediate release (IR) preparations should be
considered if more flexible dosing regimens are required, or
sometimes during the initial titration to ascertain correct dosing
levels.

10.17.5.5 Atomoxetine is generally used as a second-line treatment, but
may be considered as a first-line treatment in the following
circumstances:

- comorbid tics or Tourette syndrome
- comorbid anxiety disorder
- comorbid stimulant substance misuse. [reserve key rec tk]
10.17.5.6 If methylphenidate at the maximum tolerated dose is ineffective, or if the child or young person is intolerant to methylphenidate prescribed at low or moderate doses, atomoxetine should be considered as a second-line treatment.

10.17.5.7 Children and young people being treated with atomoxetine should be closely observed for agitation, irritability, suicidal thinking or behaviours, and unusual changes in behaviour, especially during the initial few months of a course of drug treatment, or at times of dose changes (either increases or decreases). Parents and/or carers should also be warned about, and asked to report on, the potential emergence of suicidal thinking and related behaviours, and of the potential damage to liver function in rare cases (usually manifested as abdominal pain, unexplained nausea, malaise, darkening of the urine or jaundice), with atomoxetine.

10.17.5.8 Antipsychotics are not recommended in the treatment of ADHD.

10.17.6 Non-response to treatment

10.17.6.1 If there has been an inadequate response to treatment with methylphenidate and atomoxetine, then there should be a further review of the following: diagnosis; assessment of comorbidities; response to drug treatment, occurrence of side effects and compliance; effects of stigma on treatment acceptability; school problems; motivation of child and parents; diet; and review of uptake and use of psychological treatments for parents and child.

10.17.6.2 Consider the use of a higher dose of a licensed medication. This may include exceeding ‘British national formulary’ (BNF) recommendations: methylphenidate can be increased up to 0.7 mg/kg body weight/dose (with up to three doses a day); or atomoxetine may be increased up to 1.8 mg/kg body weight per day. Side effects should be more intensively monitored.

10.17.6.3 In children and young people with ADHD unresponsive to a maximum tolerated dose of methylphenidate and atomoxetine, dexamfetamine should be considered.

10.17.6.4 Further treatment should follow referral to regional specialist treatment centres and may include the use of bupropion, clonidine, imipramine or combination treatments, including psychological treatments for both parent and child.

10.17.6.5 For clonidine, it is advised that a cardiovascular examination and electrocardiogram (ECG) should be conducted before commencing treatment.
10.17.7 Treatment of adults with ADHD

10.17.7.1 In adults, drug treatment for ADHD should only be initiated only under the guidance of a psychiatrist or specialist with training in the diagnosis and treatment of ADHD.

10.17.7.2 Prior to initiating drug treatment, adults should have a full physical and psychiatric baseline pre-treatment assessment. This should include:

- standard symptom and side-effect rating scales
- inquiry about family history of cardiac disease and a physical examination including of the cardiovascular system
- an ECG if there is past medical or family history of serious cardiac disease or an abnormal cardiac examination
- full psychiatric assessment
- risk for substance misuse and drug diversion.

10.17.7.3 Following a decision to initiate medication in adults with ADHD, methylphenidate should normally be used as the first-line drug treatment. [Key priority]

10.17.7.4 In adults unresponsive or intolerant to an adequate trial of methylphenidate, either atomoxetine or dexamfetamine may be considered.

10.17.7.5 When an adult is prescribed atomoxetine, they should be warned of potential damage to liver function in rare cases (usually manifest as abdominal pain, unexplained nausea, malaise, darkening of the urine or jaundice). Younger adults should also be warned of the potential of atomoxetine to increase agitation and anxiety, and lead to self-harming behaviour in a few individuals, especially in the first few weeks.

10.17.7.6 For adults with ADHD stabilised on medication who have persisting functional impairments associated with ADHD, a course of either group or individual CBT to address their functional impairment should be considered. [Key priority]

10.17.7.7 Drug treatment for ADHD comorbid with substance misuse should only be provided by an appropriately qualified healthcare professional with expertise in both conditions.

10.17.8 How to use medication
10.17.9 General principles for the use of medication in children, young people and adults

10.17.9.1 Prescribers should be familiar with the pharmacokinetic profiles of the full range of MR and IR preparations available to ensure that treatment regimens can be effectively tailored to the individual needs of the child, young person or adult.

10.17.9.2 In the titration phase of treatment, doses should be gradually increased until there is no further improvement (symptom reduction, behaviour change, improvements in education and/or relationships) and as long as side effects are tolerable.

10.17.9.3 Routine monitoring of side effects should include the use of standard checklists appropriate to the drug concerned.

10.17.9.4 If adverse effects become troublesome dose reduction should be considered.

10.17.9.5 Titration should be slower if the person has tics or seizures.

10.17.10 Initiation and titration of methylphenidate, atomoxetine and dexamfetamine in children and young people

10.17.10.1 During the titration phase, symptoms and adverse effects should be recorded at each dose change on standard scales (for example, Conners’ 10-item scale) by parents and teachers and progress reviewed regularly (for example, by telephone contact) with a specialist clinician.

10.17.10.2 For methylphenidate:

- Initial treatment should begin with low doses (10–18 mg per day).
- Dose of the drug should be titrated against symptoms and side effects over a period of 4–6 weeks.
- MR preparations should be given as a single dose in the morning.
- IR preparations should be used in two or three divided doses.
For atomoxetine:

- Initial treatment should begin with a total daily starting dose of approximately 0.5 mg/kg in children and young people up to 70 kg body weight. In children and young people over 70 kg body weight, the initial total daily dose should be 40 mg.

- The dose should be increased after 7 days to 1.2 mg/kg per day in those less than 70 kg and up to a maintenance dose of 80 mg per day in those over 70 kg.

For dexamfetamine:

- Initial treatment should begin with low doses of 5 mg per day.

- The dose of the drug should be titrated against symptoms and side effects over a period of 4–6 weeks.

- Treatment should be given in divided doses (2.5 mg at breakfast and then at lunch) increasing to a maximum of 20 mg per day.

- For children of 6–18 years, up to 40 mg per day may occasionally be required.

Initiation and titration of methylphenidate, atomoxetine and dexamfetamine in adults

In order to optimise drug treatment, the initial dose should be titrated over 4–6 weeks against symptoms and adverse effects (refer to the BNF and the Summary of product characteristics).

During the titration phase symptoms and adverse effects should be recorded at each dose change on standard scales (for example, DSM-IV checklist and functional impairment scales) by the individual and whenever possible by a carer (spouse, parent and/or close friend). In the titration phase, progress should be reviewed regularly (for example, by telephone contact) with a specialist clinician (for example, psychiatrist or nurse specialist).

For methylphenidate:

- Initial treatment should begin with low doses (10–18 mg per day).

- IR preparations should be given up to four times a day.

- MR preparations should be given twice daily.

- The dose of the drug should be titrated against symptoms and side effects over a period of 4–6 weeks.
1. The dose should be increased according to response up to a maximum of 100 mg per day.

10.17.11.4 For atomoxetine:

- Initial treatment should begin with a total daily starting dose of approximately 0.5 mg/kg in adults up to 70 kg body weight. In those over 70 kg body weight, the initial total daily dose should be 40 mg.

- The dose should be increased after 7 days to 1.2 mg/kg per day in those less than 70 kg and up to a maintenance dose of 80 mg per day in those over 70 kg.

10.17.11.5 For dexamfetamine:

- Initial treatment should begin with low doses of 5 mg per day.

- Treatment should be given in divided doses.

- The dose of the drug should be titrated against symptoms and side effects over a period of 4–6 weeks.

- The dose should be increased according to response up to a maximum of 50 mg per day.

10.17.12 Monitoring side effects and the potential for misuse in children, young people and adults

10.17.12.1 In children and young people taking methylphenidate, atomoxetine, or dexamfetamine, height should be measured monthly during the titration phase and then at 6-monthly intervals and weight should be measured monthly.

10.17.12.2 If there is evidence of weight loss with any treatment in adults, consider monitoring body mass index and change medication if weight loss is persistent.

10.17.12.3 Strategies to reduce weight loss or manage decreased weight gain include:

- Offering stimulant medication either with or after food, rather than before meals.

- Scheduling additional meals/snacks early morning or late evening when stimulant effects have worn off.

- Obtaining dietetic advice and prescribing high calorie foods.
10.17.12.4 If growth (reduction in expected height) is affected significantly
by stimulants or atomoxetine, consider a planned break in medication
over school holidays to allow ‘catch-up’ growth to occur.

10.17.12.5 For methylphenidate, dexamfetamine and atomoxetine routine
blood tests and ECG are not recommended unless there is a clinical
indication.

10.17.12.6 Routine liver function tests are not recommended for people
taking atomoxetine.

10.17.12.7 For children and young people taking methylphenidate and
dexamfetamine, healthcare professionals and parents should monitor
changes in potential for misuse and drug diversion, which may come
with changes in circumstances and age.

10.17.12.8 In adults, all medications prescribed and the use of non-
prescribed substances should be closely monitored throughout
treatment.

10.17.12.9 In young people and adults, sexual dysfunction
dysmenorrhoea, erectile dysfunction and ejaculatory dysfunction)
should also be monitored as a potential side effect of atomoxetine.

10.17.12.10 For methylphenidate, dexamfetamine and atomoxetine, a
sustained resting tachycardia, arrhythmia or systolic blood pressure
of greater than the 95th percentile (or a clinically significant increase)
measured on two occasions should prompt a medical referral and
dose reduction.

10.17.12.11 If psychotic symptoms emerge following the introduction of
methylphenidate and dexamfetamine, atomoxetine should be
considered as an alternative.

10.17.12.12 If seizures are exacerbated in a child with epilepsy or de novo
seizures emerge following the introduction of methylphenidate or
atomoxetine, the medication should be discontinued immediately. In
this case, dexamfetamine may be considered as an alternative.

10.17.12.13 If tics emerge, consideration should be given before medication
is reduced or stopped to whether:

• tics are drug related (tics naturally wax and wane), and

• tic-related impairment outweighs the benefits of ADHD treatment.

If tics are clearly stimulant related, consider substitution with
atomoxetine.
10.17.12.14 In adults, anxiety symptoms including panic may be precipitated by stimulants, particularly in adults with a history of co-existing anxiety. Where this problem persists, low doses and/or combined treatment with an antidepressant used for the treatment of anxiety is recommended.

10.17.13 **Improving treatment adherence in children and young people (may be relevant to adults)**

10.17.13.1 Communication between prescriber and child should be improved by educating parents and/or carers and ensuring there are regular three-way conversations between prescriber, carer and child. Clear instructions in picture/written format should be offered, which could include information on dosage, duration, side effects, schedule, whether or not supervision is necessary and how this should be done.

10.17.13.2 Peer support groups for parents and the child should be offered.

10.17.13.3 Simple drug regimens, such as once-daily long-acting doses where possible, are recommended.

10.17.13.4 Healthcare professionals should encourage children (and parents) to learn to take their medication and be responsible for their own health.

10.17.13.5 Healthcare professionals should advise parents to provide their child with visual reminders to take medication regularly (for example, alarms, clocks, pill boxes, notes on calendars/fridges, and so on).

10.17.13.6 Healthcare professionals should advise that taking medication should be incorporated into daily routines (for example, before meals or after brushing teeth, and so on).

10.17.13.7 When necessary, healthcare professionals should help parents develop a positive attitude and approach in the management of medication which might include praise and positive reinforcement.

10.17.14 **Duration, discontinuation and continuity of treatment in children and young people**

10.17.14.1 Following an adequate treatment response, medication should be maintained for as long as it remains clinically effective. This should be reviewed yearly, and include a comprehensive assessment of clinical need, benefits and side effects, taking fully into account the view of the child or young person, as well as that of parents and teachers, and how these views may differ. When deciding on the need for continued treatment, the effect of missed doses, planned dose
reductions and brief periods of cessation should be taken into account.

10.17.14.2 Although drug holidays are not routinely recommended, consideration should be given to having parent and child work collaboratively with the healthcare professional to find the best pattern of use, which may include periods without drug treatment.

10.17.15 Duration, discontinuation and continuity of treatment in adults

10.17.15.1 Following an adequate treatment response, medication should be maintained for as long as it remains clinically effective. This should be reviewed yearly, and include a comprehensive assessment of clinical need, benefits and side effects. In deciding on the need for continued treatment, take into account the views of spouse or partner, parents or friends where this is possible and acceptable; and the effect of missed doses, planned dose reductions and brief periods of cessation, and preferred pattern of use, should be reviewed.

10.17.15.2 An individualised treatment approach is important for adults, and healthcare professionals should regularly review the need to adapt patterns of use, including the effect of medication on comorbidities and mood changes.

10.18 Research recommendation

10.18.1.1 Discontinuation of medication

- Are there benefits or disadvantages to the extended/long-term use of medication (methylphenidate) compared with discontinuation of medication at 18 months? To what extent does continuing medication beyond 18 months alter quality of life, core ADHD symptoms, associated symptoms including emotional lability, potential adverse effects of continued medication, and neuropsychological function? (This would be best conducted as a medication discontinuation randomised controlled trial.)

- Why this is important: Medication is often given for periods of years, without good evidence at present of whether prolonged therapy is effective or safe.
11 Combining and comparing psychological and pharmacological interventions

11.1 Introduction
This chapter reviews the evidence on the use of combined interventions where medication and psychological therapies are used together to treat ADHD. As well as the possibility of increasing treatment effects through the use of the two modalities of intervention together, the potential value of combined treatment for ADHD is an area of interest because it might lead to beneficial effects in different domains – with medication targeting core ADHD symptoms such as inattention and psychological interventions targeting secondary problems and comorbid disorders associated with ADHD. Combining pharmacological and psychological approaches may also have the potential to deliver both immediate effects on ADHD symptoms through medication along with more long-lasting effects through the development of behavioural and cognitive skills and strategies. Another area of interest in relation to combined treatment is the potential to minimise the risks of adverse effects of medication if combined treatment can achieve treatment effects comparable with medication treatment alone but with a lower dose of medication.

This chapter also reviews the evidence from trials that allow direct comparisons to be made between the effectiveness of psychological therapies and pharmacological interventions for the treatment of ADHD.

Evidence on combined treatment for adults with ADHD
None of the included studies investigated the effectiveness of combined interventions for adults with a diagnosis of ADHD or compared the effectiveness of psychological therapies delivered to a group not receiving medication for ADHD with those receiving stimulant medication in an adult population.

11.2 Combined interventions for children with ADHD

11.2.1 Introduction
There are several reasons why non-pharmacological treatment, usually psychological, might be combined with pharmacological treatment. These are listed below.

- In severe presentations of ADHD, the impairment is such that medication when combined with psychological therapy might offer the
prospect of a more rapid improvement than with psychological interventions alone, which are likely to take longer to work. This may be particularly necessary if there is marked social dysfunction present, there is severe pressure on family or marital relationships, or the child is faced with imminent exclusion from school.

- Even if a psychological intervention is the preferred option, some young people have such severe clinical presentations that they and/or their parents may not be in a position to access the psychological techniques. The potential for medication to deliver an initial rapid improvement in the early weeks of a combined intervention might enable them to benefit from psychological techniques.

- It has been argued that stimulants may enhance conditionability, a key element of behavioural learning (Eysenck & Rachman, 1971; Sprague & Werry, 1971). In other words, stimulants may enhance the effectiveness of psychological interventions that employ behavioural and social learning principles.

- Combining stimulants with a psychological intervention may be a way of reducing the dosage and duration of medication treatment, and thus may address concerns about the use of medication (see Chapter 6).

- It has been suggested that there may be complimentary benefits in combining approaches (Gitteleman-Klein et al., 1976) in that stimulants may enhance attentional processes and reduce impulsive responding, whereas social reinforcement may help the child to internalise the value of appropriate behaviours.

- There is little evidence that stimulant medication alters the relatively poor long-term outcome for many of those with ADHD (Weiss & Hechtman, 1993). Adding psychological and other therapies might therefore yield better long-term outcomes.

- There are concerns that stimulants alone may not bring symptoms within the normal clinical range and have limited effects on other problems associated with ADHD such as prosocial behaviour (Buhrmester et al., 1992) and cognition (Pelham, 1986). Linked to this it is recognised that ADHD rarely presents with just the core symptoms of ADHD. A range of additional problems across multiple domains are usually present, which are likely to require a range of interventions (Wells et al., 2000).
Current practice

Current practice in the treatment of ADHD varies. Psychological, educational and pharmacological interventions may all be used; the decision is driven by the symptoms presented, the needs of the child and family, and the local availability of services.

11.2.2 Databases searched and inclusion/exclusion criteria

Information about the databases searched and the inclusion/exclusion criteria used for this section of the guideline can be found in Table 30 (further information about the search for health economic evidence can be found in section 10.5). Studies were included if they were RCTs that compared combined treatment for ADHD (where medication and psychological interventions are determined by the study protocol) with medication only delivered according to the same protocol as used as for the combined intervention.

11.2.3 Studies considered

From the primary RCT search, the review team identified trials comparing combined treatment with medication only. Only trials that compared groups receiving true combined interventions (that is, medication for ADHD and a concurrent psychological intervention, with both interventions determined by the study protocol) with groups receiving medication alone (according to the same protocol as the for the combined treatment group) were included in the review. Analyses comparing combined treatments with psychological therapies alone or with no treatment control conditions were not undertaken. The reason for this was that the analysis that directly compared pharmacological and psychological interventions (see 10.3 below) clearly favoured medication. If combined treatments were compared with psychological therapies alone or no treatment control conditions, findings

---

16 Here and elsewhere in the guideline, each study considered for review is referred to by a study ID in capital letters (primary author and date of study publication, except where a study is in press or only submitted for publication, then a date is not used).
favouring combination treatment might therefore only provide evidence of
the effects of medication, rather than providing support for combined
treatment *per se*.

Trials where participants received a psychological intervention as an adjunct
to medication that they were receiving as part of their ongoing usual care
were considered separately (see Chapter 6). This approach to the analysis
was adopted because where participants in a trial continue to receive
medication as usual the medication and/or protocol determining the
medication regimen may not be uniform for all participants, and if that is the
case the trial could not be considered to be true test of a combined treatment
strategy. It is also likely that adherence to medication would be higher in a
clinical trial context, with the consequence that the effects of medication
received as part of a clinical trial might be greater than the effects of
continuing to receive medication as usual. Hence, if medication modifies the
response to psychological therapies it is possible that findings from true trials
of combined treatment might differ from findings from trials that include
participants continuing with their usual medication.

An additional analysis is reported that compares an intensive and
comprehensive combined intervention for ADHD with standard care that
may include medication. This analysis, based on data from the MTA study
(MTA1999), was performed in order to provide a comparison of what might
currently be considered the best possible care for ADHD with the more
standard level of care provided in routine clinical practice.

Seven trials met the eligibility criteria set by the GDG, providing data on 948
participants. All were published in peer-reviewed journals between 1981 and
2004. In addition, 20 studies were excluded from the analysis. The most
common reasons for exclusion were because the paper reported no
appropriate data or the intervention was inappropriate (further information
about both included and excluded studies can be found in Appendix 17).

### 11.2.4 Clinical evidence for combined treatment for ADHD versus
medication only

Evidence from important outcomes and overall quality of evidence are
presented in Table 31. The full evidence profiles and associated forest plots
can be found in Appendix 19 and Appendix 18, respectively.

Quality: High
K = 4, N = 426

Evidence from included trials of treatment for children with ADHD that compare a combined intervention with receipt of the medication component of the intervention alone indicates that there is little or no advantage of any type of combined intervention over medication alone. Compared with medication there is no evidence of an added effect of combined treatment on measures of core ADHD symptoms, emotional state or self-efficacy.

The only evidence of a benefit of combined treatment over medication alone is for parent ratings of conduct problems at the end of treatment, however, the benefits of combined treatment on this outcome are only weak because the effect size is at the lower end of the small effect size range and no benefit of combined treatment was detected at later follow-up times.

The MTA study (MTA1999) is the largest trial of combination treatment for ADHD and although the MTA data suggests that there was a small benefit from combined treatment over medication management alone on parent ratings of conduct problems at the end of treatment, the effect did not reach the magnitude of a small effect size.

11.2.5 Clinical evidence for intensive combined treatment versus usual care for children with ADHD

Comparison of the MTA combined intervention (medication management plus an intensive multimodal psychological intervention for ADHD that involved interventions with the child and parent, and a classroom intervention) with the MTA community care group allows comparison of an intensive and comprehensive approach to care with standard care (MTA1999) (see Table 32).

The MTA study combined intervention provides an example of what might be considered fully comprehensive care for ADHD; this is ongoing protocol-led management of stimulant medication coupled with a complex psychological intervention, that is, a multicomponent psychological intervention that continues for a year or more, includes components directed at the child, the parent and the teacher/classroom, and has intensive components (the summer camp in the case of the MTA psychological intervention). The MTA trial participants in the community care group received routine clinical care for ADHD; two thirds of this group received medication for ADHD and community care participants might also have received non-pharmacological interventions. It is also important to note that the MTA study was US based. Standard care for ADHD in the US may differ from routine care in the UK, with the potential that a higher proportion of the children with ADHD in the community care group received medication than would be the case in a similar UK sample.

The MTA combined intervention was generally favoured over usual care on parent and teacher ratings of ADHD symptoms and conduct problems. According to the composite measure of teacher and parent ratings of core ADHD symptoms that is reported for later follow-up assessments, comprehensive care continues to be favoured over routine care 10 months after the end of the intervention, but the effect is only small. Twenty-two months after the end of the intervention neither comprehensive care nor routine care is favoured according to the composite measure of core ADHD symptoms. However, measures of conduct problems point to an unequivocal advantage of comprehensive care over routine care. At the end of the intervention both parent and teacher ratings of conduct behaviour favour comprehensive care over routine care, with a moderate effect size. The composite score for parent and teacher ratings of conduct behaviour reported for the later follow-up assessments indicates that the beneficial effect of comprehensive care over routine care reduced to a small effect 10 months after the end of treatment but increased to a large effect 22 months after the end of treatment. Parent and teacher ratings of social skills at the end of the intervention also point to small gains from comprehensive care over routine care, but these weak effects disappear at the later follow-up assessments according to a composite measure that combines parent and teacher ratings of social skills.
In contrast, parent ratings of their child’s emotional state point to a weak advantage of routine care over comprehensive treatment at the end of the intervention, but teacher ratings at the end of the intervention do not favour comprehensive treatment or routine care.

Taking all these findings into consideration there appears to be some benefit of a comprehensive intervention for ADHD over routine care. Measures of core ADHD symptoms at the end of the intervention indicate that comprehensive care is moderately more effective for core ADHD symptoms than community care, and comprehensive care may be particularly beneficial for conduct problems. However, the main factor generating the positive effects of the combined intervention may be the medication management component. In any event, the comparison between outcomes for the MTA combined intervention ‘comprehensive care’ group and the community care group does not provide a consistent indication that comprehensive care is more effective than routine care that may include medication for ADHD. The advantage of comprehensive treatment over routine care should also be considered in the context of the lack of evidence of benefit from combined treatment approaches over active protocol-determined medication regimens (see section 10.2.4).

11.2.6 Clinical evidence summary

Evidence from trials comparing combined treatment with medication interventions alone does not point to any added benefit of adding a psychological intervention to a protocol determined medication regimen. The data therefore suggests that if medication treatment for ADHD has already been instigated and the child has responded positively to treatment, then the addition of a psychological intervention to treat ADHD (whether a parent training programme or child-directed therapy) is unlikely to provide any added benefit in terms of reduced ADHD symptoms or improved behaviour, emotional state or self-esteem.

The findings on the effects of combined treatment therefore indicate that beneficial effects of psychological interventions for ADHD are not dependant on effective pharmacological treatment that allows the child with ADHD to be able to reap the benefits of a psychological intervention. It may be the case that in combined treatment trials the study-determined medication regimen has a large beneficial impact on outcomes such that any additional beneficial effects of a psychological intervention cannot be detected as there is no potential for any further improvement.

However, it should be noted that psychological interventions are effective as an adjunct to usual care medication (see Chapter 6), possibly because medication is less effective in routine clinical practice that in the context of a clinical trial. Furthermore, the MTA study (MTA1999) suggests that
combinations of interventions may be helpful in targeting different problems and promoting some outcomes, and offering combination interventions may allow children and parents to participate in treatment decisions and make choices about their own health outcomes (Taylor et al., 2004).

11.3 Comparing psychological and pharmacological interventions for children with ADHD

11.3.1 Introduction

Direct comparison of the effectiveness of psychological and pharmacological interventions for ADHD is possible where RCTs include a group receiving a psychological intervention without medication and a group receiving medication only. Studies that allow this comparison are potentially informative as they allow a direct head-to-head comparison of effectiveness between psychological and pharmacological interventions.

11.3.2 Databases searched and inclusion/exclusion criteria

Information about the databases searched and the inclusion/ exclusion criteria used for this section of the guideline can be found in Table 33 (further information about the search for health economic evidence can be found in section 10.5). Studies were only included where the both the medication and psychological interventions were determined as part of the study protocol.

11.3.3 Studies considered

From the primary RCT search, the review team identified trials comparing medication for ADHD with a psychological intervention.

Six trials met the eligibility criteria set by the GDG, providing data on 462 participants. All studies were published in peer-reviewed journals between 1976 and 1999. In addition, four studies were excluded from the analysis; two

because they were case-studies, one because of insufficient data, and one
because of methodological problems (further information about both included
and excluded studies can be found in Appendix 17).

11.3.4 Clinical evidence for psychological interventions versus protocol-
managed medication for children with ADHD

There is only sparse clinical trial evidence allowing direct comparison of the
clinical effectiveness of psychological and pharmacological interventions for
ADHD. Of the six trials that meet inclusion criteria, five are relatively small,
with the medication or psychological intervention group sizes ranging from
nine to 30. However, the MTA study (MTA1999) was relatively large, having
120 participants in the medication group and 119 in the psychological
intervention group.

For individual outcomes, the quality of the evidence was generally moderate
to high. Overall, for children with ADHD the evidence from trials that
compare stimulant medication (predominately methylphenidate) with a
psychological intervention delivered to a group not receiving medication for
ADHD generally favours stimulant medication, although where they reach
statistical significance the effects are not large (see Table 34).

### Dichotomous outcomes

### Leaving study for any reason

- **Data not pooled**
For both teacher and parent ratings of core ADHD symptoms and conduct problems at the end of treatment, stimulant medication delivers better outcomes than psychological interventions, with effect sizes in the small to moderate range. However, the benefits of stimulant medication over psychological therapies for core ADHD symptoms and conduct problems in general do not appear to be sustained at later follow-up assessments (3-6 months, 7-12 months and 13-24 months after the end of treatment). The MTA study (MTA1999) found a benefit of medication over the complex MTA psychological intervention on the composite parent- and teacher-rated measure of core ADHD symptoms at 10 months after the end of the intervention, but the effect did not reach the magnitude of a small effect size.

Stimulant medication also appears to be more effective than psychological interventions at improving social skills as rated by teachers, but this effect was small at the end of treatment, was not sustained at later follow-up assessments, and was not reflected in parent ratings of social skills, which does not point to any benefit of stimulant medication over psychological therapies at the end of treatment or any time thereafter. For emotional state (as represented by depression, anxiety, emotional adjustment and internalising symptoms) there was also a benefit of stimulant medication over psychological interventions at the end of treatment, but the effect size was small and for this outcome limited to parent ratings, with no effect on teacher ratings detected.

The lack of evidence for the sustained superiority of medication over psychological interventions for ADHD is, however, difficult to interpret. At longer follow-up time points outcomes may be influenced by the treatment a child has received since the end of the period of the experimental intervention. In particular, children who received a psychological intervention and were not on medication for ADHD during the period of the trial while the intervention was delivered may have subsequently begun to receive stimulant medication for ADHD. Notably, in the MTA trial, by the follow-up time point at 10 months after the end of the experimental intervention, 44% of the group that only received the MTA behavioural intervention had commenced medication. At 22 months after the end of the experimental intervention, the proportion of the MTA behavioural intervention group that was using medication at high levels was little changed at 45% (Jensen et al.,...
2007). In contrast 71% of MTA study participants who were in the medication management and combined intervention groups were using medication at high levels 22 months after the end of the experimental intervention, a decrease from 91% at the end of the intervention.

11.3.5 Clinical evidence summary

Whilst there is no evidence that psychological interventions are favoured over stimulant medication for any outcome, or at any time point, it is also the case that medication does not appear to be strongly favoured over psychological interventions.

11.4 The MTA study: implications for treatment decisions

11.4.1 Further considerations with respect to the treatment of ADHD – additional evidence from the MTA study

A number of publications have reported on subanalysis and secondary analysis of data gathered as part of the MTA study (for example, MTA Cooperative Group, 2004a; Jensen et al., 2007). Only primary outcome data reported for the end of treatment and 14 and 22 months post-treatment follow-up time points have been used in the analysis of the effectiveness of interventions for ADHD, but some of the further analysis reported by the MTA Cooperative Group may help inform choices made in the treatment of ADHD.

Longer term impact of MTA interventions and the relation to substance use and delinquency

The MTA study group has reported follow-up outcome data at time points beyond the end of the MTA intervention (MTA Cooperative Group, 2004a; Jensen et al., 2007). The initial primary outcome data was collected at the end of the MTA interventions (14 months after interventions were commenced), with follow-up data reported to date for 10 months after the end treatment and 22 months after the end treatment (or 24 and 36 months after the interventions were commenced). It is important to note that after the end of the MTA interventions the participants in the trial returned to usual care.

According to the outcome data collected 22 months after the end of the MTA interventions, the MTA treatment allocation groups could no longer be distinguished on any measure according to primary analysis (Jensen et al., 2007). On average MTA participants maintained some of the gains made at the end of treatment time point on measures of both ADHD and ODD symptoms. The behavioural treatment and community care groups maintained the gains they had made at the end of treatment. In contrast the combined treatment and medication management groups lost their end of
treatment advantage over the behavioural treatment and community care
groups, although they maintained gains over baseline that approximated to
the sustained gains made by the behavioural and community care groups.
These findings are, however, based on the comparison with baseline data for
each group, not on a comparison with an untreated control group, and hence
it is not possible to conclude that any of the MTA interventions have long-
term beneficial effects over no treatment. Indeed, at 22 months after the end of
treatment, prognostic factors for ADHD were found to have more of an
impact on outcomes than treatment group allocation – girls and those of
higher socioeconomic status fared better than boys.

Follow-up data gathered 10 months after the end of the experimental MTA
interventions is in line with the data gathered at 22 months after the end of
treatment (MTA Cooperative Group, 2004a). Ten months after the end of the
MTA interventions, the combined treatment and medication management
groups, which showed the greatest improvement compared with baseline at
the end of the intervention, show some deterioration, whereas the
behavioural treatment and community care groups maintain gains made in
comparison with baseline during the period of the trial intervention.

Jensen and colleagues (2007) suggest that factors that may contribute to the
convergence of outcomes for the four MTA study intervention groups at
longer-term follow-up compared with outcomes at the end of treatment may
include: a decrease in ADHD symptoms related to age independent of
treatment, changes in the intensity of medication use, and different degrees of
starting and stopping medication in the different treatment allocation groups
that occurred after the end of the MTA interventions. Other factors may also
be involved. There is a degree of convergence across the four groups in terms
of their use of medication for ADHD at follow-up. Medication use in the
group allocated to behavioural treatment increased from 14% at the end of the
MTA intervention to 45% 22 months later, whereas among MTA participants
who received the medication management intervention (including the
combined treatment group) medication use decreased from 91% to 71%. In
the community care group medication use was near unchanged – 60% at end
of treatment and 62% 22 months later. Further support for the inference that
changes in medication use may have mediated the convergence between
outcomes across the groups at follow-up is provided by analysis indicating
that the subgroup that reported stopping taking medication ten months after
the end of treatment showed the greatest deterioration (MTA Cooperative
Group, 2004b).

Substance use at 22 months after the end of the MTA interventions was lower
in the MTA participants who received intensive behaviour therapy (members
of the combined treatment and behavioural intervention groups) compared
with those who did not (members of the medication management and
community care groups) (Molina et al., 2007). However, the data did not point
to there being any associations between treatment allocation and early
substance use, growth of delinquency over time and the level/seriousness of
delinquency. Seriousness of offences was associated with self-selected use of
prescription medication, and Molina and colleagues (2007) speculate that this
may be reactive in that there may be a tendency to opt for medication in
response to increased symptom severity.

The analysis by Molina and colleagues (2007) did not point to either a
protective or adverse effect of medication for ADHD (whether study allocated
or self-selected in community care participants) on the initiation of substance
use in MTA participants. However, it should be noted that at the post-
treatment follow-up at 22 months the mean age of participants was still
relatively young (most were between 11 and 13 years of age).

Factors associated with treatment effects according to data gathered at the
end of the MTA interventions

Analysis of the MTA data points to some impacts of socioeconomic status on
treatment outcomes at the end of the intervention (Rieppi et al., 2002). For
children from better educated families, combination treatment may be more
effective than medication management alone for ADHD symptoms whereas
for low socioeconomic status families, combination treatment may be more
effective for oppositional aggressive symptoms.

Other analysis found that response to treatment in the MTA study did not
differ significantly by ethnicity after controlling for public assistance (Arnold
et al., 2003). However, at the end of the intervention medication doses
reached a higher level for African American children receiving medication
management only compared with the average for the group allocated to this
intervention. As this was not the case for children from ethnic minorities
receiving combination treatment, Arnold and colleagues (2003) suggest that it
is possible that the behavioural intervention may have neutralised adverse
effects of low socioeconomic status that might otherwise exacerbate
symptoms and lead to a need for a higher medication dose. A speculative
inference from the analysis is that white middle class children without
comorbid anxiety or disruptive behaviour may not gain from adding
behavioural treatment to medication, but children of low socioeconomic
status, or with comorbid anxiety and disruptive behaviour, especially if of
ethnic minority, may gain added benefit from combining behavioural
treatment with medication.

Other analysis looking at potential moderators of the response to treatment in
the MTA study found no moderators of response to behavioural treatment or
community care (Owens et al., 2003). However, the analysis indicated that
parental depression decreased treatment effectiveness in the medication
management group but not in the behavioural treatment group. This finding
led Owens and colleagues (2003) to speculate that the parental components of the behavioural intervention may in effect treat the parents to some degree, thus mitigating negative impacts of parental depression on the outcomes for the child. Owens and colleagues (2003) also found that a high initial severity of ADHD symptoms decreased the treatment effects from the medication management and combined treatment interventions, but as the analysis used a measure of response to treatment it is possible that this may reflect the need for those with more severe symptoms at the outset to improve more so as to be classed as responding to treatment.

A further finding unrelated to behavioural treatment reported by Owens and colleagues (2003), was that for those on medication management (that is, participants receiving the medication management or combined treatment interventions), participants in the subgroup with parental depression and a higher severity of symptoms responded better to medication if they had a higher starting IQ compared with those in this subpopulation with lower IQ. In terms of implications for treatment, Owens and colleagues (2003) suggest that their analysis indicates that treatment of parental depression may be important in order to get a positive response to treatment of ADHD using medication. They also speculate that it might be important to intervene early with medication management or combined treatment before ADHD severity increases and a positive response to treatment becomes less likely.

Analysis looking at outcomes at the end of treatment for subgroups with comorbid anxiety and disruptive behaviour (ODD or CD) pointed to some impacts on treatment effects (Jensen et al., 2001). All MTA interventions including community care were found to be effective in the subgroup with ADHD and comorbid anxiety. For subgroups with ADHD only or ADHD and disruptive behaviour (ODD or CD), medication was favoured – whether alone or in combination with behavioural treatment – but behavioural treatment alone may be contraindicated. For the subgroup with ADHD and both anxiety and disruptive behaviour, there was evidence of an advantage of combined treatment, particularly with respect to overall impairment and functioning.

Earlier analysis looking at the impact of comorbidity suggested that MTA participants with comorbid disruptive behaviours (ODD and CD) did not benefit from the addition of behavioural treatment (that is, combined treatment) over medication management alone at the end of treatment time point (MTA Cooperative Group, 1999b). A further tentative inference from the data gathered at the end of treatment is that the intensive MTA behavioural intervention may have had similar effects to routine medication because the majority (66%) of the community care group received medication for ADHD and the behavioural intervention group did not differ significantly from the community care group for end of treatment outcomes. It must, however, be noted that the absence of a statistical difference between the
groups does not prove that there is no difference between the effects of the
behavioural intervention and continued community care.

Secondary analysis looking at treatment response found that twice as many
children met criteria for successful treatment at the end of treatment time
point in the groups receiving medication management (medication
management and combined treatment groups) compared with the
behavioural intervention and community care groups (Swanson et al., 2001).
The authors infer that if medication management was adopted in usual care
the number of cases successfully treated would effectively double from 30% to 62%. The analysis also suggests that the addition of intensive psychological
treatment in combination with medication management would result in 12%
more children being successfully treated as the response rate was 56% in the
medication management group compared with 68% in the combined
treatment group (equivalent to a 20% increase in the success rate through the
addition of intensive psychological treatment).

A further analysis of the MTA study data gathered at the end of treatment
time point indicates that the more severe subgroup meeting criteria for HKD
showed a larger decrease in symptoms with medication than with behaviour
therapy, and a larger medication advantage than those not meeting criteria
for HKD (Santosh et al., 2005). Accordingly, as they show a greater response
to medication than the less severe non-HKD subgroup, Santosh and
colleagues suggest that for those with HKD medication management is
favoured as a first-line treatment. However, as the response of the non-HKD
subgroup to medication was in the same direction, albeit to a lesser degree,
the data also suggest that stimulants may be indicated for some children with
ADHD who do not meet criteria for HKD.

11.5 Health economics evidence

11.5.1 Systematic literature review

The systematic literature search identified two economic studies that
compared the cost effectiveness of pharmacological, psychological and
combination therapies in children with ADHD (Lord & Paisley, 2000;
Zupancic et al., 1998), plus an economic analysis of the interventions assessed
in the MTA Cooperative Study (Jensen et al., 2005; Foster et al., 2007). In
addition, the economic modelling undertaken to support NICE guidance on
the use of methylphenidate, atomoxetine and dexamfetamine in children with
ADHD incorporated a sub-analysis that compared combination therapies
with the evaluated medications (King et al., 2006). Details on the methods used
for the systematic search of the economic literature are described in Chapter 3.
The economic analysis of the MTA study is described in a separate sub-
section in this chapter. Information on the methods used and the results
reported in all economic studies included in the systematic literature review
are presented in the form of evidence tables in Appendix 14.
Lord and Paisley (2000) conducted an economic analysis to compare the cost effectiveness of combination therapy, consisting of methylphenidate plus behavioural therapy, with behavioural therapy alone for children with ADHD in the UK. The perspective of the analysis was that of the NHS. The study, based on a decision-analytic model, utilised clinical-effectiveness data from the MTA cooperative study. Resource use estimates were based on expert opinion and reflected clinical practice in the UK. Costs consisted of drug acquisition and pharmacotherapist costs. Costs of behavioural therapy were omitted from the analysis, as these were common in the two strategies assessed. The measure of outcome was the standardised mean difference (SMD) in the SNAP-IV score between the two treatment options. The time horizon of the analysis was 14 months, the length of the MTA study. According to the results of the analysis, the ICER of combination therapy versus behavioural therapy alone was £1,596 per SMD in the SNAP-IV score (1999 prices). This ratio ranged in sensitivity analysis from £694 to £4,545 per SMD in the SNAP-IV score. One limitation of the analysis was the use of the change in SNAP-IV scores as the primary outcome measure, which could not capture the HRQoL of children with ADHD. In addition, the study utilised clinical data from the MTA study, which was conducted in the US and examined interventions that were more intensive than typical interventions in the UK. On the other hand, the resource use estimates by Lord and Paisley (2000) referred to UK clinical practice, and therefore the results of the economic analysis should be interpreted with caution.

Zupancic and colleagues (1998) assessed the cost effectiveness of methylphenidate, dexamfetamine, pemoline, psychological/behavioural therapy and combination therapy (consisting of psychological/behavioural therapy and methylphenidate) in comparison with no treatment from the perspective of a third-party payer in Canada. Details on the methodology of the study are reported in Chapter 10. The meta-analysis of clinical studies included in the systematic literature review indicated that psychological/behavioural therapy, either alone or as an adjunct to pharmacological therapy, was not effective. The economic analysis demonstrated that methylphenidate dominated both psychological/behavioural therapy and combination therapy. The limitations of the analysis are described in Chapter 10. Additional limitations specific to the evaluation of psychological/behavioural and combination therapies were: the rather poor quality and the insufficient power of clinical studies assessing these two strategies; the assumptions regarding duration of therapy (daily provision of drugs versus 16-hour provision of psychological/behavioural therapy), which, according to the authors, might have biased the results against psychological/behavioural and combination therapies; and, finally, the choice of the outcome measure, that is, the change in CTRS scores, which might have underestimated the efficacy of psychological/behavioural therapy alone or in combination, given that this therapy has been shown to be more
effective in enhancing academic performance and improving conflicted peer relations rather than improving core ADHD symptoms.

The economic analysis of the NICE guidance on the use of methylphenidate, atomoxetine and dexamfetamine for children and adolescents with ADHD (NICE, 2006) incorporated a sub-analysis assessing the cost effectiveness of combination strategies relative to strategies involving only sequences of medications (King et al., 2006). Details on the methodology adopted in the study analysis are provided in Chapter 10. The sub-analysis including combination therapies assessed 37 strategies in total: 18 strategies consisting of all possible three-line sequences of the medications reviewed, 18 respective strategies of three-line sequences of combined treatment, and a strategy of no treatment. After excluding all strategies ruled out by dominance, two options remained: a combination strategy consisting of behavioural therapy plus first-line dexamfetamine, second-line atomoxetine, and third-line extended release methylphenidate administered every 8 hours, and a medication strategy consisting of first-line dexamfetamine, second-line instant release methylphenidate, and third-line atomoxetine. The ICER of the first versus the second strategy was £1,241,570/QALY; consequently, the authors concluded that combination strategies were not cost effective from the perspective of the NHS. However, the available clinical data for this analysis were very limited (based on one single trial comparing instant release methylphenidate alone versus in combination with behavioural therapy) and no firm conclusions could be drawn.

Overall, the existing evidence reported in Zupancic and colleagues (1998) and King and colleagues (2006) suggests that combination and psychological therapies may not be cost-effective treatment options compared with medication for children with ADHD. However, there were considerable limitations in the clinical-effectiveness data used in the economic analyses, as described above. The study by Lord and Paisley (2000) used resource use estimates representing UK routine clinical practice, and clinical data from the MTA study, which evaluated intensive interventions in the US. Considering also that the primary measure of outcome in the analysis was the SMD of SNAP-IV scores rather than a dichotomous outcome, it is evident that no safe conclusions can be made also by this analysis.

11.5.2 Economic modelling

Objective

The choice of treatment strategy among various types of interventions available to children with ADHD was identified by the GDG and the health economist as an area with potential major resource implications. The existing economic evidence in this field was limited and was characterised by considerable uncertainty; therefore a decision-analytic model was developed for this guideline to examine the relative cost effectiveness of
pharmacological, psychological, and combination therapies for children with ADHD.

**Treatment strategies examined**

The treatment strategies examined were medication versus behavioural therapy versus combined therapy (that is, behavioural therapy provided concurrently with medication). Medication was represented by use of methylphenidate in the economic model, for three reasons: methylphenidate was the only drug examined in the clinical trials comparing pharmacological with psychological and/or combined therapies that were included in the guideline systematic literature review; it is the most commonly used medication in clinical practice; finally, indirect clinical evidence suggests that it is likely the most effective drug in improving core symptoms in children with ADHD. Nevertheless, recommendations based on the results of the economic analysis refer to medication as a treatment option, and are not intended to be specific to the use of methylphenidate.

Medication was defined as use of instant release methylphenidate at an average daily dose of 25 mg for 4 weeks (titration period), followed by use of extended release methylphenidate at an average daily dose of 36 mg. Children taking medication had regular contacts with healthcare professionals (psychiatrists or paediatricians and nurse specialists), with higher intensity during the titration period. Behavioural therapy was defined as 8 weekly meetings of clinical psychologists with parents and, in some cases, children, lasting 1 hour each, plus telephone support lasting on average 1 hour. In addition, clinical psychologists had two meetings with children’s teachers at school lasting 30 minutes each, in order to provide advice.

Combined treatment consisted of both medication and behavioural therapy.

**Methods**

**Model structure**

An economic model in the form of a decision tree was developed to estimate total costs and benefits associated with provision of medication, behavioural therapy, and combined treatment to children with ADHD. According to the model structure, hypothetical cohorts of children with ADHD were started on one of the three treatment options under assessment. If children receiving behavioural therapy or medication did not respond to treatment following completion of 8 weeks of therapy (in accordance with the duration of clinical trials that provided efficacy data), they were switched to medication or behavioural therapy, respectively, or to combined treatment. However, children not responding to combined therapy after 8 weeks were not then offered medication or behavioural therapy alone, as it was assumed that none of the ‘monotherapy’ interventions would be effective following unsuccessful combination therapy. It must be noted that the model assumed that non-response to a treatment option did not affect effectiveness (that is, response rates) of subsequent treatments; this means that response rates of any treatment option a child might have received were independent from each...
other. Children on medication or combined intervention who stopped
treatment due to development of intolerable side effects were switched to
behavioural therapy. Children who switched to combined treatment because
of non-responsiveness after 8 weeks of medication were assumed not to
experience intolerable side effects from combined treatment, given that they
had not experienced intolerable side effects from medication alone. Children
completing medication or combination therapy could also experience
(tolerable) side effects that did not affect continuation of therapy. Children not
responding after two lines of treatment (or one, if they completed 8 weeks of
combined treatment and did not respond to it), were assumed to receive
‘other treatment’. This consisted of further management of children with
ADHD, including contacts with healthcare professionals, unlicensed
medications, inpatient care, or no treatment.

The time horizon of the analysis was 1 year. Children responding to any of
the treatment options assessed were assumed to continue successful
treatment beyond 8 weeks (with 100% compliance) and remain responsive
(that is, retain improved symptoms) until the end of the analysis. Children
non-responsive to treatment who moved to ‘other treatment’ remained on it
until the end of the analysis. It is acknowledged that the time horizon of 1
year is rather limited and does not allow estimation of the overall, long-term
costs and benefits associated with treatment of children with ADHD;
however, there is no sufficient evidence to allow modelling for longer periods
of time, as long-term harms and benefits of the examined interventions have
not been adequately explored.

A schematic diagram of the Markov model is provided in Figure 4.

Figure 5. Schematic diagram of the structure of the economic model
Costs and health benefit measures included in the analysis

The analysis adopted the perspective of the NHS. Health service costs consisted of intervention costs, costs of monitoring children who responded to treatment and therefore remained in receipt of any of the treatments assessed for the whole time horizon of the analysis, as well as costs of ‘other treatment’ for children not responding to the treatment options assessed.

Costs of treating side effects were not separately considered in the analysis because the majority of side effects from medication (anorexia, nausea, insomnia, headache, increased irritability, and so on) are routinely managed by healthcare professionals responsible for the monitoring of children receiving medication and were estimated not to incur extra costs.

Costs of personal social services and education services were not included in the analysis owing to lack of relevant data, but it is unlikely that these differ significantly across children receiving different types of treatment over the period of 1 year. Other societal costs, such as social benefit payments and productivity losses of carers of children with ADHD were not considered as they were beyond the scope of this analysis. Benefits were expressed in the form of QALYs. Results are reported as ICERs.

Effectiveness data and other clinical input parameters
As already discussed in the economic sections of Chapter 7, for the economic analyses undertaken in this guideline, it was decided to utilise data only from studies reporting outcomes as response rates, with response defined in a way that the GDG found both clinically meaningful and significant.

The guideline systematic review identified four studies that examined pharmacological versus psychological and/or combination therapies for children with ADHD and reported outcomes as response rates (ABIKOFF2004B; GITTELMAN-KLEIN1976B; KLEIN1997B; MTA1999B). GITTELMAN-KLEIN1976B and KLEIN1997B compared methylphenidate with behavioural therapy and combined treatment. ABIKOFF2004A compared methylphenidate with a combination of methylphenidate and a multimodal psychosocial treatment that included parent training and counselling, social skills training, psychotherapy, and academic assistance. MTA1999B compared intensive medication management with intensive behavioural therapy and a combination of the two. Definitions or response of all the above studies were considered appropriate by the GDG. For the base-case analysis, it was decided to utilise data from GITTELMAN-KLEIN1976B and KLEIN1997B, as the studies examined the interventions of interest in this economic analysis; data from ABIKOFF2004A were considered in a sensitivity analysis; data from MTA1999B were examined separately, as the study involved interventions of high intensity.

The study population in GITTELMAN-KLEIN1976B and KLEIN1997B consisted of school-age children with pervasive symptoms of ADHD and parent reports for hyperactivity or behavioural problems at home. Both studies defined response as a final score of 1 to 3 on the Clinical Global Improvement scale (that is, completely well, much improved, or improved). More details on the study characteristics can be found in Appendix 17.

Analysis of efficacy data was based on intention-to-treat; however, children stopping treatment due to intolerable side effects in the trials were not taken into account at the estimation of response rates for this treatment option in the economic analysis; this was done in order to avoid double counting because in the economic model these children have been assumed to switch to a different type of treatment and potentially respond to it.

Estimation of response rate to ‘other treatment’ was based on a published meta-analysis of follow-up studies on children with ADHD; the study reported the annual probability of continuation of residual ADHD symptoms in the population of people with ADHD (Faraone et al., 2006), which was interpreted for the purposes of this analysis as no response. From this annual rate, it was possible to estimate the response rates of children that remained under ‘other treatment’ for varying time periods.
The proportions of children who stopped medication or combined treatment due to intolerable side effects were derived from the guideline meta-analysis of studies comparing methylphenidate with placebo, including comorbid and non-comorbid populations of children with ADHD. The attributable risk of stopping methylphenidate due to intolerable side effects was calculated by subtracting the overall rate of stopping treatment with placebo due to side effects by the respective rate for methylphenidate. This attributable risk estimate was applied to children who received medication or combined treatment in the analysis, while children receiving behavioural therapy were assumed not to experience intolerable side effects that would lead to discontinuation of treatment.

Rates of side effects for children under medication or combined therapy were based on the same dataset of studies (that is, studies included in the guideline meta-analysis comparing methylphenidate with placebo in children with ADHD including comorbid and non-comorbid populations) and were estimated in a similar way. However, the existing studies did not report an overall side-effect rate, but rather provided rates of specific side effects; it was not possible to estimate an overall side-effect rate from these data as some children might have experienced more than one side effect. In order to overcome this problem, it was decided to proxy the overall rate of side effects for methylphenidate using data on the rate of appetite loss; this was selected because it is a common, statistically significant side effect of methylphenidate and also it is deemed to substantially reduce the quality of life of children with ADHD. The attributable risk of side effects for methylphenidate was therefore calculated as the difference between rate of appetite loss for methylphenidate and rate of appetite loss for placebo; this estimate was subsequently applied to children receiving medication or combined treatment; it was assumed that, for the proportion of children experiencing side effects, these persisted for the entirety of the time period when medication or combined treatment was provided. Children receiving behavioural therapy or ‘other treatment’ did not experience side effects from treatment.

Discontinuation of treatment for reasons other than intolerable side effects was not considered in the analysis owing to lack of data appropriate to inform the economic model: GITTELMAN-KLEIN1976B and KLEIN1997B reported very small discontinuation rates that were insignificant; the only other available data came from MTA1999B, which referred to intensive interventions, and therefore respective data did not reflect discontinuation of treatment options assessed in this analysis. In addition, such data could only be applied to first-line treatment, as children completing treatment without response, as well as their parents, were thought to demonstrate different attitudes towards second-line treatment, which would not be reflected in discontinuation rates characterising initiation of treatment.
The proportions of children moving to combined treatment following failure of medication or behavioural therapy was based on a trial comparing medication with behavioural therapy in which proportions of children not fully responding to the interventions assessed were subsequently switched to combined treatment (Döpfner et al., 2004).

Effectiveness data and other clinical input parameters utilised in the base-case economic analysis are presented in Table 35.

Utility data and estimation of QALYs

As already discussed in the economic section of Chapter 7, for the economic analyses undertaken in this guideline involving children with ADHD, two sets of utility scores were used: base-case analyses utilised the scores reported by Coghill and colleagues (2004), generated from EQ-5D; utility scores provided by Secnik and colleagues (2005b), produced by SG technique using vignettes of health states of children with ADHD in the UK, were used in a sensitivity analysis.

One limitation of using Coghill and colleagues’ (2004) utility scores in the current analysis was that these did not take into account any decrement in...
quality of life resulting from the presence of side effects. Nevertheless, this
was an important parameter to consider in this analysis, since children under
medication or combined therapy could experience side effects and a
subsequent reduction in HRQoL, in contrast with children under behavioural
therapy, who did not experience side effects. For this reason, a decrement in
utility resulting from the presence of side effects was estimated from Secnik
and colleagues (2005b) and was applied to the base-case utility scores to
create additional scores for responders and non-responders experiencing side
effects. Regarding the sensitivity analysis that tested the data from Secnik and
colleagues (2005b), it was assumed that utility scores reflecting no
medication/untreated ADHD expressed utility of children receiving
behavioural therapy.

Utility scores used in the economic analysis of pharmacological versus
psychological versus combined treatment for children with ADHD are
provided in Table 36.

It was assumed that HRQoL in children initially responding to treatment
improved linearly over 8 weeks starting from the utility score of non-
responders and reaching the utility score for responders (8 weeks was the
duration of interventions in the clinical trials considered in the economic
analysis), and remained at this value for the rest of the time of the analysis.
Decrement in quality of life owing to the presence of side effects was
modelled from initiation of respective treatment. Once side effects occurred,
they were assumed to remain over the whole period over which medication
or combined therapy was provided. Children who stopped treatment due to
intolerable side effects faced a decrement in quality of life for 2 weeks, after which the intolerable therapy was discontinued.

**Resource utilisation and cost data**

Owing to lack of patient-level cost data, deterministic costing of all treatment options assessed was undertaken. Relevant healthcare resource use was estimated and subsequently combined with unit prices to provide total costs associated with medication, behavioural therapy and combined treatment. Resource utilisation estimates reflected, as closely as possible, resource use described in the clinical studies utilised in the economic analysis (GITTELMAN-KLEIN1976B; KLEIN1997B). Where relevant information on resource use was lacking (for example, resource use beyond the duration of the trials) or was clearly unrepresentative of British routine practice, then estimates were produced/modified based on the expert opinion of the GDG.

For children receiving medication, the GDG estimated the average optimal daily dose of methylphenidate during titration and post-titration, which was, overall, consistent with doses reported in the clinical studies that provided efficacy data. Titration was estimated to last 4 weeks, over which time children received instant release methylphenidate. Extended release methylphenidate was administered post-titration, according to routine clinical practice in the UK. Children were attended by a psychiatrist or a paediatrician during titration. Those responding to medication were assumed to continue receiving methylphenidate until the end of the analysis, being monitored by a psychiatrist, paediatrician, or a nurse at regular time intervals. Children stopping medication due to intolerable side effects were assumed to receive methylphenidate for 2 weeks before discontinuing and to spend half of the total estimated time (during titration) with a psychiatrist or paediatrician.

Behavioural therapy consisted, in line with the interventions described in GITTELMAN-KLEIN1976B and KLEIN1997B, of 8 weekly meetings between clinical psychologists and parents of children with ADHD lasting 1 hour each, augmented by 1 hour in total of telephone contacts. In addition, clinical psychologists visited the teachers of the children at school and provided advice; two visits of 30 minutes each were assumed. Following completion of the intervention, parents of children responding to behavioural therapy attended three booster sessions with psychologists lasting 30 minutes each, in order to maintain children’s response for the remaining time of the analysis.

Resource use in combined treatment was the sum of resource use of medication and behavioural therapy, given that the two interventions are led by different types of healthcare professionals and no overlap in services provided occurs.

Regarding costs of ‘other treatment’, no data on average annual costs associated with management of children with ADHD in the UK are available. King and colleagues (2006) gave an overall estimate of £14 million spent on follow-up care of children with ADHD by health, social and education services in England and Wales (initial specialist assessment was excluded.
from these costs). Using this estimate, a prevalence of ADHD equalling 3.62% in boys and 0.85% in girls (Ford et al., 2003), and the population of boys and girls aged 5-18 in 2006 in England and Wales (Office for National Statistics, 2007), it was estimated that a child with diagnosed ADHD incurred on average a cost of £67 annually. This estimate may seem low, but it is likely to reflect the fact that some children with ADHD may not receive any treatment for this condition.

Unit prices were taken from the BNF 54 (British Medical Association & Royal Pharmaceutical Society of Great Britain, September 2007), and the Unit Costs for Health and Social Care 2006 (Curtis & Netten, 2006); 2006 prices were used. Discounting was not applied, as costs and benefits were measured over a period of 1 year.

Resource use estimates and unit costs, as well as total costs of interventions assessed over the 1 year of the analysis are reported in Table 37.

‘Other treatment’

Sensitivity analysis

A sensitivity analysis was undertaken to investigate the robustness of the results under the uncertainty characterising input parameters of the model. The following scenarios were tested in a one-way sensitivity analysis:

1. Changes in response rates to treatment:
   - use of the 95% confidence intervals (CIs) of the relative risk (RR) of combined treatment to medication (mean RR = 1.27; 95% CIs, 1.06 to 1.51)
   - use of the 95% CIs of the RR of medication to behavioural therapy (mean RR = 1.62; 95% CIs, 1.12 to 2.36)
   - inclusion of data from ABIKOFF2004a in the meta-analysis.

2. Varying proportions of children under medication or behavioural therapy switched to combined treatment following no-response.

4. Changes in resource use estimates for medication (or combined treatment):
   - 4 hours of contact with psychiatrist/paediatrician during titration
   - all monitoring conducted by doctors
   - five follow-up visits (monitoring) over 1 year
   - combination of all the above scenarios.

5. Changes in resource use estimates for behavioural therapy (or combined treatment):
   - Clinical psychologist replaced by health visitor (cost per clinic hour: £61 [Curtis & Netten, 2006] qualification costs excluded).
   - Group-based behavioural therapy for pre-school children, provided by clinical psychologists, consisting of ten hourly sessions delivered to groups of ten parents, including 1 extra hour for training and preparation (the latter at a unit cost of £29 [Curtis & Netten, 2006], reflecting effective, optimal routine practice for pre-school age children (expert opinion of the GDG). The cost of this scenario was £69 per child (excluding booster sessions, which were assumed to be provided individually, as in the base-case analysis).
   - Group-based cognitive behavioural therapy for school-age children, provided by clinical psychologists, consisting of ten hourly sessions with parents plus ten hourly sessions with children (ten parents and ten children in each group, respectively), plus 2 extra hours for training and preparation, plus two 0.5 hour individual meetings with the children’s teachers, reflecting effective, optimal routine practice for school-age children (expert opinion of the GDG). The cost of this intervention was £206 per child (excluding booster sessions, which were assumed to be provided individually, as in the base-case analysis).

6. Use of one line of treatment only; children responding to treatment remained on it for the rest of the time of the analysis; children not responding were switched to ‘other treatment’.

In addition to the above scenarios, threshold analyses were carried out to identify the values of selected parameters at which the conclusions of the cost-effectiveness analysis would be reversed. The following parameters were tested:

1. rate of side effects from medication (or combined therapy)
2. rate of stopping medication (or combined therapy) due to intolerable side effects
3. decrement in utility scores due to side effects
4. number of (individual) sessions with parents, for children under
   behavioural therapy (or combined treatment)
5. response to ‘other treatment’
6. cost of ‘other treatment’.

Results

Base-case analysis
Combined therapy resulted in greatest health benefits but at the same time it
was the most expensive treatment option. Behavioural therapy was the least
effective option and was costlier than medication; therefore, behavioural
therapy was dominated by medication. The ICER of combined therapy versus
medication was £323,279 per QALY. This value is far beyond the cost-
effectiveness threshold of £20,000 per QALY set by NICE (The Guidelines
Manual [NICE, 2006]). This means that, according to base-case results,
medication is the most cost-effective treatment option among those assessed.
Full results of the base-case analysis are presented in Table 38.

Sensitivity analysis
Results were robust under the vast majority of scenarios tested in the
sensitivity analysis. Medication remained the dominant option over
behavioural therapy or it became costlier at a cost per QALY below the NICE-
defined threshold of cost effectiveness. The only scenario that strongly
affected conclusions in favour of behavioural therapy was the delivery of
behavioural therapy in groups of parents (and children, in the case of CBT for
school-age children) rather than individually. For pre-school-age children,
behavioural therapy consisting of ten hourly sessions delivered to groups of
ten parents (plus two booster sessions provided individually to parents of
responding children) resulted in medication being more expensive than
behavioural therapy at an additional cost of £225,378 per QALY. For school-
age children, a cognitive behavioural intervention consisting of ten hourly
sessions delivered to groups of ten parents and ten hourly sessions provided
to groups of ten children, including two half-hourly individual meetings with
teachers at school (plus two booster sessions provided individually to parents
and children) resulted in an additional cost of medication versus behavioural
therapy of £111,909 per QALY. Both values are above the NICE set cost-
effectiveness threshold, which means that, under these scenarios, medication
is not a cost-effective option when compared with behavioural therapy. It
must be noted, though, that these ICER values were derived from scenarios assuming therapy groups working to full capacity; that is, delivering the service to ten parents and children each time. If parents or children drop out of therapy without being replaced by other parents or children in the group, the relative cost effectiveness of group-based behavioural therapy will be reduced. Threshold analysis demonstrated that for pre-school-age children, even 30% capacity was enough for group-based behavioural therapy to be cost-effective over medication. For school-age children, cognitive behavioural therapy was required to work at minimum 60% capacity in order to remain cost effective compared with medication.

In none of the scenarios explored was combined treatment found to be cost effective, even when it included group-based behavioural therapy. When utility data obtained by Secnik and colleagues (2005b) were used, or the side-effect rate of medication was set at 0.41 (threshold analysis), combined treatment was dominated by behavioural therapy. Threshold analysis demonstrated that at no value of the rate of side effects, rate of stopping treatment due to intolerable side effects, or decrement in quality of life due to presence of side effects, was (individual) behavioural therapy more cost effective than medication. Behavioural therapy (individually delivered) might result in more QALYs than medication at certain threshold values of the parameters examined in the threshold analysis, but with an ICER constantly exceeding the cost-effectiveness threshold determined by NICE. Threshold analysis showed that medication was not cost effective relative to individual behavioural therapy (ICER of medication versus behavioural therapy was £62,229 per QALY), when psychologists met with parents for 2 hours only (instead of 8, as modelled in the base-case analysis). It is highly unlikely though that behavioural therapy can be as effective as described in the trials utilised in this analysis with 2 hours of parent contact. Changes in effectiveness and cost estimates of ‘other treatment’ did not affect the results of the analysis in any way; this was expected, as the number of children ending in ‘other treatment’ was similar in all three treatment options examined.

Full results of the one-way sensitivity analysis are shown in Table 39.

Limitations of the economic analysis

The results of the economic analysis were based on a simple decision-analytic model developed to estimate total costs and health benefits associated with provision of medication, behavioural therapy or combined treatment over the period of 1 year. Clinical evidence was derived from two trials that reported outcomes in the form of response to treatment. The total number of participants in these two trials was small (N=125). However, further evidence coming from studies reporting outcomes in the form of changes on scales measuring ADHD symptoms that were included in the guideline systematic review and meta-analysis supported clinical evidence utilised in this analysis.

Long-term harms and benefits of the treatment options assessed have not been explored in depth. Identifying potential harms of medication in the long term is likely to reduce its cost effectiveness relative to non-pharmacological interventions and in fact may raise other concerns over its use. Owing to lack of relevant data, the time horizon of the analysis was only 1 year. Despite the short time horizon of the analysis, a number of assumptions were still required at the development of the economic model. Children were assumed to remain improved, following initial response to treatment, over the rest of the time of the analysis up to 1 year, provided that they continued medication.
under monitoring if they had responded to medication, or that they attended  
a number of booster sessions if they had responded to behavioural therapy. In  
both cases full compliance for all children was assumed, and no deterioration  
was modelled. Responsiveness to treatment was assumed to be independent  
of non-responsiveness to previous treatment provided. In reality, lack of  
response to one type of treatment could be related to improved or, conversely,  
reduced responsiveness to another type of treatment. Acceptability of the  
treatment to children and their carers reflected in overall continuation rates  
associated with pharmacological or psychological interventions for ADHD,  
was not considered, owing to lack of relevant data. However, this is an  
important aspect that may significantly affect the relative cost effectiveness of  
an intervention.

Estimates on healthcare resource use were based on the expert opinion of the  
GDG, reflecting, as closely as possible, resource use described in the clinical  
studies utilised in the analysis; however, these studies described only vaguely  
some aspects of resource use, and obviously they did not provide any  
relevant data for resource use beyond the duration of the trials (that is,  
beyond 8 weeks of treatment). Therefore, resource use estimates utilised in  
the economic analysis were characterised by uncertainty, which, nevertheless,  
was addressed in the sensitivity analysis.

Estimated costs consisted of intervention costs only; potential cost savings to  
the healthcare, social and education services resulting from improvement in  
ADHD symptoms of children were not considered owing to lack of evidence.  
It is therefore likely that the relative cost effectiveness of the interventions  
assessed for children with ADHD is different from that suggested by the  
results of the analysis. It is expected that including potential cost savings  
would alter the cost-effectiveness results in favour of more effective  
interventions (that is, mainly combined therapy and, at a lower degree,  
medication).

Utility scores used in the base-case analysis were based on EQ-5D  
questionnaires completed by parents of children with ADHD in England  
(Coghill et al., 2004). EQ-5D is a generic measure of HRQoL and as such, it has  
been recommended by NICE for use in economic evaluation. However, the  
full methods used to convert EQ-5D scores into utility scores were not  
reported in the study. In addition, the GDG expressed concerns about the  
appropriateness of using a generic measure to capture aspects of quality of  
life in children with ADHD. For this reason, utility scores developed using  
vignettes describing health states specific to ADHD (Secnik et al., 2005b) were  
used in the sensitivity analysis. Utility scores used both in the base-case and  
sensitivity analysis were generated using parents of children with ADHD as  
proxy reporters of their children’s perceptions of their own HRQoL. There are  
concerns about using parents’ ratings as proxies to children’s experience; still,  
for some groups of children who are unable to reliably report their own
perceptions and preferences, parent proxies may be appropriate (Wallander et al., 2001; De Civita et al., 2005). In the area of ADHD, no data on HRQoL preferences directly reported by children, rather than by their parents, are currently available.

A key assumption driving the conclusions of this analysis was that individually delivered and group-based behavioural therapy are equally effective. Although there is some preliminary indirect evidence to suggest this, equivalence of the efficacy between the two modes of delivery of behavioural therapy has not been unambiguously determined. In sensitivity analysis, group-based behavioural therapy (or a cognitive behavioural intervention for school-age children) was modelled using resource estimates representing optimal practice according to the GDG and further published evidence; however, its response rate was assumed to be the same as that derived from the meta-analysis of GITTELMAN-KLEIN1976B and KLEIN1997B: both of these studies examined individual therapy, though, and no trials comparing directly individual with group-based behavioural therapy have been identified. This needs to be considered when interpreting the results of the analysis.

11.5.3 Overall conclusions from the economic analysis

The results of the economic analysis indicate that medication is more cost effective than individual-based behavioural therapy for children with ADHD, as it is clearly more effective and cheaper overall. However, if the effectiveness of behavioural therapy is not significantly affected by the mode of delivery, as suggested by indirect clinical evidence, then group-based behavioural therapy is likely to be the optimal strategy in terms of cost effectiveness for this population, given that the ICER of medication versus group-based behavioural therapy was found to exceed the NICE-set threshold of cost effectiveness. Combination therapy was not cost effective under any scenario explored in the analysis.

The above conclusions are subject to a number of limitations, as already discussed. Further research is needed to fully explore the long-term harms and benefits associated with the treatment options assessed, as well as to investigate in depth the perceptions of children and their carers on aspects of HRQoL associated with ADHD. Moreover, future research needs to determine the relative effectiveness of group-based and individually delivered behavioural therapy, so that the cost effectiveness of group-based behavioural therapy versus medication can be determined with less uncertainty.

11.5.4 Economic analysis alongside the MTA study

Two studies (Jensen et al., 2005; Foster et al., 2007) assessed the cost effectiveness of the interventions examined in the MTA study (MTA Cooperative Group 1999; 2004a; 2007) from the perspective of a third-party
payer in the US. The interventions assessed in the study were medication management, intensive behavioural treatment, combination therapy, and routine community care. The economic analysis of the MTA study is discussed separately from the rest of the economic literature, because it refers to intensive interventions, which are likely to differ from pharmacological, psychological and combination therapies routinely available in the UK for children with ADHD in terms of both effectiveness and associated resource use. Details on the methods adopted in the studies, their overall limitations, and results involving the comparison between medication management and routine community care are provided in Chapter 10. Characteristics and results of the studies are summarised in the form of evidence tables in Appendix 14.

According to Jensen and colleagues (2005), intensive behavioural treatment was dominated by medication management in all sub-groups of children with/without comorbidities examined, as well as in the total study population. Consequently it was clearly not a cost-effective option. Combined treatment was more effective than medication management in the majority of the sub-groups examined; however, the ICER of combined treatment versus medication management was rather high, ranging from US$29,840 (ADHD plus both internalising comorbidities, that is, anxiety and depression, and externalising comorbidities, that is, conduct and oppositional defiant disorders) to US$74,560 (ADHD plus externalising disorder) per normalised child, with normalisation determined by scores on the SNAP scale. For children with ADHD plus internalising disorder, medication management was more effective and cheaper than combined treatment (dominant option). The ICER of combined treatment versus medication management for the total population of children with ADHD combined was US$55,253 per child normalised (all costs expressed in 2000 prices). Based on the findings of the analysis, the authors concluded that medication management, although not as effective as combined treatment, was likely to be the most cost-effective option for children with ADHD, in particular for those without comorbid disorders. For children with ADHD and both internalising and externalising disorders they suggested that combined treatment might be relatively cost effective. However, besides cost effectiveness, the authors highlighted the need to consider additional factors when making decisions on the appropriate treatment for children with ADHD, such as the presence of side effects from medication, the comfort and satisfaction of families with the treatment approach, and the family’s overall feelings about the causes of ADHD.

Foster and colleagues (2007) demonstrated that, for the total population of children with ADHD, medication management was the most cost effective among the four interventions assessed at lower willingness-to-pay (WTP) for functioning improvement (from zero to around US$55,000 per Columbia Impairment Scale effect size - CIS SE). At higher levels of WTP, combined treatment became the most cost-effective strategy. These findings applied also
to the population of children with ADHD and externalising disorder. For children with pure ADHD, medication management appeared to be cost-effective at all levels of WTP. In contrast, for children with ADHD and internalising comorbidities, intensive behavioural treatment might be cost effective at high levels of WTP, while medication management appeared to be cost effective at low levels. Finally, in children with ADHD plus both internalising and externalising comorbidities, medication management was clearly cost effective at lower levels of WTP. At higher levels, the probabilities of medication management, intensive behavioural treatment and combined treatment being cost effective were similar and no clearly cost-effective option could be identified. Based on the results of their analysis, the authors stated that, for pure ADHD, medication management was certainly the most cost-effective option at all levels of WTP. In contrast, for comorbid conditions, WTP was crucial in determining the cost-effective treatment option: for lower WTP, medication management was the most cost-effective intervention; but for policy makers willing to pay more to avert future costs such as special education and juvenile justice costs, intensive behavioural treatment alone or combined with medication management (depending on the comorbidity) was likely to be the most cost-effective treatment.

As described in Chapter 11, Schlander and colleagues (2006a; 2006b; 2006c) evaluated the relative cost effectiveness of the interventions examined in the MTA study in the context of four European countries, utilising the effectiveness data and resource use estimates reported in the MTA study, but applying country-specific unit costs. One of the analyses referred to the UK setting. The analysis adopted the perspective of the NHS (direct medical expenditures). Costs were calculated in UK£ and then converted to 2005 Euros (€). In addition to previous sub-groups identified, the authors provided results for children with ADHD combined type (according to DSM-IV), hyperkinetic/conduct Disorder (HKD/HKCD) (according to ICD-10), pure ADHD (without comorbidities), and pure HKD (without comorbidities). The measures of outcome used in the economic analyses were the number of children with ADHD normalised, the CIS ES, and also the QALYs gained by treatment.

In most sub-populations of children, intensive behavioural treatment was dominated by medication management. The two exceptions were the sub-groups of children with internalising comorbidities and children with both internalising and externalising comorbidities, when the outcome was measured as CIS ES. In these cases, intensive behavioural therapy was shown to be more effective than medication at an incremental cost of €13,030 and €113,540 per CIS ES, respectively (£8,990 and £78,300, respectively, at a conversion rate of 1UK£ = 1.45€). Combined treatment achieved higher proportions of children normalised compared with medication management in all sub-groups of children examined. The ICER of combined treatment versus medication management per normalised child in the UK reached...
€66,150 for ADHD combined type, €57,600 for pure ADHD, €37,320 for HCD/HKCD, and €26,460 for pure HKD (or £45,620, £39,720, £25,740, and £18,250 respectively, at a conversion rate of 1UK£ = 1.45€). When the measure of outcome was the CIS ES, then combined treatment was less effective than medication management in children with pure ADHD, children with pure HKD, and children with HCD/HKCD. In all these cases medication management dominated combined treatment. Medication management was dominant over combined treatment also in children with internalising comorbidities. The ICER of combined treatment versus medication management in the total population of children with ADHD was as high as €705,115 per CIS ES.

CEACs demonstrated that, for the majority of sub-populations examined, medication management had the highest probability of being cost effective among the treatment options compared, at least for low levels of WTP. When the WTP rose up to roughly €40,000, €60,000, and €80,000 per child normalised, then combined treatment appeared to be the most cost-effective option for children with both internalising and externalising disorders, the total population of children with ADHD, and children with externalising comorbidities, respectively. For children with internalising comorbidities, medication management was the most cost-effective treatment at any level of WTP per child normalised. Regarding functional improvement, medication management was also shown to be the most cost-effective option at lower levels of WTP. However, in children with internalising comorbidities intensive behavioural treatment was the most likely cost-effective option at levels of WTP of around €15,000 per CIS ES and above.

Schlander and colleagues (2006a) did not provide ICERs expressing cost per QALY gained specific to the UK context. Instead, they reported ranges of such ICERs for the four European settings examined in the analysis. However, it was possible to estimate such ratios for the various sub-populations of children with ADHD, using the reported costs per child treated in the UK context, the proportions of children normalised in the MTA study, and utility weights reported in Coghill and colleagues (2004). QALYs were estimated assuming that improvement in HRQoL occurred at time zero for responders. Decrement in HRQoL from medication was not considered in these estimates. Since intensive behavioural therapy was dominated by medication management when the measure of outcome was the proportions of children normalised, the appropriate comparison (apart from the comparison between medication management and routine community care, which has been reported in Chapter 10) was between combined treatment and medication management. The estimated ICERs from this comparison were £612,530 per QALY for ADHD combined type, £543,960 per QALY for pure ADHD, £351,780 per QALY for HCD/HKCD, and £248,060 per QALY for pure HKD.
The above results indicate that intensive behavioural therapy and combined treatment are highly unlikely to be cost effective for children with ADHD from the perspective of the NHS, given also the NICE-set cost-effectiveness threshold of £20,000 per QALY (The Guidelines Manual [NICE, 2006]). Although these results refer to intensive interventions, they lead to the same conclusions as those reported in other published studies about the cost effectiveness of behavioural and combined therapies, and the results of the economic model described in the previous section in this chapter. Medication management was the most cost-effective option compared with intensive behavioural therapy and combined treatment, at least for modest levels of WTP. However, as reported in Chapter 9, routine community care reflecting US clinical practice might be more cost-effective than medication management. However, no safe conclusions can be made, as routine clinical practice in the US may vary significantly from respective practice in the UK, and therefore the results of the analysis (which were based on US resource estimates) might not be representative of the UK healthcare setting.

11.6 From evidence to recommendations: Treatment decisions and combined treatment for children with ADHD

Evidence from studies that have compared the effectiveness of stimulant medication for ADHD against the effectiveness of the use of psychological therapies for ADHD without concurrent administration of stimulant medication may help to inform the choice of first-line treatment for ADHD. Clear evidence strongly favouring one approach or another might point to an unequivocal recommendation as to which approach should always be used first, with alternatives being employed only where children do not respond to the first-line treatment. While there is no evidence that psychological interventions are favoured for any outcome, or at any time point, it is also the case that stimulant medication for ADHD is not strongly favoured over psychological interventions, with the benefits of medication being weakest in comparison with complex psychological interventions. It also remains unclear whether the beneficial effects of stimulant medication over psychological interventions are sustained after the end of treatment. Accordingly the decision about whether to use a psychological intervention or stimulant medication for ADHD appears to be more balanced. In this context the choice of first-line intervention might be influenced by factors other than effectiveness, including possible adverse effects of medication and preferences of the child and/or parent.

The health economic analysis indicates that intensive behavioural therapy and combined treatment are unlikely to be cost effective for children with ADHD.
11.7 Recommendation

11.7.1.1 Drug treatment is not indicated for all school-age children. It should be reserved for those with moderate ADHD symptoms and impairment who have refused, or whose symptoms have not responded sufficiently to, parent-training programmes or individual psychological treatment, if this has been provided. (this recommendation is also included as 10.17.2.1 in Chapter 10).

Guideline title

Attention deficit hyperactivity disorder: diagnosis and management of ADHD in children, young people and adults

Short title

ADHD

Background

The National Institute for Health and Clinical Excellence (‘NICE’ or ‘the Institute’) has commissioned the National Collaborating Centre for Mental Health to develop a clinical guideline on attention deficit hyperactivity disorder for use in the NHS in England and Wales. This follows referral of the topic by the Department of Health and Welsh Assembly Government (see Appendix). The guideline will provide recommendations for good practice that are based on the best available evidence of clinical and cost effectiveness.

The Institute’s clinical guidelines will support the implementation of National Service Frameworks (NSFs) in those aspects of care where a Framework has been published. The statements in each NSF reflect the evidence that was used at the time the Framework was prepared. The clinical guidelines and technology appraisals published by the Institute after an NSF has been issued will have the effect of updating the Framework.

NICE clinical guidelines support the role of healthcare professionals in providing care in partnership with patients, taking account of their individual needs and preferences, and ensuring that patients (and their carers and families, where appropriate) can make informed decisions about their care and treatment.

Clinical need for the guideline

Attention deficit hyperactivity disorder (ADHD) is a heterogeneous behavioural syndrome and its diagnosis does not imply any specific cause. However various genetic and environmental risk factors have been implicated in its development. ADHD is characterised by the 'core' signs of inattention, hyperactivity and impulsiveness. There are two main sets of diagnostic criteria in current use, the International Classification of Mental
and Behavioural Disorders 10th Revision (ICD-10) and the Diagnostic and Statistical Manual of Mental Disorders fourth edition (DSM-IV). The ICD-10 definition makes reference to hyperkinetic disorder, primarily evidenced by high abnormal levels of hyperactivity, and a combined sub-type in which hyperactivity, impulsivity and inattention need to be present, together with stricter requirements for pervasiveness across situations, and exclusion of comorbidity. The DSM-IV criteria describes ADHD more broadly to include three subtypes: a combined subtype in which all three core signs are present; a predominantly inattentive subtype in which inattention is present but not hyperactivity or impulsiveness; and a predominantly hyperactive-impulsive subtype in which hyperactivity and impulsiveness are present but not inattention. Both ICD-10 and DSM-IV require 6 months duration of symptoms. The identification of ADHD in adults, and the diagnostic criteria that should underpin case recognition, are less clear and lead to uncertainties in practice.

ICD-10 and DSM-IV adopt a different approach to comorbidity. In ICD-10, secondary complications to hyperkinetic disorder include dissocial behaviour and low self-esteem. In DSM-IV common comorbidities include: Disruptive Behaviour Disorders, Mood Disorders, Anxiety Disorders, Learning Disorders and Communication Disorders. ADHD is not diagnosed if symptoms of inattention and hyperactivity occur exclusively during the course of a Pervasive Developmental Disorder or a Psychotic Disorder; but the problems may still need to be recognised and treated. It seems likely that a similar pattern of comorbidities pertains to adults with ADHD, although definitive research in this area is lacking.

A number of genetic and environmental risk factors for ADHD have been identified. Hereditary aspects, neuroimaging data and responses to pharmacotherapeutic agents support the suggestion that ADHD has a biological component. However, there is a continuing debate over the causes of ADHD.

ADHD affects children, young people and adults in different ways and to different degrees, but the consequences of severe ADHD can be serious for both the individual and their family and carers. Children with ADHD often have low self-esteem and can develop additional emotional and social problems. The secondary effects of ADHD can be damaging. For example, some children and young adults with ADHD are at increased risk of accidental harm and many later have an increased risk of automotive accidents. Moreover, affected children are often exposed to years of negative feedback about their behaviour and may suffer educational and social disadvantage. A sizeable proportion of children referred for hyperactivity disorders continue to have problems into adulthood, including emotional and social problems, substance misuse, unemployment and involvement in crime.
Estimates of the prevalence of hyperkinetic disorder / ADHD vary widely within and between countries. Prevalence estimates for hyperkinetic disorder in children and young people are around 1–2% in the UK. ADHD is estimated to affect 3–9% of school-aged children and young people in the UK, and about 2% of adults worldwide (using DSM IV diagnostic criteria). These differences are, at least in part, explained by differences in diagnostic criteria used in different countries.

Studies of clinic based diagnoses suggest that ADHD is nine times more common in males, although this gender imbalance is inflated to some extent by referral bias; epidemiological studies suggest that prevalence is only two to four times greater in males.

The prescribing of stimulant drugs for ADHD reflects the increased frequency of diagnosis of this condition. In 1998 there were about 220,000 prescriptions in England for stimulant drugs (methylphenidate and dexamfetamine) at a net cost of about £5 million; in 2004 this number had almost doubled to 418,300 at a cost of almost £13 million.

The use of CNS stimulants has been controversial and there are concerns about prescribing such medication to children. Further anxieties surround the potential for their inappropriate prescription, abuse and unauthorised trading and/or illegal selling.

The Guideline

The guideline development process is described in detail in two publications which are available from the NICE website (see ‘Further information’). The guideline development process: an overview for stakeholders, the public and the NHS describes how organisations can become involved in the development of a guideline. Guideline development methods: information for National Collaborating Centres and guideline developers provides advice on the technical aspects of guideline development.

This document is the scope. It defines exactly what this guideline will (and will not) examine, and what the guideline developers will consider. The scope is based on the referral from the Department of Health (see Appendix below).

The areas that will be addressed by the guideline are described in the following sections.

Population

The guideline will cover:

- The treatment of children aged 3 years and older, young people and adults with a diagnosis of ADHD and related diagnoses: hyperkinetic
disorder (ICD-10) will be considered, along with the three DSM-IV ADHD subtypes.

- The management of common comorbidities in children, young people and adults with ADHD as far as these conditions affect the treatment of ADHD.
- The specific management of ADHD in those individuals who also have:
  - a learning disability
  - a defined neurological disorder.

The guideline will not cover:
- the separate management of comorbid conditions
- the management of children younger than 3 years

Healthcare setting

The guideline will cover the care provided by primary, community and secondary healthcare professionals who have direct contact with, and make decisions concerning, the care of children, young people and adults with ADHD.

This is an NHS guideline. It will comment on the interface with other services such as social services, educational services, the voluntary sector and young offender institutions, but it will not include recommendations relating to the services exclusively provided by these agencies; except insofar as the care provided in those institutional settings provided by healthcare professionals, funded by the NHS. Recommendations in the guideline will nevertheless map onto the tiered model of CAMHS services specified in the NSF for children and utilised in the NICE guideline on depression in children. Some of the recommendations will be made to staff in the education services, where this may have a positive contribution to the health of a child with ADHD, either directly (where this is appropriate) or indirectly through collaborative working with CAMHS professionals.

The guideline will include:
- care in general practice and NHS community care
- hospital outpatient and inpatient care
- primary/secondary interface of care
- transition from childhood services to adult services.

Clinical management

Areas that will be covered by the guideline
- The full range of care routinely made available by the NHS.
- Validity, specificity and reliability of existing diagnostic criteria (ICD-10 and DSM-IV) in children, young people and adults, and to determine /
specify the criteria that should be used to determine the circumstances in which this guideline should be used.

• Assessment both before and after diagnosis.
• Early identification of ADHD in children at risk, and identification of factors that should lead to investigation into the possibility of ADHD.
• Pathways to treatment.
• Identification and management of risk.
• The appropriate use of pharmacological interventions, for example initiation and duration of treatment, management of side effects and discontinuation. Specific pharmacological treatments considered will include:
  o methylphenidate and dexamfetamine (currently licensed for treatment of ADHD in children and young people)
  o atomoxetine (currently licensed for treatment of ADHD in children and in adults if treatment was initiated in childhood).
  o tricyclic and other antidepressants.
  o bupropion
  o nicotine (as skin patches)
  o clonidine
  o atypical antipsychotics (particularly risperidone)
  o modafinil

Note that guideline recommendations will normally fall within licensed indications; exceptionally, and only where clearly supported by evidence, use outside a licensed indication may be recommended. The guideline will assume that prescribers will use a drug’s Summary of Product Characteristics to inform their decisions for individual patients.

• All common psychological interventions currently employed in the NHS for example, family interventions, cognitive-behavioural treatments, and parent training.
• Combined pharmacological and psychological treatments.
• Other physical treatments, including dietary elimination and supplementation.
• Treatment approaches for adults with ADHD (including longer-term outcomes and transitions from child to adult healthcare).
• Sensitivity to different beliefs and attitudes of different races and cultures, and issues of social exclusion.
• The role of the family or carers in the treatment and support of people with ADHD (with consideration of choice, consent and help), and support that may be needed by carers themselves.

Areas that will not be covered by the guideline
• Treatments not normally available in the NHS.
Status

Scope
This is the final scope.

The guideline will incorporate the following relevant technology appraisal guidance issued by the Institute:

Methylphenidate, atomoxetine and dexamfetamine for the treatment of attention deficit hyperactivity disorder in children and adolescents (including a review of guidance no.13) NICE Technology Appraisal (Published March 2006)

Previous recommendations made in other guidelines may be updated by this guideline, based on the most up-to-date evidence for this particular population.

Guideline

The development of the guideline recommendations will begin in March 2006.

Further information

Information on the guideline development process is provided in:

This booklet is available as PDF files from the NICE website (http://www.nice.org.uk/page.aspx?o=308639). Information on the progress of the guideline will also be available from the website.

Referral from the Department of Health and Welsh Assembly Government

The Department of Health and Welsh Assembly Government asked the Institute:

To prepare a guideline for the NHS in England and Wales on the diagnosis and treatment of attention deficit Hyperactivity disorder in children, young people and adults, where evidence for treatment effectiveness is available. Treatment should include the effectiveness of methylphenidate and other pharmacological and psychological interventions in combination or separately.
Appendix 2: Declarations of interests by GDG members

With a range of practical experience relevant to ADHD in the GDG, members were appointed because of their understanding and expertise in healthcare for people who misuse drugs and support for their families and carers, including: scientific issues; health research; the delivery and receipt of healthcare, along with the work of the healthcare industry; and the role of professional organisations and organisations for people who misuse drugs and their families and carers.

To minimise and manage any potential conflicts of interest, and to avoid any public concern that commercial or other financial interests have affected the work of the GDG and influenced guidance, members of the GDG must declare as a matter of public record any interests held by themselves or their families which fall under specified categories (see below). These categories include any relationships they have with the healthcare industries, professional organisations and organisations for people who misuse drugs and their families and carers.

Individuals invited to join the GDG were asked to declare their interests before being appointed. To allow the management of any potential conflicts of interest that might arise during the development of the guideline, GDG members were also asked to declare their interests at each GDG meeting throughout the guideline development process. The interests of all the members of the GDG are listed below, including interests declared prior to appointment and during the guideline development process.
Categories of interest

- Paid employment

- GDG members were asked to declare the following interests annually and at each meeting:

  **Personal pecuniary interest:** Any financial involvement or planned financial involvement with the healthcare industry in the previous 12 months and, if so whether it is ongoing. This includes:
  - holding a directorship, or other paid position
  - carrying out consultancy or fee paid work
  - having shareholdings or other beneficial interests
  - receiving expenses and hospitality over and above what would be reasonably expected to attend meetings and conferences

  **Personal family interest:** A family member with any financial involvement or planned financial involvement with the healthcare industry in the previous 12 months. This could include:
  - holding a directorship, or other paid position
  - carrying out consultancy or fee paid work
  - having shareholdings or other beneficial interests
  - receiving expenses and hospitality over and above what would be reasonably expected to attend meetings and conferences

  **Non-personal pecuniary interest:** Managerial responsibility within the past 12 months for a department or organisation that has had financial involvement with the healthcare industry or for which such financial involvement is planned. This includes:
  - a grant or fellowship or other payment to sponsor a post, or contribute to the running costs of the department
  - commissioning of research or other work
  - contracts with, or grants from, NICE

  **Personal non-pecuniary interest:** Having expressed a clear opinion on the matter under consideration which has been:
  - reached as a conclusion of a research project
  - and/or expressed as a public statement
  - Membership in a professional organisation or advocacy group with a direct interest in a matter under consideration by NICE

Any other reason why people might assume bias in the work done for NICE

To be completed in final draft

<tr>
<td>- does the waiting for a treatment influence outcome?</td>
</tr>
<tr>
<td>2.5 What is the optimum duration of treatment?</td>
</tr>
<tr>
<td>- what are the long-term consequences of treatment?</td>
</tr>
<tr>
<td>2.6 What is the most effective first line treatment and under what circumstances (e.g. epilepsy, potential for misuse, tics, Tourette syndrome, etc.)?</td>
</tr>
<tr>
<td>- what is the recommended order of combined treatments?</td>
</tr>
</tbody>
</table>

Adherence

2.7 What approaches can be used to optimise adherence with psychological treatment?

---

19 Inserted in place of question under Interventions for carers: ‘Is there evidence on: the effectiveness of combined therapies compared to a single therapy?’

20 Separate section for clinical questions on combined interventions deleted and combination comparisons rationalised to fit the scheme for psychological interventions (combinations of drugs to be dealt with in pharma. questions).
3. INTERVENTION FOR CARERS

<table>
<thead>
<tr>
<th>No.</th>
<th>Question</th>
</tr>
</thead>
</table>
| 3.1 | Are there interventions that improve the well-being of parents/carers and may provide an indirect benefit for the child, but where evidence on outcomes for the child with ADHD is not available (peer support groups, counselling, advice/information and guidance)?

4. PHARMACOLOGICAL INTERVENTIONS

<table>
<thead>
<tr>
<th>No.</th>
<th>TG</th>
<th>Question</th>
</tr>
</thead>
<tbody>
<tr>
<td>4.1</td>
<td></td>
<td>Drug effectiveness, choice and moderating factors. For people with ADHD, does</td>
</tr>
</tbody>
</table>

---

21 The clinical questions originally listed the following interventions for carers: psychoeducational interventions (advice/information, parental guidance); parent effectiveness training; counselling; CBT – however, as parent training interventions are behavioural interventions these are addressed in clinical question 2.1. The section on interventions for carers will address other interventions with carers where the aim is to improve the wellbeing of the parents/carers and where effectiveness is measured by parental outcomes. This is outside the scope of the guideline and will be addressed by a (brief) narrative overview of the types of intervention available and evidence on their effectiveness.
### Treatment decisions: Duration, discontinuation and effect evaluation

#### 4.2 Which drugs should be used as a 1st line, 2nd line, etc. treatment? How should drug treatment be initiated, dose titrated and effectiveness evaluated?

- What is the optimum duration of drug treatment* (length of time; continuous vs. intermittent treatment) and
  - when is discontinuation attempted?
  - what advice is given for discontinuation?

#### 4.3 Is there any evidence on:

- what is the most effective type of drug administration (to improve adherence) and
- what is the dose optimisation and how is this best achieved (where outcome is optimal)?

### Side effects, monitoring, precautions and abuse potential

#### 4.4 What conditions contraindicate or caution the use of specific drug treatments?

- What are the necessary baseline investigations and on-going
4.5 What are the risks of prescribing drug treatment in the presence of recreational drug use and/or alcohol use and what approaches should be taken if in the presence of recreational drug use and/or alcohol use?

Education, adherence and shared-care

4.6 How is drug treatment monitored and by who (by specialist, by GP and/or by care coordinator)?

4.7 What approaches to drug treatment can be used to support drug adherence? Are there any interventions that can improve adherence when initiating drug treatment? When there are problems regarding adherence to drug treatment in people with ADHD are there any interventions that can improve adherence with medication?

3. EDUCATION

<table>
<thead>
<tr>
<th>No.</th>
<th>TG</th>
<th>Question</th>
</tr>
</thead>
<tbody>
<tr>
<td>Education</td>
<td></td>
<td></td>
</tr>
<tr>
<td>6.1</td>

#### Eligibility criteria

| Intervention |

- Psychoeducational interventions (advice/information, parental guidance) for carers
- Parent effectiveness training
- Counselling for carers
- CBT for carers |

| Comparator |
Population (including age, gender etc) | Parents of children, adolescents, and adults with ADHD, ADD, MBD, comorbid ADHD.

Outcomes (see Outcomes document for definitions) | - Improvement on score of Conners Rating Test (including all variations of this test and subscales)
- Improvement on score of ADHD Rating Scale
- Improvement on score of DuPaul Test
- Improvement on score of SKAMP Test
- Improvement on score of SNAP Test
- Improvement on social skills
- Improvement on academic performance
- Reduction of impairment
- Leaving study early
* as in the rest of the clinical questions, outcomes are taken from children and young people with ADHD regardless if the interventions are directed at carers

Study design | RCT

Publication status | [Published and unpublished (if criteria met)]

Year of study | [Any]

Dosage | [Any]

Minimum sample size | n > 10

Study setting | [Any]

Relevant questions | Q4.1 - Drug Treatment (stimulants)

Chapter | 9 Pharmacology

Sub-section | Stimulants (methylphenidate, dexamphetamine)

Topic Group | TG3 Pharma

Search strategy | Databases: CENTRAL, CINAHL, EMBASE, MEDLINE, PsycINFO

### Amendments to filter/ search strategy

### Eligibility criteria

- **Intervention**
  - Methylphenidate (including extended release preparations)
  - Dexamphetamine

- **Comparator**
  - Waiting lists, placebo; active comparator (head to head trials, e.g. atomoxetine, TCAs, etc.)

- **Population**
  - Children, adolescents, and adults with ADHD, ADD, MBD, comorbid ADHD.

### Outcomes

(see Outcomes document for definitions)

- Improvement on score of Conners Rating Test (including all variations of this test and subscales)
- Improvement on score of ADHD Rating Scale
- Improvement on score of DuPaul Test
- Improvement on score of SKAMP Test
- Improvement on score of SNAP Test
- Improvement on academic performance
- Reduction of impairment
- Side effects (e.g. s)
- Leaving the study early

### Study design

RCT (efficacy, acceptability, tolerability, adverse events)

### Publication status

Appendix 10: Quality checklists for diagnostic studies, clinical studies and reviews

The methodological quality of each study was evaluated using dimensions adapted from SIGN (SIGN, 2001). SIGN originally adapted its quality criteria from checklists developed in Australia (Liddel et al., 1996). Both groups reportedly undertook extensive development and validation procedures when creating their quality criteria. For information about how to use these checklists please see (The Guidelines Manual).

### Quality Checklist for a Systematic Review or Meta-Analysis

<table>
<thead>

**SECTION 2: OVERALL ASSESSMENT OF THE STUDY**

| 2.1 | How well was the study done to minimise the risk of bias or confounding, and to establish a causal relationship between exposure and | | | | | | |
A cohort study can be defined as a retrospective or prospective follow-up study. Groups of individuals are defined on the basis of the presence or absence of exposure to a suspected risk factor or intervention. This checklist is not appropriate for assessing uncontrolled studies (for example, a case series where there is no comparison [control] group of patients).

7 December 2007

INTRODUCTION

Stimulant medication is a widespread and generally supported treatment for Attention Deficit Hyperactivity Disorder (ADHD). While the benefits are well-recognised, so are the negative side effects (Kutcher et al, 2004; DuPaul & Barkley, 1990). In addition to understanding the clinical and cost effectiveness aspects of the use of these interventions, an important function of developing this guideline is capturing the voice of the service user; this is particularly pertinent where the user is a young person.

In order to capture a sufficient breadth of context and depth of understanding it was decided to use a qualitative methodology, the focus group. The following sections contain an in-depth consideration of the use of this methodology with young people as participants, a comparison of quantitative and qualitative methodologies, a review of the little literature available on young people’s experience of medication for ADHD, supplemented by a broader consideration of young people’s experiences of medication for other conditions.

It is important to understand that the current research investigated the perceptions, knowledge of and attitude to stimulant medication for ADHD as a primary focus, rather than a broader consideration of the diagnostic process and use of other interventions. The latter are peripherally considered, however, both in the following review of literature and in the experimental phase.

Using qualitative research methods in young people
The use of qualitative methods with young people has been recognised as a valuable route to a closer understanding of children’s perspectives of their illness experience (Woodgate, 2000a). These methods tend to yield information that is more of a reflection of the perspectives of the child participants, rather than those of the adult researchers (Woodgate, 2000a). There are, however, considerations attached to the use of these techniques in young people, over and above those inherent with this kind of data collection. Curtin (2001) highlights the need to examine perceptions of children’s competence, consider the inequality of power between the child participants and the adult participants, and bridge the generational differences in communication styles. There is also a need to consider the reconciliation between the requirements of the sponsors of the research, and the ideals of participation (Hill et al, 1996). Ireland & Holloway (1996) also raise the asymmetrical relationship between researcher and participants. They go on to consider the difficulties relating to access to participants, as well as ethical and developmental issues. They highlight the requirement for adequate safeguards and an awareness of the potential hazards. Kortesluoma et al (2003) assert that there is very little guidance available for conducting this kind of research, the empirical and conceptual foundation for child interviewing is not very clear. The method chosen should suit both the purpose and context. The literature together forms a narrative that has a clear message- extra care is required both in the design and execution of data collection methods to ensure that information gathered are robust and useable, and that all ethical considerations relating to the vulnerable participant group are met. Much of what has been written describes the potential hazards around interviewing young people. While our chosen focus group methodology shares many of these, some are lessened (i.e. the power inequality), although there are others that must be taken into consideration which are extensions of generic focus group issues. These are not considered in the literature, so have been taken into account by the research team through extrapolation of knowledge from both arenas.

In order to ensure that competing needs of the research sponsors and ethical consideration were reconciled, our research proposal was reviewed by the Guideline Development Group, a nationally sanctioned ethics committee and local R&D committees. The research team undertaking the focus groups were experienced both in qualitative methodologies and working with young people, and carefully researched the issues described above prior to data collection.

**Young people’s experience of stimulant medication**

As highlighted above, the importance of the service user’s voice has been recognised in the methodology for this guideline. It is important, when preparing for a focus group, to understand whatever previous research has...
contributed to the knowledge of the subject area, to give a structure to the
issues to be considered, and to identify what gaps in knowledge exist to give
focus to the investigation.

However, as pointed out by Kendall et al (2003): “Rarely are children’s and
adolescent’s perspectives heard in regard to ADHD” (p. 114). In recognition
of the paucity of research in this field, Kendall and colleagues (2003) collected
qualitative data from 39 children and adolescents with a diagnosis of ADHD
regarding their perceptions and experiences of living with the disorder. Their
findings showed that taking pills was a common theme. Both positive and
negative aspects of pill-taking were mentioned. For example, many of the
children spoke of how much the medication helped them in terms of
controlling their hyperactivity, increasing their concentration, improving their
grades and helping them to be better behaved. When children were asked
what helped the most with managing their ADHD, the majority reported that
it was the medicine.

However participants also mentioned negative aspects of pill-taking, e.g. pills
tasting bad and side effects including stomach-aches and headaches.
Significantly, what was of more concern to the participants was the stigma
associated with taking pills to manage their behaviour. Children mentioned
not wanting anybody to know that they took pills for fear of being laughed at.
A number of participants also talked about not wanting to take medication
because they did not like the change it made in them. According to one
participant: “I don’t like it. I just want to be myself. My Mom makes me take
it so I can focus…but I just want to be myself”. Other comments included: “It
just like changes me…it makes me awful, like this way…It’s like, I don’t like
to play that much anymore” and “Ritalin. I don’t take it anymore. I didn’t like
how I felt on it. I felt real depressed on it.”

Recent research has investigated potentially mitigating factors. Meaux et al
(2006) conducted qualitative interviews to explore the factors contributing to
whether or not children/adolescents continue to use prescription stimulant
medications as they progress through developmental stages. Although this
research was conducted with college students (n=15), their reflections on
taking medications as children are revealing.

The data revealed a “trade-off” between the positive and negative effects of
the medication. Participants unanimously confirmed that stimulant
medications improved their concentration and focus. The greatest benefits
mentioned by participants were being able to study longer, completing more
school work, and improving reading comprehension. However, all of the
participants described negative physiological and psychological side effects of
stimulant medication. Several felt the medication made them less sociable: “It
made me feel like I didn’t have friends. I didn’t ever really play that much”
(p.220). Others described medication as “taking away from the person I am”.

Interestingly, participants who were diagnosed with ADHD later and began taking stimulant medications later were more positive and insightful in their perception of general social effects to those who were diagnosed in early elementary school.

Talking about their experiences and feelings about having to take medication during the school day evoked strong emotions. The sense of stigma was reiterated in this study, with most participants describing the frustration, anger, sadness, and embarrassment of having to leave their classroom to receive medication. The authors comment how medication may in fact make children with ADHD more aware of their differences and difficulties, leading to decreased initiative and feelings of self-worth. In some cases the feeling of being different eventually led them to stop taking their medications.

While participants who were diagnosed in elementary school seemed to have their self-identity defined by ADHD and viewed medication as “changing who they were”, participants who were diagnosed later described themselves as having “strong personalities” and viewed medication as a means to manage the challenges of ADHD. This comparison should be treated with caution however given the limited sample size. Meaux and colleagues conclude that higher levels of education about prescription medication and more careful management are required to reduce side effects and minimise the risks of misuse.

The “trade-off” between the positive and negative dimensions of stimulant medications has also been echoed in other studies. Of 102 participants surveyed, Efron et al (1998) found that most children in their study viewed medication effects favourably although a substantial proportion experienced their medication adversely. Side-effects were found to be the main determinant of children’s perceptions of negative impact. In a study of mother and child perceptions of stimulant medication, McNeal et al (2000) found that mothers perceived the medication to be more beneficial than did the children. Of note, children’s views about the benefits of medication became more positive as their concern increased over the problems associated with the condition.

One other piece of research directly gathered data on young people’s knowledge of and attitude to stimulant medication. However this study is considerably dated (conducted by Baxley et al in 1978) and concerned the views of participants with ‘hyperactive child syndrome’ (a diagnostic category preceding ADHD). The researchers found that the young people were generally knowledgeable about their medication, yet had a mixed attitude to having to take it, and associated not taking it with certain negative consequences. Many of the issues raised in this study and those outlined above are explored further in the current research.
Self-perception in young people with ADHD

A number of papers consider the issue of self-perception among hyperactive children, from differing perspectives. While this is not directly relevant to our methodology, it provides valuable background about young people with ADHD. What follows is a chronology of this research.

Hoza et al (1993) found that there was no difference between young people with ADHD and those without in comparisons of self-perceived competence and global self-worth (when internalising symptomology was taken into account). Further, they found that while the ADHD diagnosed children showed higher scores on the Children’s Depression Inventory, this difference was not significant when behaviour, school and social problems were excluded. Self-perceptions may be used to mediate performance in challenging academic and social situations. In another study, Dumas et al (1999) showed that children with ADHD perceive themselves as less competent in all areas of self perception tested (scholastic competence, social acceptance, behavioural conduct) apart from athletic competence. This would seem to directly contradict Hoza’s findings 6 years earlier.

Krueger and Kendall (2001) found that an ADHD adolescent’s sense of self is distorted, and that the development of self has been disrupted due to the neurobiology of the ADHD and the environmental factors associated with the parenting of a difficult child. Significantly, it was found that adolescents defined themselves in terms of their ADHD traits and symptoms and did not perceive themselves as being distinct from the disorder. In other words, their experience of ADHD was intrinsically related to their identity. Therapeutic interventions to address self-function are recommended to aid the stabilisation of the self.

Adding a further dimension, Frame et al (2003) showed that participation in a school-based, nurse led support group was associated significantly with increases in scores on 4 self-perception sub-scales (social acceptance, athletic competence, physical appearance and global self-worth). Hoza et al (2004) found that children with ADHD are more likely to over-estimate their competence in comparison with an adult’s assessment. Barber et al (2005), in contrast, with Hoza’s 1993 study, found that children with ADHD had lower self-perception scores than those without the condition. This is attributed to the cumulative effect of years of low self-esteem and negative self-perception. They suggest that support groups and behavioural training may be a route to improving self-esteem and self-perception. There appears to be a disparity between these findings, particularly between Hoza and Barber and Dumas. This is likely to be due to different methodological and analysis techniques, but is not of direct relevance to current work.

Other papers investigated the effect of medication on aspects of performance. Medication versus placebo was found to increase correspondence between
participant’s self-evaluations and performance of a task, although generally
effort or ability were significantly more likely to be attributed as the cause
(Millich et al, 1989). This finding was confirmed by Pelham et al (2002), who
additionally found that medication improved behaviour (this was not related
to expectancy), and that failure was attributed to the task difficulty and the
effects of medication.

Young people’s experience of medication for other conditions
Since the theoretical background relating to children’s experience of
medication for ADHD is less prolific, it was felt to be advisable to widen the
consideration of literature to include young people’s experience of medication
for other conditions. It was felt that the issues of stigma, labelling and
difference would be common or at least similar to that experienced by
children prescribed stimulants for ADHD. A study by McElearney et al (2005)
compared the knowledge and perceptions of young people with ADHD or
epilepsy of their respective medications. More of the stimulant group (40% v
32.5%) categorised themselves as non-compliant. There was a significant
difference between the 2 groups in regard to confiding in friends about their
medication. A greater number of the epilepsy group (55% v 32.5%) reported
they would tell a friend about their medication, indicating perhaps that
ADHD is a more stigmatising illness than epilepsy.

More generally, Riis et al (2007) found that healthy young people were more
reluctant to take any medication that would alter fundamental traits (such as
social comfort) than to take those that improve non-fundamental traits (e.g.
concentration ability). Implications for ADHD stimulant medication are clear,
although research would need to specifically test this hypothesis in that group
to ensure that confounding factors do not reduce, remove or even reverse the
observed effect. Buston and Wood (2000) found that young people with
asthma would not comply with their medication regime because they felt it
was ineffective, due to a denial of their condition, inconvenience, fear of side
effects, embarrassment or laziness. This is in spite of a belief in the importance
of the medication, usually following a negative experience of non-compliance.
Barriers exist, however, leading to lack of compliance. This paper shows that
the relationship between compliance drivers and non-compliance drivers is
complex, and will be investigated during the current study.

Summary
The literature considered above gives a useful if far from comprehensive view
of young people with ADHD and their relationship with prescribed
medication. This is a poorly researched and therefore little understood area,
and there is a clear need for the current research, especially in the context of
the forthcoming NICE Guideline.

METHOD
Sample
The sample consisted of 16 children (14 boys and 2 girls) who ranged in age from 9 to 15 years old. All participants were attending state schools and with the exception of one child who was of mixed race, all the children were white. 50% of the children were living in two-parent homes, and 37% of children lived in single-mother homes. Two children lived with their father; and one child lived with his grandmother. Educational achievement and type of employment were used as indicators of socio-economic status (CITE). A majority of parents had completed O-levels; one parent had attended university. 72% of parents’ job types ranged from semi-skilled to skilled work. A majority of mothers did not report having employment.

Child participants had all been diagnosed with ADHD and all were taking stimulant medication. Participants were recruited from clinics at 3 hospitals: Richmond Royal Hospital, London; The Maudsley Hospital, London; and Queen’s Medical Centre, Nottingham.

Data Collection

Semi-structured focus groups were used to collect data about how children and adolescents experience stimulant medication. Allowing children to describe their experiences through qualitative interviews has been found to be both reliable and valid (Deatrick & Faux, 1991; Sorensen, 1992). Furthermore, there is compelling evidence to suggest that children are competent research participants (Singh, 2007). Children’s competence as research participants is supported by the literature on children’s capacity and competence as patients. Children have been found to be capable of understanding the complexities of their condition; they have the capacity to give informed consent to invasive treatments, to contribute to deliberations over treatment strategies, and, in the case of diabetic children, to take responsibility for administering their own treatment (Alderson et al, 2006; Bluebond-Langner et al, 2005).

13 children were interviewed as part of a series of focus groups. 3 children were interviewed one-to-one, either because they were unable to attend the focus groups or because of a preference to be interviewed individually. Participants were interviewed in a room based at the hospital clinic. Interviews lasted approximately one hour. Written informed consent was obtained from one parent and also from the participant. Parents were also asked to complete a basic demographic questionnaire.

Focus group methodology

Focus groups are a widely used method in qualitative health research. They are often used when the research aim is to gather information in a little-understood or under-researched area. Focus groups elicit a range of experiences, opinions and feelings about a topic (Krueger & Casey, 2000). The

---

23 Data was only available on mothers. Fathers’ educational achievement and job types would be more reliable indicators of socio-economic status.
interaction in focus groups can result in enhanced disclosure, as participants challenge each other’s perceptions and opinions. Focus groups with children are less commonly used in social science health research; however, market research with children, including market research around health and well being, more commonly uses a focus group approach (eg Caruana & Vassallo, 2003). Focus groups with children provide access to children’s own language and concepts, and encourage elaboration of children’s own concerns and agendas. The collective nature of focus group discussion is often said to provide “more than the sum of its parts” (Wilkinson, 1998). Interactive data result in enhanced disclosure, better understanding of participants' own agendas, the production of more elaborated accounts, and the opportunity to observe the co-construction of meaning in action. Focus groups are, then, an ideal method for exploring people's own meanings and understandings of health and illness.

Interviews

Interviews were conducted in a conversational style and included a standard set of open-ended questions (see appendix 1 for the complete topic guide). The first half of the interview involved posing broad questions that were followed by more specific probe questions. Principle areas of investigation are listed below:

Figure 1: Principle areas of investigation

| children’s understanding of ADHD diagnosis and behaviours |
| children’s perceptions of how tablets helped them (or not) |
| children’s experiences of stigma |
| children’s experiences of non-drug interventions for ADHD behaviours |
| impact of tablets on children’s perceptions of personal agency |
| children’s experiences of psychiatric services |

The second half of the interview involved a set of games and a vignette which provided children with the opportunity to elaborate their experiences and perceptions of medication in more creative and imaginative ways. The primary aims in this section of the interview were to:

a. contextualize children’s perceptions of tablets within their perceptions/understandings/experiences of other means of improving behaviour

b. elicit ideas from children about resources that could help them have more positive experiences of ADHD diagnosis and medication

The following methods were used in the second half of the interview (see appendix 1 for further elaboration).
1. Children were asked to compare how the experience of taking tablets was similar to, or different from, doing other things that were commonly considered good for them (figure 2).
Figure 2: How do tablets compare?

Let’s imagine there are other things you could do that helped you with your behaviour. How are these the same as, or different from, taking your tablets? Which would you rather be doing?

Piano lessons
Vitamins
Eating green vegetables
Brain implant

2. Children were asked to respond to a vignette that elicited their ideas about what sorts to things can help a child’s behaviour (figure 3).

Figure 3: Interventions Vignette

Your favourite sports hero/heroine drops by one night wanting advice from you. He/she has a won who is having difficulty with his behaviour, especially his attention, focus, concentration. The doctor thinks the child has ADHD. Your sports hero wants to know what kinds of things he/she can do to help the child’s behaviour get better. Let’s make a list of things we know that can help this child.

3. Children were asked to think up and discuss an invention that could help children with ADHD.

4. Children were asked to rank order a list of items that described common concerns voiced by school-age children. Each item was written on a separate card, and children were asked to put the cards in order of what they worried about most, to what they worried about least. The list included the following items:

Global warming
Having ADHD
Taking tablets
Exams
Homework
friendships

Global warming and exams were included on the list because these concerns were found to be significant sources of anxiety in a recent large cohort study of UK school-age children (Alexander & Hargreaves, 2007).

Data Analysis

All interviews were digitally recorded and transcribed. All interviews analysed using rigorous qualitative coding practices that meet established...
criteria of validity and relevance to qualitative health research (Mays & Pope 2000). Focus groups were coded using content analysis. The coding process captured the data on two analytic levels: individual concepts were coded first, then these concepts were grouped together under higher order themes. Systematic coding meant that it was possible to code at both the individual level and at the group level. Group level data were represented in the frequency with which concepts and themes were expressed by group members. Transcript excerpts elucidated the meaning of codes.

A coding frame was drawn up by the lead author (IS) and validated within a coding team. The coding team applied the same codes to a transcript in order to discuss their definition and validity. This discussion resulted in refinements to the structure of categories and sub-categories, as well as refinements to individual codes. The coding team was able to reach agreement on the validity of a majority of codes.

RESULTS

I. ADHD Behaviours

Throughout the interviews and focus groups, children identified a broad range of behaviours as symptoms of ADHD (figure 4). This range maps on to the symptoms outlined in DSM-IV and ICD-10. The most frequently discussed types of behaviours were impulsiveness, physical aggression, and hyperactivity. Children discussed impulsiveness in terms of an inability to restrain themselves from verbal or physical reactions. Impulsiveness frequently overlapped with physical aggression, which children discussed as punching, kicking, pulling hair, usually of other children, but also sometimes of adults. Anger was an important motivating emotion in these activities, but children also frequently reported feeling regret for their actions immediately afterwards. Hyperactivity was discussed in strong terms by children, including going mental, mad, beserk, nuts. Children felt these types of behaviours to be particularly annoying to others.

Behaviours identified as symptomatic of ADHD were also frequently discussed in terms of their positive dimensions. Hyperactivity especially was fun, feels good, and lets off steam. Children felt powerful when acting aggressively and hyper; in some cases, children thought these behaviours gave them increased credibility with peers. Peers were thought to fear how out-of-control and overwhelming children with ADHD could be. Children were able to perceive the tension between their experiences of the more negative and more positive aspects of their ADHD symptomatic behaviours. The majority of participants were not disturbed by this tension.

</table>

Figure 4: ADHD behaviours and their qualities
II. Tablets: Perception of impacts

Children discussed a range of ways in which their tablets helped them (see figure 5. Tablets were discussed primarily in terms of their impact on social behaviour, and less in terms of their impact on school work and school-related functioning. The positive effects of the tablets on behaviour were reported most clearly and consistently by children with aggression problems (see textbox 1). They reported that tablets helped them not to feel angry; the tablets helped to calm them down, and to think first before acting out. Children felt that these positive effects had an associated positive impact on their ability to make and retain friendships.

The most salient impact of tablets in the classroom context was their perceived effect on disruptive behaviour. Many children reported that tablets helped them to be less disruptive in the classroom. Disruptiveness was discussed both in terms of verbal disruptiveness (I’m always talking when I shouldn’t be); and physical disruptiveness (I can’t sit still). Most groups had to be encouraged to identify other ways in which tablets might be having an impact on school work and school-related functioning. Children thought that tablets had a positive effect on their ability to focus and to concentrate on work. This positive impact overlapped with children’s improved ability to contain their physical and verbal energies (I can sit there and do my work better). Children also reported that aspects of their school work, such as writing and maths, had improved as a result of tablets. Some children reported receiving better marks in school and on standardized tests as a result of taking tablets.

Textbox 1: Perceived impact of tablets on anger

Male child:

It’s like a wall between the rest of my body and my anger, and it’s like a thousand to one against – with my anger. And I can’t – just can’t control it
However, discussion of the positive impacts of tablets on school work was frequently associated with individual and collective disagreement as to the validity of a particular impact. For example, some children felt that tablets had a positive impact on reading, writing and maths; and others did not. The degree of effects on school work and school-related functioning was also debated. For example, some children felt that tablets did improve their focus and concentration on school work, but they also still reported having significant trouble in this area.

**III. Attitudes toward tablets**

**i. Basic knowledge about tablets**

Children’s knowledge of the name of their tablets and frequency of dosing was generally good. Most children were able to identify these. Children’s knowledge of their dosage level was weaker, and was often expressed in terms of how many tablets they had to take in one day. A few children identified their tablets as “stimulants” and discussed stimulants as *real drugs*. Most children, but not all, understood that their tablets had a primary impact on the brain.

**ii. Expressed attitudes**

Generally, children had positive attitudes toward their medication for ADHD (see figure 6). Most children felt taking this medication was *necessary* for them, and it had become a *normal* part of their lives. They resisted alternatives to medication largely due to an unwillingness to experiment with something different; children felt their tablets were *familiar, relatively easy to take, and safe.* When asked to consider how a list of non-medical means of improving behaviour (see Section IV.ii) might match up against tablets in terms of efficacy, all children felt that tablets were the most efficacious form of treatment for ADHD behaviours. They also felt that tablets were an *essential*
part of treatments that incorporated non-medical means of improving behaviour.

Children did not report having strong anxieties about taking medication. When asked to rank a list of stressors from least to most anxiety-provoking, tablets were consistently at or near the bottom (see Textbox 2).

Textbox 2: Contextualizing the burden of ADHD diagnosis and medication

Here are some things children worry about. (Stressors were written on individual cards). Can you line them up for me in order of the things you worry about most, to the things you worry about least. You can line them up and then see if it’s right. If not you can discuss and re-arrange things.

Global warming
Having ADHD
Taking tablets
Exams
Homework
friendships

In the context of this generally positive attitude, more negative reactions to medication were also frequently expressed. The most frequently expressed reaction was also the most difficult for children to explain: a feeling that tablets were annoying. Participants appeared to have a shared understanding of this experience of tablets, even though the experience was difficult to communicate to others. The annoying nature of tablets was most often related to the need to take them. It was unclear whether it was the pragmatics of taking tablets (eg, daily dosing, remembering to take tablets; taste of tablets); the requirement of taking them (eg not having a choice); or the more existential meaning of the need for tablets (eg having a mental disorder, being “different”) that was most distressing to children. All these dimensions were inherent to varying degrees in the expressed experiences of tablets being annoying.

iii. Relationship of tablets to sense of self

Almost all children believed that they needed to be on their medication for ADHD. Perceptions of the need for tablets ranged from medium to high. If a child raised a question about his/her need for medication, other children would frequently challenge the child’s view. Understanding of how long it was necessary to stay on medication was not as frequently shared. Some children felt that they would grow out of ADHD; others felt it was a life-long illness. Some children referenced the fact that adult ADHD was now a recognized disorder. Most children felt it would become possible to cope with ADHD behaviours without the help of medication. Older children were more likely than younger children to question the need for life-long medication, and more likely than younger children to talk about a desire to come off medication in the near future.

Children tended to have a continuous, rather than a dichotomous, sense of themselves on and off tablets. Only a few children expressed feeling that they were a different person on and off medication; eg being a Jekyll and Hyde. On further probing, such initial dichotomous statements were amended into continuous self-descriptions.

Most children expressed ambivalent self-conceptions on an off medication. For example, some children felt they were more fun off medication; but these same children knew that when they were more free they were also potentially more annoying to others and more out of control. Some children described themselves as more normal off medication, which was a positive self-description. However, they also described their normal selves as beserk and mental, which was fun in certain situations, but horrible in others. Children had a good understanding of the context-bound nature of how their behaviours would be interpreted. Their evaluations of their own behaviours as well as their evaluations of the need for tablets were strongly associated with their understanding of context.

iv. Experience of side-effects

The most commonly discussed side-effects of tablets were problems with appetite and sleep. A few children had experienced acting like a zombie on certain medications and/or at certain dosage levels. For most children side effects were not expressed as severe problems, even if in some cases, children reported getting extremely little sleep. In the context of the group discussion, side-effects were reported with a degree of authority and even pride, which may have mitigated against fuller discussion of how problematic these experiences actually were.

v. Compliance

Compliance with medication was reported to be generally good, especially amongst the younger children. Older children were more likely to have
experimented with not taking their medication to see whether anyone would notice, and to see how well they themselves could control their behaviours. Other reasons for not taking medication were related to medication being annoying. Some children said that sometimes they just couldn’t be bothered to take their medication. A majority of children in this study were responsible for remembering to take their medication. Younger children were more likely to forget to take their medication, and to need assistance with the responsibility of remembering to take it. A majority of children took medication all the time. A few children reported taking drug holidays at weekends and school holidays. A few children felt they had the option to stop taking tablets if they wanted to.

Children’s compliance with medication was apparently tacitly monitored by their peer group. Children reported relatively frequent occurrences of friends asking if they had taken their medication – either as a reaction when the index child was exhibiting problematic behaviours; or as an encouragement to forgo medication (when friends thought that medication had inhibiting effects that made the index child less fun to be with).

IV. Alternatives to medication

i. Experience of non-drug interventions

Few children reported experiences of non-drug interventions that were memorable or productive in their view. Some children received additional support in the school day; three children reported having received counselling. Two children reported that counselling was helpful to him. A majority of parents of child participants were currently, or had previously, experimented with a range of non-drug interventions, including Omega 3s, removal of E-numbers in the diet, IQ vitamins, low sugar/caffeine diet. Children tended to be aware of these interventions but expressed no strong opinions about them. Several children reported that they had begun sports programs that helped release energy, and made them feel good. These programs included boxing and football.

ii. Children’s ideas for non-drug interventions

In response to a vignette, children were asked to brainstorm means of helping a child with ADHD symptoms manage his/her behaviour (textbox 3).

Textbox 3: Interventions Vignette

Your favourite sports hero/heroine drops by one night wanting advice from you. He/she has a won who is having difficulty with his behaviour, especially his attention, focus, concentration. The doctor thinks the child has ADHD. Your sports hero wants to know what kinds of things he/she can do to help the child’s behaviour get better. Let’s make a list of things we know that can help this child.
Children came up with answers easily and there was agreement within and across groups as to the efficacy of the proposed methods. The most frequently mentioned methods were playing sports; drawing/doodling; and stress balls. Specific sports included boxing and football, as mentioned above. Two children mentioned a punching bag. One child said fighting was helpful, by which he may have meant boxing. Less frequently mentioned non-drug methods of managing behaviour were reading, watching television, and playing computer games.

When asked to compare the probable effectiveness of non-drug methods with the effectiveness of tablets, none of the participants felt non-drug methods were more effective than drug intervention. All participants felt that non-drug methods would be most effective if used in conjunction with medication.

iii. Inventions for ADHD children
All groups and individuals were asked to think of something they would want to invent, to help children with ADHD (textbox 4).

Textbox 4: Inventions Probe
Let’s imagine you are an inventor and wanted to create a way to help children with ADHD. What might you invent?

Several children discussed alternative drug delivery systems, including better tasting drugs; less frequently administered drugs; and drug dosing on demand. This last was described by one participant as a “scratch dot” which could be scratched in the moment that the drug was needed, to deliver an immediate dose for an hour or two. The desire for a drug that had a short-term, targeted effect was also associated with a desire for a drug that didn’t have pervasive effects: I wish it only affected the parts of me that need it. However, other children reported being glad that they only needed to take medication once a day, and were happier knowing that it’s always working in me.

Another major category of response to this question was desire for a means of communicating to others what it was like to have ADHD. Proposed methods of communication included a book about kids with ADHD; and a video about ADHD (see textbox 5).
Textbox 5: Interactive ADHD video game

**Male child:** [I would invent] a video game where you actually took a picture of yourself and then put it into the game. And then you actually were this character running round, doing stuff that children do in a day so then these people could actually play on it... people who haven’t got this thing [ADHD] that we’ve got can actually have a go and see what our life is like and, so they would actually know how we feel. So then they’ll learn not to treat us in a way that’s different to everybody else... You can have, like, other characters that have been nasty to you without your tablets. You could have a level without your tablets and with, so then they’d know the difference with your tablets and without.

V. Agency

(Agency is defined as the degree to which an individual feels he/she can affect behaviours, people, circumstances and/or events)

i. Personal agency over behaviours

All children in this study reported feeling that their behaviours were problematic to some degree. No children attributed these problematic behaviours solely to their ADHD diagnosis or to a lack of tablets. Frequently, when an individual child made such attributions he/she would be challenged by the group. All children admitted using their **diagnosis as an excuse** for their behaviours at some point. Children felt that tablets helped them with their behaviours as outlined above; however, no child reported feeling that tablets entirely resolved their problematic behaviours. Children generally reported **feeling responsible for management of their behaviours**, and felt that **tablets assisted** them to some degree with **self-management**.

ii. Agency over definition of behaviours

Agency over definition of their behaviours was more problematic for many children. In general, children did not report feeling that they had a voice in how their behaviours were classified and defined. They agreed that some of their behaviours were problematic, and referred to my ADHD, but many children were aware of the **contextual nature of the interpretation of behaviours**. The contextual nature of interpretation of behaviours only conferred agency on a child in situations when peer-generated social codes had more moral authority than adult-generated behavioural prohibitions. One frequently mentioned example of such a situation was bullying that involved denigration or disrespect for a child’s family. In such circumstances there was general agreement amongst participants that aggressive retaliation was socially and morally justified. Children sometimes used their ADHD and/or lack of tablets as an excuse for their behaviour following the fight. This can be seen as a strategic use of a particular interpretation of their behaviour. Children defined this sort of retaliation in moral terms, even if the impulsive, aggressive behaviours were also indicative of clinical symptoms. Children...
rarely reported feeling regret over their behaviours following such incidents (see Textbox 6).

Textbox 6: Moral dimensions of aggressive impulses

| Male child: …Sometimes I play basketball and I don’t take my tablets and I might get into a fight and then I might do something really dumb… I don’t necessarily like to fight. When I take my tablets I can’t fight for my whole life. When I take them they make me, like, so calm I won’t do anything… [Another time someone said] “Hopefully when your sister’s born she’ll be born with Down’s Syndrome because you’re spastic.” I got so angry so then in school I just got him and then I didn’t stop punching him until he – until I, like, smashed up his nose and stuff because I got so angry because I could take anything that comes in if they say it to me, but about my family I can’t take it. |

Lack of agency in the definition of their behaviours was most frequently experienced in the classroom. Children felt that teachers were unfairly focused on their behaviour, assuming that it would be more problematic than that of other children. Children felt this was a result of having a diagnosis of ADHD. Some children felt watched by teachers who were evaluating whether or not their behaviours were a sign that they had forgotten to take their medication. Children also experienced teachers as being able to define their behaviours according to the needs of teachers, rather than the needs of children. For example, some children felt that teachers attributed behaviours to ADHD as a way of explaining behaviours away. This was contrasted with teachers assessing the ways in which children with ADHD might be helped through structural changes in the classroom and/or the school day.

iii. Agency over the future

Children generally felt that they would be able to exercise choices with regard to their future, although they also tended to acknowledge their limitations. Many children were concerned about whether they would need to keep taking their tablets as adolescents and adults. All children in this study felt that this decision would eventually be their own decision to make.

VI. Stigma

i. stigma associated with tablets

Experiences of stigma related to directly to medication were less frequently expressed than experiences of stigma related more generally to ADHD diagnosis and behavioural symptoms. Tablet-related experiences of stigma had an impact on children’s sense of self in that these experiences often involved name-calling and bullying, eg. “druggie”; “tablet boy” etc (see textbox 7). Children reported feeling bad.
about being called names and they generally associated experiences of stigma with feelings of low self-confidence and low self-esteem. Children frequently got into fights as a result of being verbally bullied.

Children felt exposed by the need to take tablets, especially if they needed to take tablets during the school day. The need to take tablets made them feel different in a negative way.

Textbox 7: Bullying and retaliation related to tablets

**Male child:** Someone says, “Oh, you’re a druggie addict,” so I just smacked him one.

**Interviewer:** A drug addict?

**2nd male child:** I get that. I get that. I did. A boy came up... “Why are you on drugs?” I said, “They’re not drugs. Even if they were drugs, I wouldn’t bring them into school. I’d probably have them at home.”

**1st male speaker:** So I says – he says – “Why are you a drug addict?” I says, “I’m not.” He says, “Yes you are.” So I just smacked him one and he went, “No you’re not,” went off crying.

**ii. Stigma associated with ADHD behaviours and diagnosis**

In general, stigma associated with ADHD behaviours and diagnosis was expressed as the primary experience of stigma. Two participants kept their diagnosis secret from friends and members of the extended family. All children reported feeling that their ADHD behaviours gave them bad reputations with peers, teachers and parents of peers. There was general agreement that children with ADHD were thought to be dumb. A majority of children reported being called names and bullied about their ADHD behaviours and/or ADHD diagnosis and need for tablets.

Children reported that the negative assumptions of others about them were especially burdensome. They felt they received negative differential treatment because of their diagnosis. Both girls in the study (in separate groups) reported feeling that teachers ignored them completely because of their ADHD diagnosis. They felt the teachers had given up on them. In general children felt there was a lack of empathy and a lack of understanding of children with ADHD. They felt peers and teachers were unkind; and they reported experiences of feeling different and isolated.

**iii. Protections against stigma**
All children in this study reported having close friendships that helped to protect them from bullying. In several cases, friends who knew about the index child’s ADHD diagnosis would come to the rescue of the index child in a fight that resulted from bullying. The rescue often manifested as an effort to get the index child to stop and to think about what he/she was doing. Other times friends would simply drag the index child away from the situation (see textbox 8).

ADHD diagnosis could be turned around to serve as a protection in situations that arose as a result of stigma. For example, friends would use the ADHD diagnosis to frighten off a name-calling bully; eg he told them I had ADHD and I was crazy. Frequently, ADHD was used as an excuse following a fight; eg. I couldn’t stop because of my ADHD. Almost all children in the study acknowledged using ADHD as an excuse to get out of situations like this.

Textbox 8: Peer protection and ADHD as an excuse

| Male child: If someone starts on me and I know I’m going to start on them. And they know to ask --- and then my friends will help – come in and back me up. Otherwise I get them on the floor and I knee them in the back… My friends will say, “He’s got ADHD.” |
| 2nd male child: I kept butting this boy in the head… You can’t help it. |
| Interviewer: Is that what you say? But do you believe that? |
| 1st male child: No, oh… |
| 2nd male child: No I just use it. |
| Interviewer: You’re using it as an excuse then? |
| 3rd male child: Sometimes. |

VII. Discussion

Children who participated in this study had a generally positive experience of tablets. This does not mean that they liked being on medication; rather that they were willing to put up with the “annoying” dimensions of taking medication in return for the perceived benefits. Medication was not viewed as a panacea; children had reasonable understanding and expectations of their medication. Individually and collectively children associated their tablets primarily with helping to improve their social behaviours, and, consequently, their relationships with peers. While improvements in school work and school functioning were often noted, these received less attention than improvements in social behaviour. Similarly, side effects of medication were commonly experienced in this group of children, particularly appetite suppression and insomnia. However, side effects did not make up a major theme of children’s discussions individually or collectively. All children interviewed felt that they needed to be on their tablets; older children were more likely to be looking ahead to a time when they could manage without tablets.
Children had varied experiences of both formal and informal non-drug interventions aimed at helping them with their ADHD symptoms. With the exception of sports, particularly boxing, few of these interventions were thought to be very effective. All children in the study believed medication to be the most effective available treatment for their ADHD symptoms. However, children also understood that ADHD diagnosis and effective drug treatment did not mean that they were absolved of responsibility or of agency in their behaviours.

One of the most strongly stated, and most resonant, desires communicated by this group of children was for better public understanding of ADHD. Children felt this would create empathy for their situations and relieve them of some of the stigma of negative assumptions attached to ADHD diagnoses. Experiences of stigma due to ADHD behaviours and diagnosis were common; experiences of stigma related directly to ADHD medication were less frequently expressed by children in this study. Experiences of stigma, such as bullying, name-calling, negative assumptions, and differential treatment were distressing to children, and negatively affected their self-evaluations, self-esteem and self-confidence. Close friendships were an important protective factor against the initiation and/or continuation of fights that arose as a result of the child with ADHD being bullied. These friendships were mentioned as or more often as medication, as factors that helped children to restrain their impulse to fight and/or to continue fighting.

Findings in this study are similar to other recent qualitative findings (Singh, 2007a, b) that do not find strong support for concerns that children taking stimulant medication for ADHD are ethically compromised. A major ethical concern has been that stimulant medication potentially endangers children’s agency (eg President’s Council on Bioethics, 2003). However, children in this study expressed a significant degree of agency over their behaviours. A frequent topic of discussion amongst boys in particular, was the moral dimension of the decision to fight, or not to fight. Certain instigating comments (eg about a boy’s family) made it morally problematic not to fight the name-caller, even if it was socially inappropriate to fight on the playground. Children expressed a significant trust in their personal agency when discussing a process of making moral assessments of situations and choosing and judging their behaviour according to these assessments.

Similarly, concerns that taking medication could confer significant stigma on children (eg Conrad, 2006) were not supported by this study. Children did report experiences of stigma as a direct result of taking tablets; however, experiences of stigma as a result of ADHD diagnosis and symptomatic behaviours was far more frequently expressed. Feelings of being different and feeling alienated were also stronger around diagnosis and ADHD behaviours, than around the need for medication. To the extent that medication helps to
alleviate some ADHD symptoms, and helps to foster peer relationships, it would appear that the social benefits of medication outweigh the social burdens.

In view of the distress many children experienced in relation to ADHD diagnosis, ADHD behaviours and tablets, it is troubling that only one child in this study viewed their clinical encounters within child psychiatry services as having a therapeutic component. While no child had any strong complaints about services; several children reported not being able to get in to see a clinician; and feeling that they would like more time with a psychiatrist. Some children felt that clinicians didn’t really care about them. A majority of children felt appointments were routine and boring, and that appointments were primarily for medication checks and scripts.

Sport, especially boxing, is clearly considered therapeutic by boys with ADHD, especially those with aggression problems (Singh, 2007). Many children in this study reported being kept inside during lunch time as punishment for their disruptive behaviours. This is counter-productive for this group of children, as they need to “let off steam” in order to better manage their behaviours. Clinical work with children, families and schools could emphasize and encourage the positive aspects of sport for this group of children.

There are few qualitative studies involving children with ADHD, and even fewer studies that attempt an in-depth investigation of children’s experiences of medication. The controversial nature of ADHD diagnosis and drug intervention for young children has the potential for fueling unproductive polemic debates about the safety, efficacy and/or validity of medication for young children. In view of this background, it is important to attempt to contextualize the discussions with children in this study. One means of contextualization is to examine the relative significance of matters discussed with children in this study. How much do children worry about their ADHD diagnoses and their tablets, when compared to other things children reportedly worry a great deal about?

ADHD and medication were important aspects of this group of children’s lives. All children reported various daily reminders of the burden of mental disorder and the need to take medication. However, when compared to a list of other stressors, “ADHD diagnosis” and “taking tablets” were not what children in this study reported they were worrying about most. Younger children worried most about friendships and global warming, while older children worried most about exams and friendships. While friendships and academic performance are often problematic for children with ADHD, these concerns are not uniquely related to having ADHD. A large cohort of UK children identify these concerns as their primary sources of anxiety (Alexander & Hargreaves, 2007). In the present study, ADHD diagnosis was
ranked as more worrying than taking tablets for ADHD by almost all children. Results from this study therefore consistently suggest that children have relatively more positive experiences of medication, as compared to more negative experiences of ADHD diagnosis and behavioural symptoms.

VIII. Limitations

This study is based on focus groups and a small number of individual interviews with 16 UK children. While all interviews and the analysis were intensive, systematic and rigorous, findings have within-group validity, and should be generalized with caution. The importance of certain themes may have been amplified by the particular dynamics of groups made up largely of young boys, who gave honest answers to questions, but also wished to impress each other and the interviewer. In addition, this study, as is the case for many studies in psychiatry, may have attracted a group of children with a certain range of experiences with ADHD diagnosis and medication. Selection bias cannot be ruled out as a factor in these findings. Only two girls participated in the study (12%), and both girls were teenagers. Therefore the analysis is heavily skewed towards boys’ experiences of ADHD diagnosis and medication. This study does not adequately capture experiences that might be unique to girls with ADHD.

Appendix to focus group study

FOCUS GROUPS TOPIC GUIDE

Welcome
Names
Why we are here:

To talk about your experiences with tablets for ADHD

We are here to learn from you. Your job is important: what you say to us today will help doctors all over the UK better understand how to help children with ADHD.

There are NO right or wrong answers.

No reason to feel embarrassed – everyone here is friendly and wants to hear from you.

The RULES:
YOU ARE THE EXPERTS
DON’T INTERRUPT OTHERS
SPEAK LOUDLY AND CLEARLY
(explain that this is for good politeness and for good quality recording!)

Questions:

I.

1. So, what is ADHD?

2. Why do you think you need to be taking tablets for ADHD?

PROBE: TYPES OF BEHAVIORS

3. In what ways do you think the tablets have helped you?

PROBE: behaviour, school work, social life, self-esteem

4. Have the tablets caused you any problems?

PROBE: stigma, alienation, side-effects, shame

5. Does anyone else know you have ADHD or take tablets for ADHD?

6. Other than taking tablets, do you get any special help from teachers or other doctors?
PROBE: educational help, counselling, psychotherapy, have parents received any help?

7. Do you think you need to take tablets?

PROBE: Experimentation with not taking meds? Efforts to discontinue meds? For how long do you believe you will need to take these tablets? What other sorts of things help you with your behaviour?

8. What would happen if you said you didn’t want to take your tablets anymore right now?

9. What’s it like going to see the doctor who gives you the script for your tablets?

PROBE: comfort level, interaction, anxiety

II. GAMES:

A. Let’s imagine there are other things you could do that helped you with your behaviour. How are these the same as, or different from, taking your tablets? Which would you rather be taking? (PROBE EACH ITEM)

a. piano lessons
b. vitamins
c. eating green vegetables
d. brain implant

B. VIGNETTE.

Your favourite sports hero/heroine rings your house one night wanting advice from you. This person has a son who is having the sorts of difficulties a child with ADHD has. The sports hero wants to know what kinds of things he/she can do, to help his child.

1. Let’s make a list of all the things we know that can help a child’s behaviour.

PROBE: Have you tried this? What’s it like?

2. Can you line up all these ways of helping, from the thing that you think is best to the thing you think is worst?
   • In what ways are these best and worst? Eg. most effective, least effective; nicest to take; least nice to take, etc.
   • Where do tablets fit into this list?
C. Let’s imagine you are an inventor and wanted to create a way to help children with ADHD. What might you invent?

D. Here are some things children worry about. Can you line them up for me in order of the things you worry about most, to the things you worry about least. You can line them up and then see if it’s right. If not you can re-arrange things!

1. Global warming
2. Having ADHD
3. Taking tablets
4. Exams
5. Homework
6. Friendships

III. FINAL QUESTIONS

1. If there were more tablets that made it easier for you in other ways, for example, tablets to improve your memory, would you want to take them too?
2. Anything else you would want doctors, parents or other kids to know about taking tablets for ADHD?
Appendix 16: ADHD Consensus Conference

Part 1. Summaries of presentations provided by Consensus Conference speakers

The value and limitations of the concepts of ADHD and hyperkinetic disorder in guiding treatment - a clinician’s perspective

Dr David Coghill
Senior Lecturer in Child and Adolescent Psychiatry, Division of Pathology and Neuroscience (Psychiatry), University of Dundee

The presentation will look at the value and limitation of ADHD as a concept and develop ideas by looking at the questions posed in the outline of the Position Statement.

To what extent do the phenomena of overactivity, inattentiveness and impulsiveness cluster into a particular disorder that can be distinguished from others and from normal variation?

Internal Validity
Inattention, overactivity and impulsivity are all continuous variables which appear to be complex characteristics distributed throughout the population with a fairly normal distribution; these are normally distributed characteristics which therefore blend into the normal. The distinction of what is and what is not normal has to be, by definition, arbitrary.

Factor analysis suggests that their distribution is not random but shows a strong coherence with each other and far less coherence with behaviours characteristic of other conditions such as phobia, aggression or anxiety.

At what level, and in what circumstances do these become impairing for the person?

To some extent where to draw the line as to when symptoms and behaviour are impairing is arbitrary, as it is on a continuum. Symptoms must be related to impairment.

The key issue is, how do symptoms relate to impairment?

Impairment can be measured in several ways however the Children’s Global Assessment Scale (C-GAS) provides a relatively simple and valid measure
Scored from 0 – 100 with 0 indicating the most severe impairment and 100 the most healthy and well functioning child.

DSM-IV field trials used a Children’s Global assessment Scale (C-GAS) score of ≤ 60 (which implies impairment requiring specific treatment) and determined the number of symptoms required to be present to reach this cut-off. Five symptoms of ADHD were required. To avoid false positives the numbers were increased to six or more symptoms of inattention or hyperactivity – impulsivity.

Problems occur with children whose impairment, due to their ADHD symptoms is really quite severe, but who technically do not meet the diagnostic criteria.

**Impact of ADHD on Overall Functioning**

An important part of ADHD impairment is its breadth including:

- Social, academic, interpersonal, family burden, self worth.
- What is particularly interesting as a clinician is how to reduce the functional impairments consequent to these symptoms and these comorbidities.

**Impact of untreated and undertreated ADHD**

Apart from on the individual themselves:

- Healthcare System - 50% increase in bike accidents, 33% increase in ER visits, 2–4 times more motor vehicle crashes.
- School and Occupation - 46% expelled, 35% drop out and lower occupational status.
- Family - 3–5 times increase in parental divorce or separation and 2–4 x increase in sibling fights.
- Employer - increase in parental absenteeism and decrease in productivity.
- Society – there is twice the risk of substance misuse, at earlier onset and individuals are less likely to quit in adulthood.
- Children with ADHD are in the bottom five percent of children for their quality of life.

**The clinical picture for the individual**

The symptoms of inattention, hyperactivity and impulsivity combined with a number of psychiatric comorbidities such as ODD and CD lead to a number of psychosocial impairments across a number of domains: self, school (work) Home and social.
Is there evidence for a characteristic pattern of developmental changes, or outcome(s)?

ADHD symptoms were designed for primary school children and an adult with ADHD is a child with ADHD who has grown up but continues to have problems. The symptoms experienced by these groups will differ and the levels of symptoms and impairment may not necessarily change at the same rate. Although individuals may have symptoms throughout their life they may not demonstrate impairment until later in life.

In children the patterns of symptoms / behaviours is characterised by: motor hyperactivity, aggressiveness, a low levels of tolerance, impulsiveness, easily distracted. In adults the pattern is characterised by: inattentiveness, shifting activities, easily bored, impatient, restlessness.

There is a characteristic pattern of developmental changes. During the pre-school years the child may show some level of behavioural disturbance. Once at school academic, social and self esteem problems begin to manifest themselves. As an adolescent, additional issues surrounding smoking and injury begin to appear and by the time that the individual is of college age, a pattern of academic failure, occupational difficulties substance misuse, injury and self esteem is apparent. As an adult, relationship problems will also occur.

Is there a specific response to clinical, educational and/or other interventions?

Home and school based behavioural treatments and treatment with methylphenidate, dexamfetamine, atomoxetine and several other drugs reduce symptoms and improve functioning. However, treatment with other psychoactive medications such as the SSRIs or anti-psychotics does not have the same effect.

Is there evidence for a consistent heritability, neurobiological or other causality?

One of the arguments against ADHD is we do not know the cause. The causes of ADHD are multifactoral, leading to a common behavioural phenotype. Therefore to search for a cause is probably not something that is going to bear fruit.

ADHD aggregates in families with 3 to 5 times increased risk in first degree relatives and twin studies suggest considerable heritability with between 65 and 90% of the phenotypic variance explained by genetic factors. There are also associations with a range of environmental risks (mainly non-shared factors) such as pre and perinatal complications, low birth weight, prenatal
exposure to benzodiazepines, alcohol and nicotine and brain diseases and injuries.

Gene-environment interactions are likely to play a significant part. Genetic variations cause functional abnormalities in both dopaminergic and noradrenergic neurotransmission within frontostriatal pathways. This in turn leads to deficits in executive and reward related functioning and subsequently the behavioural manifestations of ADHD.

Finally in terms of response to medication, ADHD kids’ memories were as poor on a memory task as elderly people with Alzheimer’s, and reverted back to normal with one dose of medication.

The Value of the Concept of ADHD

- Reliability and validity well established
- Define a group of children with considerable impairment
- These impairments touch not only the person with the diagnosis but also their family and community
- Define a group who have a high risk of suffering from a wide range of other difficulties
- Provides a starting point and an anchor from which clinicians can base their assessments
- Define a group who respond (and will benefit from) to treatment
- Define a group with disability currently under recognised and under treated in the UK
- Defines a group whose numbers are relatively stable across time and across cultures
- Do not assume pathophysiology where this is not warranted but have strong associations with a range of biological measures e.g. heritability, pathophysiology neuropsychology.
- The diagnoses are now almost universally used in research studies into the causes, associations and treatment of ADHD. This provides a strong link between scientific research and clinical practice.

The Limitations of the Concept of ADHD

- Can lead to dispute and misunderstanding as to which system is “correct”
- Categorical definition of a dimensional concept
- Inattentiveness symptoms are not adequately defined
- Defines a heterogeneous group
- Can be misused if impairment is not adequately considered
- The exclusion of comorbid forms within the ICD 10 criteria is not helpful when that is the picture of the case in front of you
• Can lead to difficulties in identifying those requiring treatment
  – E.g. those with subthreshold symptoms but considerable
    impairment.
• Research has tended to focus on pure ADHD cases with much less
  information of those with comorbidity
• Research has tended to concentrate on reduction in core symptoms
  rather than on the broader outcomes of impairment, quality of life and
  comorbidity
• Neither is adequate for understanding pre school or adult populations
  and have limitations with respect adolescents

The case for wider recognition of ADHD – from a paediatric
perspective

Dr G D Kewley
Consultant Paediatrician/Physician, Director of Learning Assessment & Neurocare
Centre, Horsham, West Sussex

1. Previous significant under-recognition of ADHD. As noted with concern
by the author in 1998 (Kewley, 1998) there was continuing under-recognition
of ADHD, because of i) persistent reliance on the ICD-10 hyperkinetic
terminology; ii) psychosocial only causes were seen as being solely
responsible for all children’s behavioural problems; iii) the copious myth and
misinformation and the professional and societal ignorance about ADHD,
its nature and complications persisted, and iv) there were divisions between
professional groups, fixed professional beliefs, theoretical standpoints and a
tendency to debate over the heads of the sufferers. Despite the fact that
ADHD was the most referenced childhood condition in the Index Medicus
during the 70s and 80s (Cantwell, 1996), the above difficulties had meant that
ADHD was not validated in the UK until the NICE report of 2000 (Lord &
Paisley, 2000), was significantly under-recognised and was very slow to be
considered as part of the provision of effective child, adolescent and adult
mental health services. Although since 2000 there has been an improvement
in recognition and validity of ADHD, all of the above problems persist and
affect the recognition and provision of effective children’s mental health
services today. Clinical experience and review of international literature
concluded that DSM-IV-R had been a much more effective way of providing
effective services. The NICE 2000 report noted that medication usage,
however, is but one means of reflecting the increased recognition and
diagnosis of ADHD.

2. Guidelines. It was noted that over the past 8 years there has been a degree
of convergence between the DSM-IVR and hyperkinetic (ICD-10) approaches
to the diagnosis of ADHD (Swanson et al., 1998). The publications of the
Eunithydes Group (Banachewski et al., 2006; Taylor et al., 2004) in recent years have led to a much more clinically relevant evidence-based approach. In clinical practice it has become increasingly realistic to use European guidelines to guide patient management. Previously such guidelines had been more theoretical than practical and clinicians had tended to rely more on North American guidelines, such as the Texas Algorithms (Piliszka et al., 2000) and those from the American Association of Child & Adolescent Psychiatry. Recent European guidelines have been increasingly relevant in guiding audit and helping management patient care. However, there is still a need for guidelines for complex case management and for working between professional groups such as the youth justice system, social workers, substance misuse, etc. It was also clear that both paediatricians and child psychiatrists had a role in managing children and adolescents with ADHD.

3. Professional and societal recognition of the progression and life span issues of ADHD - relevance to guideline development. Many international studies have emphasised the long term difficulties of having untreated ADHD and the need for differing professional bodies to work together. For example the British Cohort Study (Brasset-Grundy & Butler, date?) in a 30 year prospective longitudinal study showed that people with childhood ADHD were significantly more likely to face a wide range of negative outcomes at age 30, spanning domains of education, economic status, housing, relationships, crime and health and that their adult lives were typified by social deprivation and adversity. This British study reflects a number of international studies.

Such long term studies confirm the vulnerability created by ADHD. They emphasise the need for wider recognition of ADHD in relation to criminal behaviour, school under-achievement and exclusion, special schooling provision, workplace issues, teenage pregnancies, motor vehicle accidents and gambling. Another related issue is that many older people, who were educated prior to the recognition of ADHD as a valid condition, still have ongoing, impairing symptomatology as late adolescents or adults.

4. One such subgroup of particular concern is those with long term difficulties of ADHD and related difficulties who have entered the youth justice system. The risk factors for such youths are having ADHD with associated early onset of disruptive behaviour disorder, substance use disorder and/or bipolar disorder.

There are many studies in the criminology literature, which tend to run in parallel to ADHD literature (Farrington, 1996; Moffitt et al., 1996). For example the UK National Epidemiologic Study in 1999 (Stephenson & Goodman, 2001) showed that 6% of 5-10 year old boys have conduct disorder, a high percentage of which entered the youth justice system. Other studies show that up to 90% of those with early conduct disorder have coexisting...
ADHD (McArdle et al., 1995). Studies raise the possibility of effective medical treatment as part of an overall package of help. Many studies also show a significantly high incidence of ADHD in the juvenile offender population (Rosler et al., 2004). It would be helpful for guidelines to be established, not only with the medical profession but also with other professions such as the Youth Justice Board, social services, tertiary education, teenage pregnancy initiatives etc.

Approximately 200,000 youths enter the youth justice system annually (The Home Office, 2003). ASSETT mental health screening showed that up to 75% of such youths considered themselves to be excessively impulsive (Youth Justice Board, date?). Studies have also shown that re-offending rates can be reduced from approximately 60% to 10% with effective multimodal management including management of ADHD (McCallon, 2000). There is a strong case to be made for guidelines within education and the health profession that link much better with the youth justice and substance abuse services. Consideration is currently being given to whether or not responsibility for such youth could be with education and health rather than primarily with the Home Office and Youth Justice Board (Allen, date?).

5 Summary.
Despite greatly improved recognition of ADHD in recent years, it would appear it is still currently under-recognised both in terms of incidence, treatment and effective management, especially if DSM-IV-R criteria are to be used.
Paediatricians and child psychiatrists have a part to play in the diagnosis and management of the condition, as do many other professional groups.
Guidelines for the management of adult ADHD should also be developed.
Future guidelines, if they are to be more representative of children’s mental health issues, and of the progression of ADHD, should be developed not only for the medical profession, as per the NICE guidelines, but also in conjunction with other service providers, such as education, youth justice and substance misuse services.
Broader recognition of the reality, the family impact, the chronic course and lifespan issues are essential re public policy development, as an issue of social reform and in the development of effective child, adolescent and adult mental health and educational services.

12.1 Concept of hyperkinetic disorder and ADHD and its
treatment implications

Dr Paramala J Santosh
Clinical Lecturer in Child & Adolescent Psychiatry, Institute of Psychiatry

This presentation will look at Hyperkinetic Disorder and ADHD. If you are looking at the symptom counts in the DSM, you need a greater number of symptoms than in the ICD-10 in order to make a diagnosis. However an assumption that this means identifying fewer cases using DSM would be incorrect.

In Hyperkinetic Disorder filters are applied, starting with the exclusion of anxiety and depression. You also need pervasiveness (symptoms across two settings) and impairment. (DSM focuses impairment rather than symptoms across two settings).

Applying these filters mean that you will have a smaller number with Hyperkinetic Disorder as a diagnosis, as opposed to ADHD.

MTA Study

This study can be used to show how figures can change by just using different criteria, for example the percentage of children diagnosed would vary whether parent, teacher or combined reports were used. Impairment and how you rate it and at what degree of impairment you say "it is important and needs treatment" is relevant. Because it is a question of how you set the threshold and that changes the numbers very dramatically. Differences in rates of diagnoses can therefore be explained by the way in which diagnostic criteria are applied.

Summary of MTA Study

This study was looked at to see whether the use of hyperkinetic disorder versus ADHD has an influence in terms of outcomes and treatment. (One factor to consider when looking at this study is that the intensity of the treatments used may not be transferable to clinical settings)

The target population was children with a DSM-IV diagnosis of ADHD (combined type) plus a wide range of comorbid conditions and demographic characteristics. The study group was 579 and the treatment strategies used in the randomly allocated groups were:

- Behavioural management (Parent training, Child-focused, School based)
• Medication management (Methylphenidate, if titration unsuccessful
  open titration of dextroamphetamine, pemoline, Imipramine)
• Combined treatment
• Community care

The combined treatment that was having medication plus behavioural
intervention was the best.

The next question to be asked was whether the the MTA findings of combined
ADHD could be generalised to hyperkinetic disorder? Starting with the initial
579 children with the diagnosis of ADHD (combined type) 147 were excluded
for Anxiety / Depression, of the remaining, once other filters were applied
145 had a diagnosis of HKD.

Hyperkinetic Disorder

One of the main findings was that if you had hyperkinetic disorder, then
using stimulants would be a good option as you had a higher chance of
responding to medication. Children with Hyperkinetic Disorder are
prescribed stimulants; this will also be the case for children with ODD / CD
(behavioural therapy is not used).

Anxiety and Depression

If you had anxiety and depression, it is the combined treatment that was
important; not just the behavioural intervention, but behavioural plus
medication would be better than medication alone.

Mild or Borderline ADHD

You could get the same response with either behavioural intervention
or stimulant use. The treatment recommendation for ‘Borderline’ ADHD is
behaviour therapy, then stimulants, if this is not effective the diagnosis is
reviewed.

Non-Hyperkinetic Disorder

The one thing that stood out clearly in the data set was that inattention being
reported in schools seemed to actually be a predictor that medication helped
the inattention in school. Here medication should be a reasonable choice.

Health Economics

Medication usage was effective in terms of treatment and even the
community care as usual was beneficial.
If you look at intensive behaviour therapy versus community care, then if you had a diagnosis of hyperkinetic disorder, it was almost costing twice as much as the ADHD construct.

If you had hyperkinetic disorder or hyperkinetic conduct disorder, the likelihood of the behavioural strategy alone working over the medication is going to be less cost effective.

Even the intensive behavioural strategy used in this study, was never better than medication.

**What are practical applications of the MTA study in clinical practice?**

Possible models include:

- Telephone-based Medication Monitoring and Stabilisation Clinic - CIPP
- 1 week MTA titration phase strategy
- Day patient observation with differing doses of stimulants
- Intense monitoring offered only when routine treatment fails
- Do these strategies matter when we now have long-acting drugs?

NICE guidelines should also be trying to look at how clinicians can be helped to do better clinical monitoring and titrating, as opposed to just deciding whether someone needs to receive a drug or not.
12.2 Predictive validity of broad versus narrow classification of hyperactivity

Dr Russell Schachar, MD, FRCP(C)
Department of Psychiatry, Neurosciences and Mental Health Research Institute, The Hospital for Sick Children, University of Toronto, Ontario, Canada

Address for correspondence: R. Schachar, The Hospital for Sick Children, 555 University Avenue, Toronto, ON, M5G 1X8, Canada, russell.schachar@sickkids.ca

At one extreme of the debate about the validity of the diagnosis of childhood hyperactivity are those who assert that the diagnosis is invalid no matter what criteria are applied (ref). More often, however, the question is framed around the appropriate breadth of the diagnosis. Some hold that only a narrowly defined syndrome such as Hyperkinetic Syndrome (HKD) as defined in the International Classification of Diseases-10 (ICD-10) has diagnostic validity and that a more broadly defined syndrome such as attention deficit hyperactivity disorder (ADHD) as defined in DSM-IV (ref) captures a group of children who either has no disorder whatsoever or a group who is similar to children with other and presumably more valid and clinically meaningful diagnoses such as conduct disorder (CD). Figure 1 shows several hypothetic functions relating severity of the phenotype on the y axis and accumulating underlying risk on the x axis. A narrowly defined diagnostic entity is shown in red; a broadly defined entity in blue.

In Model A, risk accumulates slowly without behavioral, cognitive or other manifestations until some threshold is exceeded. Beyond that threshold, the disorder is manifest and further risk does not substantially alter the phenotype. This is essentially the pathogen-disease model of disorder.

Model B shows a variation of the first function. At some level of the trait, there is a substantial increase in the expression of the disorder just as in model A. But in model B, the narrowly defined entity misses many individuals with risk who are captured by the broader criteria. The big difference between broad and narrow entities is prevalence although the narrow entity could show more risks depending on the slope of the function relating risk to symptoms over the hypothetical diagnostic threshold. According to this
model, both the broadly and the narrowly defined entities are different from unaffected individuals.

Model C shows a different function in which phenotypic expression increases linearly with increasing risk. There is no point at which there is a substantial and discontinuous increase in phenotypic expression with accumulating risk. Accordingly, a disorder defined narrowly by the presence of severe expression (the most symptomatic, the most impaired, those with the most evidence of some underlying pathogen or dysfunction) would differ in degree rather than in kind from a more broadly defined entity. Under these circumstances, there can be no easy solution to the classification problem. There will always be individuals who fall just below the boundary of the category and sub-threshold cases will differ only in degree from supra-threshold cases. Under these circumstances, factors other than validity of the defined entity will determine where the threshold is set. ICD-10 criteria are narrower than those for DSM in terms of pervasiveness, the range of symptoms required for criteria to be met (symptoms of inattention, hyperactivity and impulsiveness) and treatment of comorbidity.

We evaluated these models by assessing the predictive validity of HKD and ADHD in a sample of approximately 1000 consecutive referrals to a specialty clinic for attention, learning and behavior problems. First, we compared children who met criteria for HKD, ADHD-combined subtype (ADHD-C), ADHD-inattentive subtype (ADHD-IA), ADHD-hyperactive impulsive subtype (ADHD-HI) and controls on a range of clinical and cognitive characteristics. Then we excluded cases with any comorbid condition (conduct (CD) or oppositional disorder, generalized or separation anxiety disorder, reading disability) and compared HKD, ADHD, and control groups once again. Only one in ten cases that met criteria for ADHD also fulfilled criteria for HKD. The HKD group was more severe in that they exhibited a greater number of parent and teacher rated symptoms followed by the ADHD-C, ADHD-HI and ADHD-IA groups in descending order. Despite differences in symptoms severity and pervasiveness, HKD, ADHD-C, ADHD-IA, ADHD-HI differed little in teacher and parent rated impairment, exposure to psychosocial adversity (e.g., low socioeconomic status, single parent-headed homes, etc.), recurrence risk for ADHD in first degree family members, comorbidity (except for lower rate of CD in the ADHD-IA group), intelligence, reading scores, and measures of working memory (digit span backward) and inhibitory control (stop signal reaction time in the stop task). All of these groups had more deviant or extreme scores in each of these characteristics than did controls. After excluding comorbidity, HKD, ADHD and CD groups differed little in recurrence risk for ADHD in family members, exposure to psychosocial adversity, intelligence, digit span backwards, and reading performance; all three of these groups differed from controls. HKD was marked by more severe inhibitory control deficit than the ADHD, CD and control groups. The HKD, CD and ADHD groups were more impaired
according to parent and teacher ratings. In addition, parents rated the CD

group as more impaired than the HKD and ADHD groups whereas teachers
rated the HKD group as most impaired than the ADHD and CD groups.

In summary, these results support the predictive validity of both the narrowly
(HKD, ICD-10) and the broadly (ADHD, DSM-IV) defined entities and rejects
the hypothesis that either broadly or narrowly define hyperactivity or both
are invalid clinical entities or nothing more than that which is predicted by
their common comorbidities (Model A). There was only minimal evidence in
these data for a quantitative increase in the severity of associated risks with
increase in severity or pervasiveness (Model C). There was a trend for
inhibitory control to be worse in HKD compare with ADHD-C, ADHD-HI,
and ADHD-IA groups in that order. These results do not isolate a unique
feature of childhood hyperactivity. In conclusion, the most clearly supported
model is Model B which posits that both the broadly and the narrowly
defined entities exceed the threshold for a valid diagnostic entity.

Finally, it should be recalled that in North America the small subgroup of
narrowly defined HKD cases would all meet criteria for ADHD; the
predictive validity of the later group will be more marked than was found in
this study where HKD cases were separated from ADHD. By contrast, in the
UK and other countries which follow ICD-10 diagnostic practice, at least nine
of ten impaired children will not receive a diagnosis. More than half of these
cases do not receive any other diagnosis and will therefore not receive a
diagnosis commensurate with the seriousness of their disorder.
Social and cultural issues in ADHD diagnoses and psychostimulant treatment

Dr Ilina Singh
Wellcome Trust University Lecturer in Bioethics and Society, The London School of Economics and Political Science

Prof Nikolas Rose
Professor of Sociology, Convenor of Department of Sociology, The London School of Economics and Political Science

Presentation to the NICE ADHD Diagnosis Guideline Consensus Conference
17 October 2006

Reliable diagnosis rates for ADHD are difficult to find in any national context. It is also difficult to know the true epidemiology of ADHD in any national context, and prevalence rates vary widely, from 0.5% - 26% in the UK; and from 2% - 18% in the US. There is however good systematic data on worldwide consumption of methylphenidate (and dexamphetamine), collected by the United Nations International Narcotics Control Board. There is also detailed data available from IMS Health.

Both these sources demonstrate an enormous variation in global consumption of methylphenidate. Average consumption rates have increased dramatically between 1999-2003, averaging 5-7 fold increases. There are a wide variety of possible explanations for this variation, including (and not limited to) true epidemiological variation across countries in ADHD, the impact of national prescribing practices, medical training, parenting ideology, drug policies, health insurance, educational practices, teaching, and so forth. The bottom line is this: we don’t know why this variation exists.

The global variation in stimulant drug consumption does point to the fact that social and cultural factors are key to understanding patterns and trends in ADHD diagnoses and psychostimulant treatment. This does not mean that ADHD may not also have an organic aetiology. Socio-cultural analysis can make an important contribution to identifying and evaluating key environmental factors that shape ADHD diagnosis and stimulant drug treatment patterns.

It is unclear which level of socio-cultural analysis would be most useful. Potential analyses cover a wide range of targets: from a macro-level study of by-nation variation in methylphenidate consumption, to a micro-level study of the beliefs and practices of individual teachers and psychiatrists in local settings.

Evidence of socio-cultural factors in ADHD diagnosis and treatment can inform the Guideline by providing understanding of the pathway to
diagnosis of ADHD, and the key consequences of diagnosis of ADHD for the child and family. This is particularly important now that ADHD is no longer understood as a disorder of childhood. There is little or no longterm data on the “career” of the ADHD patient. We need to understand more about this career in order to assess the risks and benefits of 1. a narrow versus wide diagnosis; and 2. recommendations of longterm drug treatment.

We also need to avoid mistakenly attributing to the child consequences of social situations and cultural forces. This means we must have better (objective, sound and uniform) diagnoses for ADHD. However, even if this can be realized, in the absence of a biological marker for ADHD, there will always be an inherent dilemma about whether to cast the ADHD net widely or narrowly (by supporting a wide or a narrowly constructed diagnostic guideline). The costs and benefits of either approach must be very carefully weighed.
In this presentation we explored the status of categorical models of Attention Deficit/Hyperactivity Disorder (ADHD) as they underpin current diagnostic formulations in the DSM-IV and the ICD-10 and anchor debate about future revisions of these manuals. The presentation draws on the ideas published in a published journal article (Sonuga-Barke, 1998). The presentation had three major elements. Part one involved a discussion of the defining role of diagnostic systems in clinical and scientific practice related to ADHD. We reviewed the historical development of the role of diagnostic systems and their political and economic foundations. Part two was a review of three major themes relating to categorical models of childhood disorder.

First - we discussed the inevitability of categorisation in clinical practice given the imperative to identify those individuals in need of intervention – i.e. clinicians are inevitably categorisers and so categorical diagnostic systems go with the grain of clinical practice. Furthermore, we highlight the social psychological basis of categorical models of disorder by arguing that clinicians, like other humans, when faced with challenge of understanding complex human behaviour, tend to use heuristic devices that involve inferring traits on the basis of behavioural observations and drawing categorical boundaries even when these are not obviously present.

Second, we examined the relationship between clinical categorization and science. Here we focused on the role that the values and assumptions inherent in categorical diagnostic systems and the way that influence scientific practice – the hypotheses that are tested and the methods that are used to test them. In assuming that disorders, such as ADHD, are discrete entities qualitatively different from the normal variation of behaviour we bias our search for categorical boundaries between normality and abnormality and over-interpret evidence in favour of the validity of conditions. However, there is a need for a bridge of common meaning between the “laboratory” and the “clinic” and categorical diagnostic models support this vital function.

Third, we considered the different ways that one could respond to this recognition of the role of assumptions in the scientific study of categorical models of disorder. After considering a number of options (including the
rejection of diagnostic approaches on the grounds that they are social constructions) we argued that Meehl’s scientific realism whereby scientific assumptions are turned into specific testable hypotheses was the most valuable approach. The hypothesis that ADHD is a true category, or as Meehl calls it, a taxa, has not been tested sufficiently to date. However, genetics studies using DF analyses that look at the relationship between symptom severity and heritability do not support the taxa hypothesis of ADHD. More recent and more sophisticated studies using advanced taxanomic analyses also find no evidence for the existence of an ADHD taxa e.g., Haslem et al 2006; Frazer et al., 2007). It appears that ADHD is better modelled as a continuous trait rather than a discrete category.

We conclude by highlighting the dilemma between this empirical reality (that ADHD is better regarded as the extreme of normal variation rather than a distinct category) and the practical necessity and psychological inevitability that clinicians will make categorical decisions. We conclude by highlighting concerns over the transparency, communicability and implementability of a dimensional system for the diagnosis of ADHD while accepting that it may be a better model for science. Adopting such a model in future diagnostic formulations may run the risk of dismantling the bridge of meaning between clinic and lab – paradoxically inhibiting the process of diagnostic refinement and so the relevance of scientific findings to clinical practice.

Arguments against the use of the concept in clinical practice:
including whether it should be used never or sparingly
Dr Sami Timimi
Consultant Child Psychiatrist, Lincolnshire Partnership NHS Trust

The main problem with current theory and practice in ADHD is the
prevalence of the underlying assumption that ADHD is a genetic
neurodevelopmental disorder and that clinicians have valid and reliable ways
of identifying what behaviours are the result of such neurodevelopmental
disabilities in any individual child. This narrow biomedical construction
causes a polarisation of views and attitudes with proponents of this view
claiming “there is no such disagreement [about ADHD being a valid
disorder]- at least no more so than there is over whether smoking causes
cancer, or whether a virus causes HIV/AIDS” (Barkley et al, 2002) whilst
opponents claim “Its as simple as this: if no physical examination, lab test, X-
ray, scan or biopsy shows an abnormality in your children, your child is
normal” (Baughman,1998).

Current evidence does not support a simplistic view of ADHD type
behaviours. Genetic studies have relied on poor standards of evidence (such
as the disputed ‘equal environment’ assumption), and have failed to
consistently replicate genetic associations, thus the null hypothesis stands- No
genes exist for ADHD. Similarly neuro-imaging studies suffer from serious
methodological failings and interpretive inadequacies, thus there are
currently no neurological markers for ADHD (nor are there likely to be).
Conceptual problems are endemic in ADHD these include: high co-morbidity,
cross-cultural variations amongst raters and the rated, the behaviours are
qualitatively common behaviours leading to large variations in prevalence,
the gender distribution, and the circularity of construct (the behaviours define
the disorder, the disorder defines the behaviours).

The most important implication of the dominance of biological theory in
ADHD is that it has led to a rapid rise in the use of biological remedies as first
line and often only treatment for those diagnosed with ADHD. This is
problematic. Although stimulants have proven efficacy (up to 4 weeks), the
long term outcome literature available does not support stimulants being
effective in the long term (an important finding given that many end up on
stimulants for many years). Current treatment protocols have come to rely too
heavily on the MTA study (1999). However this had major methodological
and interpretive flaws, with the 24 month follow up study (MTA, 2004)
having less positive findings for medication, with children on medication
experiencing significant side effects. Indeed William Pelham who was on the
board of the MTA studies recently concluded “No drug company in its literature
mentions the fact that 40 years of research says there is no long-term benefit of
medications. That is something parents need to know.” (Quoted in Hearn, 2004).
The literature on medication has exaggerated stimulants effectiveness and
minimized its risks (which include serious risks such as cardiac disease, psychosis and sudden death).

However, we still have the reality that many children and many families are struggling to understand and deal with a range of behavioural and educational problems that we currently call ADHD. Some appear to benefit from diagnosis and prescription of medication, but we must balance this with our social responsibility for public health.

Alternative and useful ways forward can be found through incorporating discourses and research from related fields such as philosophy and transcultural/anthropological psychiatry which can provide both theory and practice with conceptual and practical tools to engage with questions of values, ethics, diversity and the changing nature of the challenges and circumstances that children and families live in.

The implications of this line of thinking are many. For the purposes of guidelines in diagnosing ADHD this means that ADHD should not be viewed as neurodevelopmental, diagnosis should come under the remit of mental health not paediatrics, the diagnosis should be reserved for more serious cases that are not responding to a variety of currently available clinical approaches, and when a diagnosis is made this should not lead to a long term prescription.

Part 2: Draft diagnosis chapter (part 1) sent to peer reviewers

Part 1 - Validity of the ADHD diagnosis

1.1 Introduction

This guideline is applicable to people above the age of three and of all levels of intellectual ability who show symptoms of hyperactivity, impulsivity or inattention to a degree that impairs their academic progress, mental development, personal relationships, or physical or mental health. This includes people with ADHD whether or not they have other comorbid mental disorders or whether the ADHD symptoms result from genetic, physical environmental or social environmental causes. This chapter sets out to look at the issues of diagnostic categorisation and assessment that should trigger the use of this guideline. It is in two parts: part I addresses the validity of DSM-IV ADHD and ICD-10 hyperkinetic disorder as diagnostic categories; part 2 provides guidance for clinical practice.

1.2 The validity of ADHD as a diagnostic category

The Guideline Development Group (GDG) acknowledged at the outset that the use of the diagnosis of ADHD has been the subject of considerable controversy and debate and that the diagnosis itself has varied across time and place as diagnostic systems have evolved (Rhodes et al., 2006). Points of controversy identified by the GDG included the reasons for the wide variation in prevalence rates reported for ADHD and the nature of the aetiological risk factors for ADHD.

The GDG wished to evaluate evidence for the validity of the diagnostic category of ADHD and formulate a position statement. It was recognised that defining psychiatric disorders is a difficult process due to the overlapping nature of behavioural and psychiatric syndromes, the complexity of the aetiological processes and the lack of a ‘gold standard’ such as a biological test—in this regard ADHD is no different from other common psychiatric disorders. Furthermore, in keeping with other common behavioural disorders there is no clear distinction between the clinical condition and the normal variation in the general population (see Section A3). This is comparable to normal variation for medical traits such as hypertension and type II diabetes, as well as psychological problems such as anxiety. Controversial issues surround changing thresholds applied to the definition of illness as new knowledge and treatments are developed (Kessler et al., 2002) and the extent to which functioning within the ‘normal cultural environment’ should determine clinical thresholds (Sonuga-Barke, 1998; Rosenman, 2006). As a result of considering these issues, a central question for this chapter is to
delineate the level of ADHD symptoms and associated impairments required
to trigger the use of this guideline.

It was recognised from the start that undertaking a systematic review of
diagnostic categories is not a straightforward exercise for behavioural and
psychiatric disorders because in most cases definitive diagnostic tests for the
presence or absence of disorder do not exist. The relative lack of a validated
reference standard (indicated by SIGN diagnostic study quality assessment,
see Appendix A) means that the question of validity for the diagnosis of
ADHD needs to draw on evidence from a wide range of sources. There is also
potential for ascertainment bias particular in clinic-referred populations and
considerable variation by clinical and demographic subgroups, disease
prevalence and severity, and use of different behavioural and symptom
measures (Whiting et al., 2004). The GDG wish to emphasise that psychiatric
nosology is a dynamic and developing field and changes are to be expected
over time as more data are accrued.

To ensure that a transparent, structured approach was taken, the GDG agreed
to use one similar to the Washington University Diagnostic Criteria (Feighner
et al., 1972). This approach involves setting out criteria for validating a
particular disorder and seeing how far a particular set of phenomena are
consistent with those criteria. Using these criteria as a framework, this chapter
sets out to answer the following questions:

A: To what extent do the phenomena of hyperactivity, impulsivity and
inattention, which define the current DSM-IV and ICD-10 criteria for ADHD
and hyperkinetic disorder, cluster together in the general population and into
a particular disorder that can be distinguished from other disorders and from
normal variation?

B: Is the cluster of symptoms that defines ADHD associated with significant
clinical and psychosocial impairments?

C: Is there evidence for a characteristic pattern of developmental changes, or
outcomes associated with the symptoms, that define ADHD?

D: Is there consistent evidence of genetic, environmental or neurobiological
risk factors associated with ADHD?

These questions were taken to relate to both DSM-IV ADHD and ICD-10
hyperkinetic disorder criteria. Hyperkinetic disorder is a more restricted
definition of ADHD that forms a subset of the DSM-IV combined subtype of
ADHD. The term ‘hyperactivity’ has been used in some studies to mean the
cluster of hyperactive, impulsive and inattentive symptoms. In this guideline
the term ‘hyperactivity’ is restricted to mean the combination of symptoms
that defines overactive behaviour and the term ‘ADHD symptoms’ is used to refer to the combination of hyperactive, impulsive and inattentive symptoms.

1.3 Methodology

A literature search was conducted for existing systematic reviews and meta-analyses on CINAHL, EMBASE, MEDLINE, PsycINFO. The initial search found 5,516 reviews of which 9 were relevant to the questions about ADHD and application of the Washington Diagnostic Criteria. Where insufficient evidence was found from previous systematic reviews, a search for primary studies was carried out (see Appendix B). We selected reviews for inclusion in this chapter if they met the SIGN quality assessment criteria for systematic reviews and cohort studies. For diagnostic and factor analytic studies we established a set of criteria approved by NICE (Appendix C).

In addition to the review of the literature, a consensus conference was held to bring together experts in the field who held a range of views and could address the concept of ADHD from different perspectives. This provided an opportunity to debate the key issues surrounding the use of this diagnostic category and thereby to assist the GDG with the task of deciding what should trigger the use of the guideline and for whom the guideline is intended. A summary of the consensus conference is provided in an Appendix to this chapter (Appendix D).

1.4 Reviewing the validity of the diagnosis: summary of the evidence

A: To what extent do the phenomena of hyperactivity, impulsivity and inattention, which define the current DSM-IV and ICD-10 criteria for ADHD and hyperkinetic disorder, cluster together in the general population and into a particular disorder that can be distinguished from other disorders and from normal variation?

The evidence addressing this issue is divided into three main questions:

(A1) Do the phenomena of hyperactivity, inattention and impulsivity cluster together?

(A2) Are ADHD symptoms distinguishable from other conditions?

(A3) Are the phenomena of hyperactivity, inattention and impulsivity distinguishable from the normal spectrum?

1.4.1 (A1) Do the phenomena of hyperactivity, inattention and impulsivity cluster together?
No evidence was found from the systematic search of reviews that was of
direct relevance to this question. This is because, despite a large primary
literature, few systematic reviews in this area have been undertaken.
Therefore a systematic search of factor-analytic studies was carried out.
Additional factor-analytic and cross-sectional studies were identified by the
GDG (Appendix E). None of these studies met the SIGN inclusion criteria that
requires an appropriate reference standard for diagnostic measures, but did
meet the extension to the SIGN criteria approved for this review: the aim of
the question was to evaluate whether the phenomena of hyperactivity,
inattention and impulsivity cluster together in the population, rather than to
assess the accuracy of diagnostic tests.

The inclusion criteria for factor-analytic studies were defined as follows: (i)
that the study addresses an appropriate and clearly focused question and, (ii)
that the sample population being studied was selected either as a consecutive
series or randomly, from a clearly defined study population.

Evidence

Many factor analyses indicate a two-factor model; ‘hyperactivity-impulsivity’
and ‘inattention’. This has been replicated in population-based studies (Lahey
et al., 1994; Leviton et al., 1993; Wolraich et al., 1996) and clinical samples
(Bauermeister et al., 1992; Lahey et al., 1988; Pelham et al., 1992). Single factor
‘hyperactivity-impulsivity’ is also supported by Dreger and colleagues (1964)
early study where the factor ‘hyperactivity’ was defined as ‘impulsive,
excitable hyperactivity’. More recent factor analytic studies based on DSM-IV
criteria support previous findings that the symptoms of inattention and
hyperactivity-impulsivity are distinct symptom domains in children (Molina
et al., 2001; Amador-Campus et al., 2005; Zuddas et al., 2006) and adolescents
(Hudziak et al., 1998).

Looking specifically at children identified as having a behavioural problem
Conners (1969) found ‘hyperactivity’ and ‘inattention’ as separate and distinct
factors. The factor structure of adolescent self-report behavioural data was
investigated by Conners and colleagues (1997) and found 6 factors including
‘hyperactivity’ and ‘cognitive problems’. The ‘hyperactivity’ factor included
characteristics such as being unable to sit still for very long, squirming and
fidgeting and feeling restless inside when sitting still. The ‘cognitive
problems’ factor consisted of having trouble keeping focused attention,
having problems organising tasks and forgetting things that were learnt.
Similar results were found in Conners’ (1998) further study were attentional
problems that overlap with the DSM-IV criteria for inattentive subtype of
ADHD, with a similar overlap between the factor items and DMS-IV criteria
for hyperactivity-impulsivity.
Some studies have identified three factors; ‘hyperactivity’ and ‘impulsivity’ as two distinct factors in addition to ‘inattention’ in both the general population (Gomez et al., 1999; Glutting et al., 2005) and clinical populations (Pillow et al., 1998). However, Gomez and colleagues (1999) showed that the model fit for the three-factor solution was only marginally better than the two-factor model. In the study of Pillow and colleagues (1998) of boys with ADHD, the impulsive and hyperactive symptoms formed a single factor when oppositional-defiant and conduct disorder items were also included in the factor analysis.

Werry and colleagues (1975), however, found that hyperactivity, impulsivity and inattention formed a single factor using both population control and ‘hyperactive’ samples.

Using a Latent Class Analysis (LCA) that identifies clusters of symptoms that group together, Hudziak and colleagues (1998) found that hyperactivity-impulsivity and inattention could exist as a ‘combined’ type latent class as well as separate hyperactive-impulsive and inattention latent classes. The latent classes map closely to the DSM-IV criteria, with DSM-IV combined type falling entirely within the severe combined type latent class. Individuals with the DSM-IV inattentive subtype fell either within the severe inattentive or the severe combined latent classes.

The clustering of hyperactivity, impulsivity and inattention appear to be stable across a number of countries. Ho and colleagues (1996) found separate robust dimensions for ‘hyperactivity’ (the combination of inattention and hyperactive-impulsive behaviour), ‘antisocial’ and ‘neurotic’ behaviour in a sample of 3,069 Chinese schoolboys. Correlations among different dimensions were similar to those reported in European and US samples. Taylor and Sandberg (1984) compared data from 437 English schoolchildren with published data from the US and New Zealand. They identified a factor of hyperactivity-inattention that was distinct from conduct disorder. The comparisons supported the view that English schoolchildren were similar to their contemporaries in the US and New Zealand with differences in prevalence rates between different countries accounted for by discrepancies in diagnostic practice.

In adult population samples a two-factor model has been identified (DuPaul et al., 2001; Smith & Johnson, 2000) as well as a three-factor model (Kooij et al., 2005). Glutting and colleagues (2005) assessed university students aged 17 to 22 using parent-rated information in addition to self-rated data. They reported slightly contrasting findings within each set of data; exploratory and confirmatory analysis showed that DSM-IV ADHD symptoms generated a three-factor model in the self-report data and a two-factor model in the parent-informant data.
Although most studies show separate factors for ‘inattention’ and
‘hyperactivity-impulsivity’, these are highly correlated in children (Gomez et
al., 1999) and adult samples (Kooij et al., 2005).

There may be age-dependent changes in the factor structure. Bauermeister
and colleagues (1992) found that there was a single ‘attention/impulsivity-
hyperactivity’ factor in pre-school children, and separation into two factors in
school-age children. Nearly all the studies of school-age children reported two
factors. In contrast, the study from Glutting (2005) using college students aged
17 to 22 found three factors, with the separation of hyperactive and impulsive
symptoms. Similarly Kooij and colleagues (2005) using adult samples
identified three separate factors.

Summary
Factor-analytic studies indicate that ADHD symptoms cluster together in
general population samples. The number of factors varies between studies,
with most finding two correlated factors for hyperactivity-impulsivity and
inattention; others find that hyperactivity and impulsivity can be
distinguished and a few find one combined factor of all three domains. These
findings have been observed in both population and clinical samples and in a
number of different cultural settings. LCA in population samples detects
clustering of symptoms into groups that are similar but not identical to DSM-
IV criteria for ADHD.

1.4.2 (A2) Are ADHD symptoms distinguishable from other conditions?

No systematic reviews were identified in the literature that addressed this
question. The GDG considered that the most important and controversial
distinction to be made was between ADHD and oppositional-defiant and
conduct disorders. These are also the most commonly reported comorbid
problems in children and adolescents diagnosed with ADHD and define a set
of behaviours that might be difficult to distinguish from ADHD. It was
therefore decided to restrict a formal literature search to identify studies that
indicate whether a distinction can be made between ADHD, oppositional-
defiant and conduct problems. Additional references were identified by the
GDG members (see Appendix F).

Evidence

1.4.2.1 ADHD and oppositional-defiant and conduct problems

Most of the studies using factor-analytic approaches for the analysis of ADHD
symptoms report separate factors for hyperactivity-impulsivity, inattention
and oppositional-defiant or conduct problems. These include most of the
studies reviewed in the previous section on factor structure of ADHD
symptoms (for example, Bauermeister et al., 1992; Connors et al., 1969;
Connors 1997; Ho et al., 1996; Pelham et al., 1992; Taylor et al., 1984; Werry et al., 1975; Wolraich et al., 1996). These studies are highly consistent in being able to separate oppositional-defiant and conduct problems from hyperactivity-impulsivity and inattention. Although the symptoms fall into separate dimensions there are significant correlations between the behavioural factors.

Frouke and colleagues (2005) conducted a diagnostic study of 2,230 Dutch pre-adolescents from the general population. LCA revealed that ADHD symptoms clustered together with symptoms of oppositional-defiant disorder and conduct disorder. A further study from the Netherlands of disruptive behaviour in 636 seven-year-old children (Pol et al., 2003) came to similar conclusions. LCA using the same data identified three main classes of children with: (i) high levels of ODD and ADHD, (ii) intermediate levels of ODD and ADHD with low levels of CP, (iii) low levels of all disruptive problems. No classes were identified with only ADHD, ODD or CP.

King and colleagues (2005) identified seven distinct groups using a cluster analysis that identified discrete groups: ADHD with inattention (ADHD-I), ADHD with hyperactivity-impulsivity (ADHD-H/I), ADHD with both hyperactivity/impulsivity and inattention (ADHD-C), ADHD-C with ODD, and ADHD-I with ODD. For both the inattentive symptoms and combined inattentive/hyperactive-impulsive symptoms they found clustering either with or without symptoms of ODD.

Latent dimension modelling by Ferguson and Horwood (1991) looking at children with ADHD and conduct disorder (CD) suggested that these could be seen as independent dimensions, although they are highly inter-correlated. However the two often occur independently of each other and only partially share aetiological factors.

ADHD can be a precursor of other problems. When ADHD and disruptive behavioural problems coexist the history usually suggests that symptoms of ADHD appear first before the development of disruptive behavioural problems. A follow-up of a community sample of children with ADHD symptoms but no oppositional behaviour between the ages of 7 and 17 revealed that children with ADHD symptoms could develop oppositional behaviour at a later stage, but that the reverse pathway from oppositional behaviour to ADHD was uncommon (Taylor et al., 1996).

Population twin studies find that symptoms of ADHD are distinct from but share overlapping familial and genetic influences with conduct problems (Thapar et al., 2001; Silberg et al., 1996; Nadder et al., 2002). Multivariate twin modelling suggests that while the genetic influences on conduct disorder are largely shared with those that influence ADHD, there are in addition important environmental factors that influence the risk for conduct problems.
but not ADHD (Thapar et al., 2001). Nadder and colleagues (2002) conclude
that the co-variation of ADHD and ODD/CD is the result of shared genetic
influences with little influence from environmental factors. However there are
substantial environmental influences on ODD/CD, especially when they are
not accompanied by ADHD (Silberg et al., 1996; Eaves et al., 1997). The
heritability of ADHD symptoms is also higher than that for ODD/CD
symptoms in these studies.

### 1.4.2.2 ADHD and other co-occurring conditions

Population twin studies find that symptoms of ADHD are distinct from but
share overlapping familial and genetic influences with other
neurodevelopmental problems including reading difficulties (Gilger et al.,
1992; Willcutt et al., 2000; Willcutt et al., 2007), impaired general cognitive
ability (Kuntsi et al., 2004) and developmental coordination disorder (Martin
et al., 2006).

ADHD is reported to co-occur with personality disorder in young offenders
(Young et al., 2003). A prison survey found that 45% of incarcerated young
adults had a previous history and persistence of ADHD symptoms (Rosler et
al., 2004). The distinction between ADHD and personality disorder in adults
raises important nosological questions and remains poorly investigated.

Dysthymia, depression and anxiety symptoms and disorders are frequently
associated with ADHD in adults. In the US National Comorbidity Survey,
adults with ADHD had increased rates of mood disorders, anxiety disorders,
substance misuse disorders and impulse control disorders (Kessler et al.,
2006).

### Summary

In the majority of factor-analytic studies ADHD symptoms are found to
represent separate but correlated factors from oppositional behaviour and
conduct problems. When symptom clusters are considered, ADHD symptoms
are often found to group together with oppositional behaviour. Longitudinal
studies suggest that ADHD represents a separate condition that is a risk factor
for the development of oppositional and conduct problems. Twin studies
suggest overlapping genetic influences on ADHD and conduct problems but
the genetic influences estimated by twin studies are greater for ADHD than
ODD/CD and there are environmental influences on ODD/CD that do not
act on ADHD. The correlation between ADHD and several
neurodevelopmental traits (cognitive ability, reading ability, developmental
coordination, and pervasive developmental disorders) is due largely to the
effects of shared genetic influences. In adults, co-occurring symptoms,
syndromes and disorders are frequently found to exist alongside the core
ADHD syndrome, but their distinction from ADHD and the reasons for high rates of co-occurrence are not well addressed in the current literature.

1.4.3 (A3) Are the phenomena of hyperactivity, inattention and impulsivity distinguishable from the normal spectrum?

No systematic reviews were identified that were of direct relevance to this question. The previous search for primary studies revealed two factor-analytic studies relevant to this question. Also, the GDG members identified further factor-analytic and genetic studies (see Appendix G).

Evidence

Many studies have found a strong correspondence between quantitative measures of ADHD and the categorical diagnosis (Biederman et al., 1993; Bird et al., 1987; Biederman et al., 1996; Boyle et al., 1997; Chen et al., 1994; Edelbrock et al., 1986). These studies show that children with ADHD appear to be at one extreme of a quantitative dimension and this on this quantitative dimension there is no obvious bi-modality that separates children with ADHD from non-ADHD children.

Twin studies using individual differences approaches (reviewed in Thapar et al., 1999; Faraone et al., 2005) and De Fries-Fulker extremes analysis (Gjone et al., 2006; Levy et al., 1997; Willcutt et al., 2000; Price et al., 2001) estimate similar heritability for ADHD symptoms from general population twin samples. These studies indicate that the genetic influences on ADHD are distributed throughout the population; there is no obvious threshold or cut-off between ADHD and the continuous distribution of symptoms in the population.

ADHD can be divided into multiple latent class groups distinguished on the basis of three symptom groupings: attention, hyperactivity-impulsivity and the combination of these two symptom domains. In addition, the symptom groups are separated on the basis of low, medium and high levels into distinct severity groups. Twin data from female adolescents in Missouri and children in Australia both found that a similar pattern of familial segregation for the latent classes suggesting that familial influences can distinguish between ADHD and the normal range of behaviour (Rasmussen et al., 2004). These data provide some evidence for the distinction of ADHD into inattentive, combined and hyperactive-impulsive subtypes and suggest that ADHD might be distinguishable from the normal range on the basis of familial risks to siblings.

Summary

ADHD: full guideline DRAFT (January 2008)
Most analytic approaches are unable to make a clear distinction between the diagnosis of ADHD and the continuous distribution of ADHD symptoms in the general population. Twin studies suggest that familial and genetic influences on groups with extremely high ADHD symptom scores are the same as those that influence ADHD symptom levels throughout the general population. LCA can however be used to distinguish groups with high, moderate and low ADHD symptom levels and suggests that these groups might be distinguished on the basis of familial risk factors. The current literature does not address the difference in interpretation of the latent class and quantitative approaches. The GDG concluded that on the basis of current evidence, ADHD was similar to other common medical and psychiatric conditions that represent the extreme of dimensional traits such as hypertension, obesity, anxiety and depression.

1.4.4 B: Is the cluster of symptoms that defines ADHD associated with significant clinical and psychosocial impairments?

There were no systematic reviews that addressed this question. A search for cohort studies was carried out and additional primary studies were identified by the GDG members (see Appendix H).

Evidence

1.4.4.1 Academic difficulties

Follow-up studies of people diagnosed with ADHD in childhood have consistently indicated impairment in their academic functioning. Children and adolescents with ADHD have been shown to have greater impaired attention, less impulse control, greater off-task, restless and vocal behaviour (Fischer et al., 1990), poor reading skills (McGee et al., 1992) and speech and language problems (Hinshaw, 2002) when compared with healthy controls. These impairments often lead to grade retention (Hinshaw, 2002), to a lower probability of completing schooling when compared with children who do not have ADHD (Mannuzza et al., 1993), suggesting potential long-term ramifications for vocational, social and psychological functioning into adulthood (Biederman et al., 1996; Young et al., 2005; Wilson & Marcotte, 1996).

An important question about educational impairment of children with ADHD is whether this is determined primarily by the presence of high levels of ADHD symptoms or the association with co-occurring conditions such as conduct disorder. Wilson and Marcotte (1996) found that the presence of ADHD in adolescents increased the risk for lower academic performance and poorer social, emotional and adaptive functioning, but that the additional presence of conduct disorder further increased the risk for maladaptive outcomes. In another study the association of conduct disorder with academic
underachievement was found to be due to its comorbidity with ADHD (Frick et al., 1991).

1.4.4.2 *Family difficulties*

Impaired family relationships have been reported in families of children with ADHD. Follow-up studies indicate that mothers of children and adolescents with ADHD have more difficulty in child behaviour management practices and coping with their child’s behaviour (August et al., 1998), and display higher rates of conflict behaviours, such as negative comments, social irritability, hostility and maladaptive levels of communication and involvement (August et al., 1998; Fletcher et al., 1996).

Family impairment also permeates the parent’s lives. Parents of children with ADHD report having less time to meet their own needs, fewer close friendships, greater peer rejection, less time for family activities, which might lead to less family cohesion and a significant effect on the parent’s emotional health (Bagwell et al., 2001).

1.4.4.3 *Social difficulties*

Girls with ADHD tend to have fewer friends (Blachman & Hinshaw, 2002) and greater problems with peers and the opposite sex (Young et al., 2005).

Hyperactive children with or without conduct problems have higher rates of problems with peers and higher rates of social problems because of lack of constructive social activities (Taylor et al., 1996). In a study by Ernhardt and Hinshaw (1994) it was reported that a diagnosis of ADHD significantly predicted peer rejection; however aggressive and non-compliant disruptive behaviours were important and accounted for 32% of the variance in peer rejection.

1.4.4.4 *Antisocial behaviour*

Antisocial behaviour is more prevalent in children and adolescents with ADHD than non-ADHD groups. Some studies show increased rates of antisocial acts (for example, drug misuse) in comparison to children who do not have ADHD (Barkley, 2004; Mannuzza et al., 1998).

Follow-up studies have also shown that people with high levels of ADHD symptoms had significantly higher juvenile and adult arrest rates (Satterfield & Schell, 1997). Young adults with a diagnosis of ‘hyperactivity’ in childhood were more likely to have a diagnosis of antisocial disorder than healthy controls (32% vs. 8%) and drug misuse (10% vs. 1%) at follow-up (Mannuzza et al., 1991).

ADHD is also a risk factor for psychiatric problems including persistent hyperactivity, violence, antisocial behaviours (Biederman et al., 1996; Taylor et
In a prospective follow-up of 103 males diagnosed with ADHD, the presence of an antisocial or conduct disorder almost completely accounted for the increased risk for criminal activities. Mannuzza and colleagues (2002) reported that antisocial disorder was more prevalent in children with pervasive and school-only ADHD. However, Lee and Hinshaw (2004) reported that the predictive power of ADHD status to adolescent delinquency diminishes when key indices of childhood externalising behaviour related to ADHD are taken into account.

Boys with ADHD and high defiance ratings show significantly higher felony rates than healthy controls (Satterfield et al., 1994). However, ADHD diagnosed in childhood increases the risk of later antisocial behaviour even in the absence of comorbid ODD or CD. Mannuzza, 2004).

1.4.4.5 Other problems
A 10-year prospective study of young people with ADHD found that the lifetime prevalence for all categories of psychopathology were significantly greater in young adults with ADHD compared with controls. This included markedly elevated rates of antisocial, addictive, mood and anxiety disorders (Biederman et al., 2006).

Both cross-sectional epidemiological studies and follow-up studies of children with ADHD show increased rates of unemployment compared with controls (Biederman et al., 2006; Kessler et al., 2006; Barkley et al., 2006). Adults with ADHD were found to have significantly lower educational performance and attainment, with 32% failing to complete high school; they had been fired from more jobs and were rated by employers as showing a lower job performance (Barkley et al., 2006). The survey from Biederman (2006) showed that 33.9% of people with ADHD were employed full time vs. 59% of controls.

Summary
ADHD symptoms are associated with a range of impairments in social, academic, family, mental health and employment outcomes. Longitudinal studies indicate that ADHD symptoms specifically are associated with both current and future impairments; additional impairments also result from the presence of co-occurring conditions, in particular conduct problems. Adults with ADHD are found to have lower paid jobs and lower socioeconomic status. Impairment is an essential factor to be considered in the diagnosis of ADHD. While it is clear that the presence of high levels of ADHD symptoms is associated with impairment in multiple domains, it is not possible to delineate clearly a specific number of ADHD symptoms at which impairment arises.
1.4.5 C: Is there evidence for a characteristic pattern of developmental changes, or outcomes associated with the symptoms, that define ADHD?

The search for systematic reviews and meta-analyses identified one review that was of relevance to this question. Additional reviews and primary studies were identified by the GDG members (see Appendix I).

Evidence

There is evidence for continuity of ADHD symptoms over the lifespan. Faraone and colleagues (2006) analysed data from 32 follow-up studies of children with ADHD into adulthood. Where full criteria for ADHD were used approximately 15% of children were still diagnosed with ADHD at age 25. In addition, the meta-analysis found that approximately 65% of children by age 25 fulfilled the DSM-IV definition of ADHD ‘in partial remission’, indicating persistence of some symptoms of ADHD associated with continued clinically meaningful impairments.

Relative to controls, levels of overactivity and inattention are developmentally stable (Taylor et al., 1996). Longitudinal studies of children with ADHD show similar rates of ADHD in adolescence (Biederman et al., 1996; Faraone et al., 2002; Molina & Pelham, 2003).

Population twin studies have also addressed the stability of ADHD symptoms throughout childhood and adolescence. Rietveld (2004) reported that parent ratings of attentional problems were moderately stable from age three to seven, and greater stability from age seven to ten. They further showed that such stability appeared to be mediated largely by overlapping genetic influences such that most, but not all, genetic influences at one age influenced ADHD at another age. Price and colleagues (2005) reported similar findings with correlations around 0.5 between ADHD symptoms at ages two, three and four. This stability was estimated to be mediated 91% by genetic influences. Kuntsi and colleagues (2004) extended these data to age eight, and found similar moderate stability between the data for age two, three and four and the data for age eight. Larsson and colleagues (2004) completed a similar longitudinal twin study of eight- to 13- year olds and found fairly high stability between the two ages; they further concluded that this stability was due to shared genetic effects. Change in symptoms between childhood and adolescence was thought to be due to new genetic and environmental effects that become important in adolescence.

In adolescence and adult life, symptoms of ADHD begin to associate with other diagnoses that are seldom made in childhood. Adolescent substance misuse, in particular, seems to be more common in people with the diagnosis of ADHD (Wilens et al., 2003), though it is not yet clear whether it is the ADHD per se that generates the risk or the co-existent presence of antisocial
activities and peer groups. The mechanisms involved can include one or more of the following: first that individuals with ADHD may seek out highly stimulating or risky activities; second that individuals with ADHD are exposed to higher levels of psychosocial risks for development of substance use disorders, resulting from educational and social impairments, social exclusion and antisocial behaviour associated with ADHD. Third, that various substances, including cannabis, alcohol and stimulants can attenuate ADHD symptoms and are therefore sometimes used as a form of self-treatment.

Summary

There is evidence for the persistence of ADHD symptoms from early childhood through to adulthood. Longitudinal studies confirm that ADHD persists into adulthood but developmentally appropriate criteria have yet to be developed for ADHD in adults. Using child criteria, approximately 15% of children with ADHD retain the diagnosis by age 25 but a much larger proportion (65%) show persistence of symptoms with associated impairments. The profile of symptoms may alter with a relative persistence of inattentive symptoms compared with hyperactive-impulsive symptoms, however the evidence base for this conclusion is poor, using developmentally appropriate measures of hyperactivity-impulsivity in adults. There was no evidence to warrant a different diagnostic concept in childhood and in adulthood. Familial and genetic influences in ADHD symptoms appear to be stable through childhood and early adolescence, but there is a lack of data on the continuity of aetiological factors into adulthood.

1.4.6 D: Is there consistent evidence of genetic, environmental or neurobiological risk factors associated with ADHD?

The literature search identified seven systematic reviews and meta-analyses. GDG members identified additional reviews and primary studies (see Appendix J).

Evidence

Dickstein and colleagues (2006) completed a systematic meta-analysis of 16 neuroimaging studies that compared patterns of neural activity in children and adults with ADHD and healthy controls. Their results indicated a consistent pattern of reduced frontal activity (hypoactivity) in people with ADHD.

Willcutt and colleagues (2005) reviewed 83 studies that had administered executive functioning measures and found significant differences between ADHD and non-ADHD groups where the former showed executive function...
deficits. The size of the difference between children with ADHD and
unaffected controls while significant was moderate rather than large.

Differences in executive functioning between ADHD and non-ADHD groups
have also been reported in adults (Hervey et al., 2004; Boonstra et al., 2005;
Schoelin et al., 2005; Woods et al., 2005). The results of studies of ADHD in
adults suggest a wide variety of general and specific performance on
cognitive-experimental tasks that are similar to those seen in children. The
review from Hervey and colleagues (2004) did not point to a domain-specific
neuropsychological deficit, but rather multiple domains revealed some degree
of impairment on at least a subset of the tests considered within each domain.
The interpretation of these studies remains controversial but most authorities
agree that both executive and non-executive processes are disrupted in people
with ADHD. Recently it has emerged that the strongest and most consistent
association with ADHD is for intra-individual variability (Klein et al., 2006).

A systematic meta-analysis of molecular genetic association for associated
markers in or near to the dopamine D4 (DRD4), dopamine D5 (DRD5) and
dopamine transporter (DAT1) genes, found strong evidence for the
association of DRD4 and DRD5 but not DAT1 (Li et al., 2006).

A systematic review of 20 population twin studies found an average
heritability estimate of 76%. In most cases, heritability in these studies is
estimated from the difference in the correlations for ADHD symptoms
between identical and non-identical twin pairs, as reported by parents and
teachers: with the correlation for identical twin pairs in the region of 60-90% and
for non-identical twin pairs being half or less half of this figure in most
studies (Faraone, 2005). Under the equal environment assumption for the two
types of twin pairs heritability can be estimated as twice the difference in the
two sets of correlations. Although some people question the assumption of
‘equal environment’ for identical and non-identical twins, this does not
impact on the question of validity since the high twin correlations observed in
these studies indicates that ADHD symptoms are highly familial. The equal
environment assumption impacts on estimates of the proportion of the
familial risk that is due to genes or equal environments (for example, Horwitz
et al., 2003). It should also be recognised that high heritability does not
exclude the important role of environment acting through gene-environment
interactions (Moffitt et al., 2005).

Linnet and colleagues (2003) completed a systematic review of the evidence
for association between prenatal exposure to nicotine, alcohol, caffeine and
psychosocial stress. They concluded that exposure to tobacco smoke in utero
is associated with an increased risk for ADHD. In contrast contradictory
findings were found for the risk from prenatal maternal use of alcohol and no
conclusions could be drawn from the use of caffeine. Studies of psychosocial
stress indicated possible but inconsistent evidence for an association with ADHD.

Summary

There is consistent evidence of familial influences on ADHD symptoms in the general population. Under the equal environment assumption these familial influences are thought to be largely genetic in origin. Environmental measures associated with ADHD have been identified, the most certain being the association with maternal use of tobacco during pregnancy. It is not known whether these environmental risks represent direct or indirect risks through correlated environmental or genetic factors. Specific genetic variants that are associated with a small increase in the risk for ADHD have been identified in the dopamine D4 and close to the dopamine D5 receptor genes. Analysis of ADHD versus non-ADHD groups has identified consistent changes in brain function and performance on neurocognitive tests; however differences from controls are not universal, do not characterise all children and adults with a clinical diagnosis of ADHD, and do not usually establish causality in individual cases.

1.5 Limitations

In line with methodology agreed with NICE the approach adopted was initially to identify all available systematic reviews and meta-analytic studies that related to the questions on validity of the diagnosis. While this was possible for much of the neurobiological and genetic and environmental data there were few systematic reviews in other areas such as the factor- or cluster-analytic studies. Where systematic reviews were not available for these studies of ADHD symptoms and studies that investigate the differentiation of ADHD from oppositional and conduct problems, systematic reviews of the primary literature were conducted. For other sub-questions addressed in this section the systematic evidence was supplemented with expert opinion, drawing on evidence known to members of the GDG. The lack of specific reference standards for the diagnosis of ADHD led to an adaptation of the SIGN criteria (see Appendix A) to ensure sufficient quality of the data used to derive recommendations for this guideline.

When considering the Feigner criteria for validity of a psychiatric disorder, the question of whether there are specific responses to clinical, educational and other interventions for ADHD was excluded, since the data to answer this question was very limited. For example it was not possible to identify studies that investigated the effects of stimulant treatments in disorders other than ADHD and there were limited published data on the effects of stimulants in people who do not ADHD. A paper that did not meet the quality control criteria for the evidence sections of this chapter, investigated the response to dexamphetamine and placebo in a group of 14 pre-pubertal
boys who did not fulfil criteria for ADHD (Rapoport, 1978). When amphetamine was given, the group showed a marked decrease in motor activity and reaction time and improved performance on cognitive tests. The very small numbers used in this study and lack of further similar studies means that considerable caution must be taken in drawing firm conclusions. Nevertheless, the similarity of the response observed in children without ADHD to that reported in children with ADHD provides further evidence that the aetiological mechanisms that give rise to ADHD are similar to those that influence levels of ADHD symptoms through the population. However the key difference from treatment of people with ADHD is that the ‘behavioural symptoms’ that responded to medication were not causing impairment in the children in this study.

1.6 Position statement on validity of ADHD

Hyperactivity, inattention and impulsivity cluster together both in children and in adults and can be recognised as distinct from other symptom clusters, although they frequently co-occur alongside other symptom clusters.

Symptoms of ADHD appear to be on a continuum in the general population. ADHD is distinguished from the normal range partly by the number and severity of symptoms and partly by the association with significant levels of impairment.

The importance of evaluating impairment and the difficulty in establishing recognised thresholds on the basis of symptom counts alone needs to be addressed. It is not possible to determine a specific number of symptoms at which impairment arises.

There is evidence for psychological, social and educational impairments in both children and adults with ADHD.

ADHD symptoms persist from childhood through to adulthood. In a significant minority, the diagnosis persists and in the majority, sub-clinical symptoms continue to be detectable.

In adults the profile of symptoms may alter with a relative persistence of inattentive symptoms compared to hyperactive-impulsive symptoms.

There is evidence of both genetic and environmental influences in the aetiology of ADHD. It is not known the extent to which there is diversity in the aetiology of the disorder.
Contemporary research suggests that environmental risks are likely to interact with genetic factors, but there is currently limited direct evidence to support this view.

There is evidence of genetic associations with specific genes, environmental risks and neurobiological changes in groups of children with ADHD. However no neurobiological, genetic or environmental measure is sufficiently predictive to be used as a diagnostic test.

The diagnosis remains a description of behavioural presentation and can only rarely be linked to specific neurobiological or environmental causes in individual cases.

Hyperkinetic disorder (ICD-10) is a narrower and more severe subtype of DSM-IV combined type ADHD. It defines a more pervasive and generally more impairing form of the disorder. Both concepts are useful (Santosh et al., 2005).

There was no evidence of a need to apply a different concept of ADHD to children and adults. However age-related changes in the presentation are recognised.

All current assessment methods have their limitations. There is evidence of the need for flexibility and for a consideration of levels of impairment in assessments and when deriving appropriate diagnoses.

1.7 Consensus conference

In addition to a review of published evidence on the question of validity, a consensus conference was held to bring together experts in the field with a range of views, in order to debate the key issues of the use of ADHD as a diagnostic category. The aim was to provide a range of contemporary perspectives that would assist the GDG with the task of deciding what should trigger the use of the guideline and for whom the guideline is intended (see Methods Chapter x). The speakers delivered a 15-minute presentation addressing the key questions relating to the validity of the ADHD diagnosis set out by the GDG followed by questioning from the GDG members and a subsequent discussion of the presentation among members of the GDG. Each presenter was subsequently asked to provide a summary of their presentation and these are also presented in Appendix A.

1.7.1 Discussion on consensus conference presentation

Different presenters brought their own perspectives and this contributed to highlight the importance of a multi-disciplinary approach to the diagnosis
and treatment of children with ADHD. The conference did not consider
diagnosis and treatment of adults with ADHD. Here some of the issues that
were raised, and the areas of controversy arising from differences in the
perception of the different speakers at the consensus conference, are
discussed.

The evidence presented at the consensus conference indicated that there was a high degree of unanimity across presenters (coming from a wide range of perspectives) about the fact that there is a group of people who could be seen as having distinct and impairing difficulties and who should trigger the use of this guideline. While recognition of a particular group was agreed upon, uncertainty about the breadth of diagnosis was discussed, namely, whether the use of a narrow (ICD-10 hyperkinetic disorder) versus a broad (DSM-IV ADHD) diagnosis should be used. The problems of using a narrow diagnosis are: (i) the under-recognition of people that are in need of help and, (ii) the lack of connection with the research literature, which is based mainly on broader definitions such as DSM-IV. It was established that the main differences between people falling into narrow or broad diagnoses are the breadth of symptoms (requirement for both inattentive, and impulsive-overactive behaviour versus only one domain being sufficient), more or less stringent criteria for situational pervasiveness and the requirement for no major comorbidity (apart from oppositional-defiant or conduct disorder under ICD-10). Both groups present similar problems of impairment. Overall there was general agreement that both the use of broad (DSM-IV) ADHD diagnosis and narrow hyperkinetic disorder criteria were useful.

One of the major issues of controversy in the UK setting is the very high and variable prevalence rates reported in the literature. For example, recent prevalence figures range from 6.8 to 15.8 for DSM-IV ADHD (Faraone et al., 2003) while the British Child and Mental Health Survey reported a prevalence of 3.6% in male children and less than 1% in female (Ford et al., 2003). Reasons for this are discussed in Faraone and colleagues (2003) who conclude that prevalence rates derived from symptoms counts alone, or from ratings in one setting, were higher than those that took into account functional impairment. For example Wolraich and colleagues (1998) estimated prevalence to be 16.1% on the basis of symptom counts, but 6.8% when functional impairment was taken into account. A study in the UK that specifically addressed the role of impairment found that among seven- to eight-year-olds 11.1% had the ADHD syndrome based on symptom count alone (McArdle et al., 2004). In contrast, 6.7% had ADHD with Children Global Assessment Scale scores (CGAS: measuring impairment) less than 71 and 4.2% with CGAS scores less than 61. When pervasiveness included both parent and teacher reported ADHD and the presence of psychosocial impairment prevalence fell lower to 1.4%. The literature on prevalence therefore indicates that the rate of ADHD is sensitive to the degree of impairment associated with the symptom criteria and the degree to which the disorder shows situational pervasiveness.
All the speakers acknowledged the importance of functional impairments in relation to diagnosis. In other words, that diagnostic thresholds should be based on pragmatic grounds such as impairment and the need for treatment. However, there was also agreement that defining suitable thresholds for impairment is difficult due to the breadth of areas in which people with ADHD can be impaired. The level and types of behaviour that define the normal range remain a contentious issue.

On considering when this guideline would be triggered, the GDG concluded that it would be difficult to be prescriptive for any individual case, but that measurement of impairment linked to the symptoms of ADHD is a key component of the decision. Significant problems can arise at various levels, including personal distress from symptoms of the disorder, difficulties in forming stable social relationships and emotional bonds, difficulties with education and long-term risk for negative outcomes such as emotional problems, antisocial behaviour and addiction disorders. The group concluded that treatment response should take into account the severity of the disorder in terms of clinical and functional impairments and evidence should be looked for on the impact of severity of the disorder on treatment response. Overall this is an area in which further research is required to investigate both the short- and long-term outcomes of ADHD and its relation to severity of the condition.

One of the areas of controversy highlighted in the consensus conference was the degree of impairment and severity of ADHD needed to trigger the diagnosis, and related to this, treatment with medication. There is concern in some quarters that the diagnosis automatically leads to treatment with medication and this is not always desirable when the breadth of the definition includes people who might gain substantial benefit from education or psychosocial interventions alone. However even the most ardent supporters of non-medical interventions in ADHD recognised the importance of medical treatment in the most severe cases. In this context the participants in the consensus conference made an important contribution by raising the question of suitable thresholds for ‘significant impairments associated with ADHD symptoms’ and hence the proportion of children fulfilling criteria for the disorder and triggering use of the guideline.

One conclusion is that the acceptable thresholds for impairment are largely driven by the contemporary societal view of what is an acceptable level of deviation from the norm and level of impairment that requires treatment. However the GDG did not consider that the diagnosis should be reserved only for the most serious cases, since the broader concept of ADHD is important in triggering educational and behavioural approaches in addition to medical approaches. The GDG concluded that defining appropriate thresholds of impairment associated with the disorder was important, but...
that treatment implications might be different for individuals falling above or below particular thresholds.

Confirmatory factor-analytic studies clarify that ADHD symptoms represent a distinct set of symptoms and behaviours that co-vary together in both clinical and control populations. However these cross-sectional studies are far less informative than longitudinal studies that can clarify the predictive outcomes of early ADHD. There are however a few studies that provide suitable data on the relative outcomes of ADHD and other disruptive disorder such as ODD, which are important in delineating specificity in the outcomes related to ADHD. The available evidence suggests that when considering the link between ADHD and conduct problems, ADHD comes first and conduct problems develop later. In contrast there is no evidence that conduct problems in the absence of ADHD lead to the later development of ADHD. The small amount of suitable longitudinal outcome studies highlights an important area for future research.

The consensus conference also raised questions about the interpretation of family, twin and adoption studies and the relative contributions between genetic and environmental influences indicated by these studies. The argument against genetic influences is not strong unless one questions the conventional interpretation of twin data. But it is non-controversial that parent and teacher ratings of ADHD symptoms/behaviours show MZ correlations around 70-80% and DZ correlations around 20-40%; numerous studies replicate this. The usual interpretation of these findings is that the difference in MZ and DZ correlations are mainly the result of genetic influences. The alternative argument that the equal environment assumption is incorrect leads to the conclusion that familial influences are important, but not necessarily genetic. Either way, it is non-controversial that ADHD is familial and this in itself is strong evidence that the construct is sufficiently delineated to show such clear familial effects; that is, that the level of ADHD symptoms in one child strongly predicts the level of ADHD symptoms in his or her siblings. Interestingly there are limited data from twin studies using ADHD cases (for example, concordance rates for the clinical disorder), so the literature mainly uses extremes analysis of rating scale data. Similarly there is a lack of twin data in adult populations.

The GDG agreed that polarised positions in this debate are not helpful since the contemporary understanding of complex behavioural disorders emphasise the importance of interactions between genes and environments. The GDG wish to stress that the role of important genetic influences does not exclude an important role for environmental influences since individual differences in genetic risk factors are likely to alter the sensitivity of an individual to environmental risks. In this event, reducing environmental risk would be expected to reduce the risk for ADHD. Furthermore, the extent to which there are genetic influences has no direct bearing on the choice of
treatment approaches since both medical and psychosocial interventions (or a combination of the two) could be important in improving treatment outcomes.

1.8 Evidence summary

ADHD should be considered a valid clinical disorder that can be distinguished from co-occurring disorders and the normal spectrum. ADHD is distinguished from the normal spectrum by the co-occurrence of ADHD symptoms with significant clinical, psychosocial and educational impairments. These impairments should be enduring and occur across multiple settings.

Hyperkinetic disorder is a valid diagnosis that identifies a sub-group of people with ADHD with severe impairment in multiple domains.

ADHD commonly persists throughout childhood and into adult life where it continues to cause considerable psychiatric morbidity.

The quality of the evidence included in this review was variable and lacked any ‘gold standard’ because no diagnostic tests for ADHD have been developed or tested. In the absence of a gold standard for the validity of diagnosis of ADHD or hyperkinetic disorder a lower level of evidence was included in this review.

Although the quality of individual studies included in this review was variable, evidence consistently showed that children and adults with ADHD had associated impairments.

1.9 Clinical practice recommendations

1.9.1.1 For the diagnosis of ADHD or hyperkinetic disorder to be made, and for this guideline to be considered appropriate, the following criteria should be met:

1. Symptoms of ADHD (DSM-IV) or hyperkinetic disorder (ICD-10) should be sufficient to reach a formal diagnosis in DSM-IV or ICD-10.

2. ADHD should be considered in all age groups (children, adolescents and adults), with symptom criteria adjusted for age appropriate changes in behaviour.

3. The level of impairment resulting from symptoms of hyperactivity and or inattention should be:
1.9.1.2 In determining the clinical significance of impairments resulting from the symptoms of ADHD in children, the views of the child should be taken into account, wherever this is possible.

1.9.1.3 The diagnosis of ADHD should only be made by specialist psychiatrists or paediatricians following a full assessment of the child, adolescent or adult; including all relevant settings.

1.9.1.4 After making a diagnosis of ADHD or hyperkinetic disorder subsequent assessment and treatment should follow the guideline recommendations.

<td>Just because we can diagnose a trait does not mean it is a disease. Your title could leave some people with the mistaken impression that if you can identify a trait and label it, that it can then be called a disease. The validity of the diagnosis – whether you can reliably identify it in some children – is an interesting question, but in this document it is simply a distraction from the main question. The essential question for the NICE committee should be: Is the disease concept of ADHD valid? With that in mind section 1.4 1, 1.4.2, 1.4.2.1, and 1.4.2.2 have little relevance. The most important section, which most of my comments address, is 1.4.6.</td>

<td>You might note that the methodology used to create the Washington University Diagnostic Criteria has been widely accepted and that similar approaches have been used to validate categories for the Research Diagnostic Criteria, the DSM and the ICD criteria (when relevant validating data have been available). My point is that your choice of the WDC is far from arbitrary as there is some consensus as to what the “rules of evidence” should be for asserting the validity of a psychiatric disorder. The intellectual foundation for all these criteria relies heavily on the concept of “construct validity” so well articulated by Paul Meehl decades ago.</td>

| 22 | CC | David Coghill | 1.2 para 2 | Furthermore, in keeping with other common behavioural disorders there is no clear distinction between the clinical condition and the normal variation in the general population

The meaning of this sentence is rather unclear. I think it is confusing (or maybe confounding?) symptoms and impairment and to do with the precise words used. There is a continuity of symptoms between those with the disorder and the population. However those with the clinical condition have both high levels of symptoms and impairment leading to a clearer “distinction” between the two. Whilst this may seem trivial the actual sentence is contrary to the conclusions and will be picked up by those who wish to point out that NICE says “there is no clear distinction between the clinical condition and the normal variation in the general population” without clarifying the context of the quotation. | No reference suggested. | Comment addressed, see sections 5.3 (third paragraph) and 5.5.3. |
| 80 | PR | Jonathan Leo | 1.3 | I think that somehow you need to mention that your literature review was very selective and systematically ignored review articles that were critical of the ADHD diagnosis. As you are aware of both the controversy surrounding the diagnosis and those authors who have addressed the problem, I am assuming that it was a conscious decision to ignore one side of the debate. There is a large body of literature that sees forces other than biology as the References suggested: Gale (2006) Ritalin requests often deemed inappropriate. Medscape. References included in the NICE guideline as evidence (found by systematic searches or identified by GDG members) have to | | |
source for the dramatic rise in the diagnosis of ADHD. This literature comes from wide and varied sources and is representative of a large segment of the mainstream media and academia. Since one reason that NICE is taking on this difficult task is because the ADHD diagnosis is controversial, it does not make sense to simply ignore critical publications. Just summarizing the reviews from mainstream psychiatry journals does not give a balanced view, especially when one considers that it is extremely difficult to get anything published in a psychiatry journal or medical journal that is critical of the ADHD diagnosis. You even acknowledge that in one section of the document that, because there was limited data, “…the systematic evidence was supplemented with expert opinion, drawing on evidence known to members of the GDG.”

By selectively choosing data in support of a particular point of view it suggests that your conclusions were made first, and the studies were then subsequently chosen to support your conclusion, and not the other way around, that a group of non-partisan academics analyzed all the data and then came to a conclusion.

As just one example of how the debate is framed in academic journals, in 2002, a group of scientists published the International Consensus Statement on ADHD. The consensus statement had several surprising and remarkable declarations such as:

“Numerous studies of twins demonstrate that family environment makes no significant separate contribution to these traits” (Which runs counter to the NICE document).

“One gene has recently been reliably demonstrated to be associated with this disorder...”

“Neuroimaging studies of groups with ADHD also demonstrate relatively smaller areas of brain matter.”

“Most neurological studies find that as a group those with ADHD have less brain activity...”

When a group of academicians sent a Letter to the Editor of Child and Family Psychology Reviews about the Consensus Statement, the editor responded that the letter could be published, but only if Dr. Barkley, the lead author of the Consensus Statement, was given the courtesy of having the last chance to respond. However, this was not a courtesy initially granted to the academicians critical of the rising diagnosis of ADHD, who Barkley and his
co-authors compared to members of the flat-earth society. Thus, the authors of the Consensus Statement were given a second chance to cite evidence in support of the biological basis of ADHD, yet rather than cite several specific articles; they instead mentioned that there were hundreds and hundreds of articles. However, good science is not determined by how high the papers can be stacked but by the quality of the papers. To paint those concerned about the rising use of stimulants as somehow on the fringe, shows how isolated academicians can become from the general public. For the GDG to not acknowledge anyone critical of the diagnosis in their own review puts the GDG in the same category as the Consensus authors. Does NICE want to be in the same category?

Nowhere in the GDG document is there a discussion about the ethics of giving a performance enhancing drug to improve academic success in school - a major reason the drug is used in the first place. For instance, take the announcement about a recent survey, “Results of a survey of physicians suggest that parents often request a ‘behavioral drug,’ such as Ritalin, with the goal of enhancing their child’s academic performance rather than treating an illness.” (Gale, 2006, Italics added). The headlines expressed surprise at this practice, yet the practice of prescribing stimulants to improve academic performance is exactly why these medications are prescribed in the first place, and, it is fully sanctioned by the medical community. According to Joseph Biederman, “If a child is brilliant but is doing OK in school, that child may need treatment, which would result in performing brilliantly in school” (Gale, 2006). In fact, no official organization that supports the use of stimulants has ever said that using stimulants to improve academic performance is inappropriate. Even the GDG has not said this is inappropriate. Is it?

82 PR Jonathan Leo 1.4 In your framing of the question, you ask if environmental factors are associated with ADHD. You then address one review covering the evidence of prenatal exposure to drugs. Again you have systematically ignored a large body of evidence. Perhaps this section is the biggest flaw in your document. Any academic reading this discussion will have a hard time taking your seriously if you cannot think of a single environmental influence coming from the home or school environments that contributes to ADHD. Either you need to comment on this research or explain why you are ignoring it. For instance, a recent study showed that children from divorced families are twice as likely to be diagnosed with ADHD. (CMAJ, Strohschein, References suggested: Strohschein (2007) Prevalence of methylphenidate use among Canadian children following parental divorce. CMAJ, 176(12):1711-4. Paper included. Comment addressed, see section 5.8.)
And prior studies have shown that children from single family homes are more likely to be diagnosed with ADHD. For more information I have attached two tables and a discussion from Dr. Nicky Hart at UCLA who addresses the differences in the ADHD diagnosis across the socioeconomic strata in England and Wales. The data will appear in a forthcoming book: ADHD and Health Inequality.

The statistical evidence generated by the British government as part of its policy making function runs against the impression that ADHD is best thought of as a bio-medical phenomenon. The social distribution of the disorder follows the contours of the class mortality gradient. In other words, it fits the classic profile of health inequality: low prevalence at the top, and high prevalence at the bottom of the social hierarchy. Children exhibiting the symptoms of emotional and conduct disorders, and those afflicted with the troubling symptoms of attention deficit and hyperactivity disorder are much more likely to be poor, to be raised by single and / or unemployed parents, to grow up in neighbourhoods scarred by the signs of under-privilege and to be exposed to stressful life events and social relationships in their early lives.

Figure 1 displays the class gradient of psychiatric morbidity as a whole in British children. The rate is around 4% among children in families where the main breadwinners are employed in higher professional occupations (e.g. lawyers, doctors, professors). It is 4 times higher (16%) in families where parents are either (chronically unemployed or have never worked at all. Hart (in press) Health inequality in ADHD. McMillan Paper excluded: not peer-reviewed.
This group includes single parent families headed by young women with no labour market experience prior to becoming mothers. The rate of ADHD British style (hyperkinetic disorder) follows the same course. It increases from 0.5% in professional families to 2.6% in households with no attachment to the labor market, a five-fold increase. In between these two poles of social privilege and under-privilege, the risk of mental disorder is around 6% in other middle class strata before ‘jumping’ to more than 8% in the lower supervisory/technical occupations, from this point onwards, it rises steadily on each successive downward rung of the social hierarchy. If we take the lower supervisory occupational category in figure 3, as the division between the middle (white collar) and working class (blue collar) strata of British society (containing respectively 56 and 44 percent of the...
population), we can conclude that social class is strongly associated with children’s mental well being. Working class kids face a much higher probability of experiencing the symptoms of mental disorder in all its forms than their peers in middle class homes, hyperkinetic disorder is no exception.

The occupational class gradient of ADHD can be translated to another variable representing the social and economic geography of health inequality. This variable is based on the ACORN classification which uses the census characteristics of the area where a child lives (the postal code) to summarize its salient social characteristics. Figure 4, classifies the same sample of children by the quality of their living environment. In a literal sense this variable represents the social and economic environment of daily life and therefore the differential opportunities for physical and intellectual development in childhood.
Once again, we find the social gradient so typical in the health inequality research literature. The symptoms of childhood psychiatric morbidity in areas populated by wealthy families are only half the rate of areas where families with moderate means make their homes. The gap is even wider between the most advantaged and the least disadvantaged neighborhoods and it applies to all mental as well as hyperkinetic disorder.

<td>1.4.1</td>
<td>First para after sub heading ‘Evidence’. I have a problem with the use of the word ‘symptom’ in this chapter. The issue of the diagnostic validity is a contentious one as illustrated by the lengths the GDG have gone in consulting widely. ‘Symptom’ implies an illness or disorder about which someone is complaining. Question A in 1.2, repeated at the start of 1.4, and question A1 at the start of 1.4.1 are careful in using the neutral term ‘phenomena’ to describe the behaviours of interest. This seems appropriate given that the whole point of this chapter is to reach conclusions about whether ADHD is or is not a useful construct. To then use the word ‘symptom’ seems to suggest that the issue is already decided. Its use may be appropriate when referring to clinical samples but the use at the end of this paragraph relates to a study where the sample is unclear. This usage recurs in 1.4.1 and throughout the chapter. For example 1.4.3 has ‘phenomena’ in the title but then refers to ‘continuous distribution of symptoms in the population’ in para 3. I will not list all examples here, and as stated above, ‘symptom’ may be appropriate for research on clinical samples but I think language could be used more carefully and would advocate a word search of the document and consideration on each occasion of the word ‘symptom’ whether it is in fact the best word available.</td>

is also noted that “there is no obvious threshold or cut-off between ADHD and the continuous distribution of symptoms in the population.” In the introduction to the document it is stated that “in keeping with other common behavioural disorders there is no clear distinction between the clinical condition and the normal variation in the general population.” The GDG conclude that “most analytic approaches are unable to make a clear distinction between the diagnosis of ADHD and the continuous distribution of ADHD symptoms in the general population” in other words the answer to question 1.4.3 is, according to the evidence presented, “no”.

74 CC Sami Timimi 1.4.4 Is the cluster of symptoms that defines ADHD associated with significant clinical and psychosocial impairments? The GDG provides evidence that is consistent with ADHD being associated with significant impairment. However what is not properly addressed is the nature of this association and direction of causality. For example with regards academic difficulties it is noted that “These impairments often lead to grade retention (Hinshaw, 2002), to a lower probability of completing schooling when compared with children who do not have ADHD (Mannuzza et al., 1993)” This association could be mediated by a third factor, such as lowered self-esteem, boy-unfriendly school curricula, frustration, learning difficulties etc. that leads to both ADHD symptoms and poor school performance. In family difficulties it is mentioned that “Follow-up studies indicate that mothers of children and adolescents with ADHD have more difficulty in child behaviour management practices and coping with their child’s behaviour (August et al., 1998), and display higher rates of conflict behaviours, such as negative comments, social irritability, hostility and maladaptive levels of communication and involvement (August et al., 1998; Fletcher et al., 1996). Family impairment also permeates the parent’s lives. Parents of children with ADHD report having less time to meet their own needs, fewer close friendships, greater peer rejection, less time for family activities, which might lead to less family cohesion and a significant effect on the parent’s emotional health (Bagwell et al., 2001).” A vast repertoire of attachment studies also suggest that this association might well indicate important causal factors for ADHD symptoms (i.e. theses family difficulties cause rather than are caused by ADHD, or more likely interact in varying degrees and combinations depending on the family and individual). With regard anti-social behaviour the GDG note “In a prospective follow-up of 103 males diagnosed with ADHD, the presence of an antisocial or conduct disorder almost completely

<td>Whilst we agree in principle, our own personal experiences and that of having worked with and supported many families for over a decade through the ADHD Support Group, there is clear indications that parents are still being subjected to accusations of ‘poor parenting’. As parents, not only are we dealing with the family members needs, that of siblings but with professional bodies such as health, education and social care in which to access an appropriate multi-agency, multi-disciplinary service for the ADHD family member, no one body taking responsibility in which to meet the needs of those with ADHD or that of family members. Such dealings may lead to conflict between parent carers and service providers, therefore having an impact on service delivery. A high percentage of parents and family members living with ADHD may be accessing mental health services for that of their own needs.</td>

<td>Could it be that by the time the ADHD child is a teenager they may feel that they are somehow different to their friends, but may not understand why? To the ADHD adolescent, they often think that there is some kind of secret code going on between others. This ever widening void is being caused by their inability to learn the code of social cues—those nuances of physical expression and movement that carry half of any conversation and convey personal attitude, varying emotions and defence (or lack of it) between other</td>
</tr>
</tbody>
</table>
The ADHD adolescent may have a two way body language problem involving interpreting others and giving the right signals in return. They may try and copy those around them, without being aware of the subtle complexities or of what is or is not socially acceptable.

‘Too many children fail to achieve their full potential and face involvement in crime, poor health, early unwanted pregnancies, substance misuse or under-achievement in education because services fail to spot the emerging risks or to intervene early enough to co-ordinate the support necessary. We know that factors such as poverty, failure at school, mental health, family problems or antisocial behaviour can each be possible indicators of future problems’. (Cross Cutting Review of Children at Risk for the 2002 Spending Review).

Adults with ADHD we have found may have a criminal record of some sort, this highly impacting on their accessing appropriate adult educational programmes, many with no educational qualifications, (under-achieving academically) poor record of school attendances or exclusions from education, all of which are contributing factors and play a major role in their employment or future employment status. Multi-agency working to include occupational therapists during transitional services would perhaps contribute towards meeting the needs of those with ADHD and working alongside future employers.

You might also mention the data showing ADHD patients to be at high risk for traffic citations and traffic accidents. You could also mention their increased health care utilization.

Many children accessing CAMHS or Paediatric services may do so until aged 16-17yrs. A high percentage of this group may not be referred onto the adult community mental health teams, therefore a child who has received a multi-agency as well as a medicinal approach to treatments for ADHD may well end up in that ‘grey area’ of their not accessing the appropriate health care and treatments could all be contributing factors to their possibly of their self-medicating on other substances.

First para after sub heading ‘Summary’, line 10 – is ‘appropriate’ correct?

<td>PR Stephen Faraone</td>
<td>1.4.5</td>
<td>The summary states: “There was no evidence to warrant a different diagnostic concept in childhood and in adulthood.” This seems a bit too strong. The DSM itself allows for a different diagnostic concept: 1) the category of in partial remission can be used for adults; 2) a subjective feeling of restlessness can be diagnostic of motor hyperactivity. Russ Barkley’s new book (and some of his prior work) suggests that the current ADHD symptoms are not developmentally sensitive and there have been some initiatives to re-write the ADHD rating scale (e.g., work by Spencer and Adler) so that the questions are more relevant to adults. Also, I think that the greater reduction of hyperactive-impulsive vs. inattentive symptoms is more strongly supported than you suggest. But these are all, for sure, debatable points. </tbody>
</table>
GDG speculate as to why rates of substance abuse is higher in those with ADHD symptoms (is this a ‘characteristic’ outcome?) stating “The mechanisms involved can include one or more of the following: first that individuals with ADHD may seek out highly stimulating or risky activities; second that individuals with ADHD are exposed to higher levels of psychosocial risks for development of substance use disorders, resulting from educational and social impairments, social exclusion and antisocial behaviour associated with ADHD. Third, that various substances, including cannabis, alcohol and stimulants can attenuate ADHD symptoms and are therefore sometimes used as a form of self-treatment.” Whilst it is unclear why the GDG felt the need to speculate (without evidential references) on this issue, narrow linear biomedical paradigms seems to have allowed them to overlook fairly basic scientific issues. The relationship between ADHD and substance misuse that they are referring to is an association, and thus a third (or more) factor may be responsible for both the substance misuse and ADHD symptoms (such as low self-esteem, family conflict, learning difficulties, co-morbid conditions etc.) making the required criteria of ‘characteristic’ difficult to establish.

|   |   | 1.4.6 | Is there consistent evidence of genetic, environmental or neurobiological risk factors associated with ADHD? The GDG concludes “Specific genetic variants that are associated with a small increase in the risk for ADHD have been identified in the dopamine D4 and close to the dopamine D5 receptor genes. Analysis of ADHD versus non-ADHD groups has identified consistent changes in brain function and performance on neurocognitive tests; however differences from controls are not universal, do not characterise all children and adults with a clinical diagnosis of ADHD, and do not usually establish causality in individual cases.” [my italics] The GDG were provided with several papers providing a critical evaluation of research in this area. None were cited in this document. The GDG after reviewing the evidence and mentioning that “The quality of the evidence included in this review was variable and lacked any ‘gold standard’” go on to recommend that ADHD is valid and to make a diagnosis the following criteria should be met: “Symptoms of ADHD (DSM-IV) or hyperkinetic disorder (ICD-10) should be sufficient to reach a formal |
|76|CC|Sami Timimi|Comment addressed, see section 5.8.1 ‘Physical environmental risks’. No specific references suggested. Comment addressed, see section 5.9. |
diagnosis in DSM-IV or ICD-10. ADHD should be considered in all age
groups (children, adolescents and adults), with symptom criteria adjusted for
age appropriate changes in behaviour. The level of impairment resulting
from symptoms of hyperactivity and or inattention should be at least
moderately clinically significant on the basis of interview and or direct
observation in multiple settings, and pervasive (occur in all important
settings) including social, familial educational and or occupational settings.”
This is essentially no different to current DSM-IV criteria and one wonders
what the point of this expensive, time consuming exercise was if this is the
best the GDG can come up with, particularly when the GDG provide little
guidance as to how a clinician is to interpret words like ‘moderately’, and
‘significant’. Given that the chair of the group is well publicised for believing
that ADHD is under-diagnosed in the UK, and that using DSM-IV criteria
gives prevalence rates of between 3-7%, this guideline is likely to result in an
increase of ADHD diagnosis. Given these potentially far reaching
implications for children and adults in this country and the tenuous
evidential support in the document, the basis for the GDG’s conclusions
must be questioned.
The GDG state that “It was recognised that defining psychiatric disorders is a
difficult process due to the overlapping nature of behavioural and
psychiatric syndromes, the complexity of the aetiological processes and the
lack of a ‘gold standard’ such as a biological test—in this regard ADHD is no
different from other common psychiatric disorders. Furthermore, in keeping
with other common behavioural disorders there is no clear distinction
between the clinical condition and the normal variation in the general
population”. The phrase ‘two wrongs don’t make a right’ came to mind on
reading this. A get out clause that because other psychiatric diagnoses are
problematic constructs (and there is a large literature that attests to this), it is
acceptable for a lowering of standards and evidential basis with which to
evaluate ADHD, is a circular argument to excuse poor science and
insufficient rigour.
The GDG state that “Furthermore, in keeping with other common
behavioural disorders there is no clear distinction between the clinical
condition and the normal variation in the general population (see Section
A3). This is comparable to normal variation for medical traits such as
hypertension and type II diabetes” Such a spurious analogy reveals the
extent to which the GDG have ignored one of the most important differences
between physical states and psychiatric ones – meaning. 120/80 BP means the same whether it is measured in New York or New Delhi and reflects a physical state (universalism). Further, the pathophysiological processes resulting from high Blood Pressure are known and independent of the meaning any culture ascribes to symptoms (essentialism). This is not the case for behavioural presentations such as ADHD, which has varying interpretations and meanings, just as beliefs about what is a ‘normal childhood’ and ‘normal child development’ varies enormously over time and between cultures. It is of concern that the GDG seems unaware of the diverse literature (from disciplines such as transcultural psychiatry and psychology, philosophy, anthropology, and sociology) criticising the inappropriate use of univeralist and essentialist models (drawn from the biomedical paradigm) in multicultural societies. This is considered a very basic error. Such an approach leads to institutional racism as it assumes that the beliefs and practices about children and childhood drawn from a narrow Western biomedical paradigm is the standard through which to judge those cultures who have differing beliefs and practices with regards their paradigms for understanding the nature of childhood, childhood problems and child care and rearing. This replicates the dynamics of colonialism and such attitudes being promoted for our institutional practices are simply unacceptable in modern multicultural Britain.

The most disappointing aspect of the document is the missed opportunity for a more erudite approach to the question of diagnosis. Given the poor quality of the document it is likely that the current GDG simply does not have the objectivity, knowledge, or sophistication to produce an evidence-based, ethical, and progressive review and set of guidelines that could help curtail bad practice, but more importantly provide guidelines that take practice beyond current simplistic paradigms to make it fit for the realities of multi-cultural 21st century Britain. Psychiatry has been increasingly grasping the complexity that comes from a territory that sits at the meeting point of many disciplines’ discourses. Medicine too has increasingly grasped these cross-disciplinary perspectives leading to growth of practices such as narrative medicine and values based medicine to try and encompass the subjective, cultural, social, political, economic and psychological influences on physical health and medical treatment. In this respect psychiatry should be providing a lead for the rest of medicine as we increasingly move away from redundant dualistic conceptualisations such as mind/body, nature/nurture, and
universal/relative and toward accepting multiplicity in a way that reflects the diverse nature of the client group we wish to assist. Engagement with these issues would lead to an ability to examine validity of ADHD from a number of angles, recognising that there are many different approaches to this question that reflect different values and aims. For example, in addition to scientific validity, there are considerations of pragmatics, utility, administrative, consistancy, relevance, coherence, precision, fecundity, epistemic, ethical, ontological, and so on. Using these multiple positions would enable greater transparency and openness to the novel and more flexible guidelines that have greater likelihood of enabling more appropriate engagement with the diverse issues clients with ADHD symptoms present with. It is clear to this author at least, that the current GDG is simply not up to that task.

81 PR Jonathan Leo 1.4.6 Comments on D4, D5, DAT1
Regarding your citation of specific genes involved in ADHD. The evidence is mixed at best. And furthermore any connection would only be an association not a cause. Regarding D4 (DRD4) you state there is strong evidence for an association but this is not representative of the scientific literature. According to Willcutt (who you cite earlier): “Similar to the results for DAT1, however, this result [DRD4] was not replicated in all samples and does not appear to be necessary or sufficient to cause ADHD. Moreover, the association with ADHD is much stronger in case-control comparisons than in family-based designs, suggesting that some significant results may be due to differences in gene frequencies in the populations from which the ADHD and comparison samples were drawn” (Faraone et al., 2001).
In a detailed 2006 survey of the evidence in support of DRD4, DAT1, and other candidate genes, Waldman and Gizer (p. 421) concluded, “It should be clear…that for each [ADHD] candidate genes studied, there is a mixed picture of positive and negative findings.” Or as Willcutt stated: “For 14 of the 27 candidate genes a significant association with ADHD has been reported in at least one study; however, virtually all of these results have been replicated inconsistently or await independent replication (Table 2).
Moreover, each of these genes appears to account for a relatively small proportion of the variance in ADHD symptoms (e.g., Faraone, Doyle, Mick, & Biederman, 2001), suggesting that none are likely to be necessary or sufficient to cause ADHD.” Or as Faraone has stated (2005, p. 1319) with regard to genome wide scans, “The handful of genome wide scans that have been performed so far are inconsistent and there is much debate about the evidence for a role for genetic factors in ADHD.”
References suggested:
- Pliszka (2006)
been conducted thus far show divergent findings and are, therefore, not conclusive.” Regarding your summary of the genetic studies it would be more straightforward to say, “At this point in time no genes for ADHD have yet been identified.”

In advertisements for ADHD the supposed genetic basis for ADHD is often used to justify medical treatment. However, left unsaid in these same advertisements, is that a presumed genetic defect is in no way a necessary prerequisite to prescribe stimulants. As of now, the medical community finds it entirely acceptable to prescribe medication for psychological stress brought on by environmental stressors. One needs to look no further than foster care programs which medicate an inordinate number of children. Presumably the common factor in these children is not their genetic makeup but their common environmental triggers. Although ADHD is considered a genetic defect, looking for a common gene in foster home children to explain their behaviour would seem to be a fruitless effort. Conversely, the results of a survey of environmental stressors in their lives would probably be very fruitful. The diagnosis and medication of children in foster homes is perhaps the best example of how, genes and biology aside, it is an acceptable practice to medicate children whose behaviour is explained by the environment.

“Although some people question the assumption of the equal environment assumption for identical and non-identical twins this does not impact on the question of validity since the high twin correlations observed in these studies indicates that ADHD symptoms are highly familial.”

This is a very confusing sentence as it mixes up “familial” with “genetic.” It appears to be written by someone who does not understand the genetic studies. The claim that high MZ concordance shows that ADHD is “familial” is erroneous. MZ concordance for speaking Italian is 100%, but does this mean speaking Italian is a genetic trait? The EEA does not just have an impact on estimates of genetic factors - if it is false then the twin method is deeply flawed.

“There is consistent evidence of familial influences on ADHD symptoms in the general population. Under the equal environment assumption these familial influences are thought to be largely genetic in origin.”
This is very problematic and should be reworded. The EEA pertains only to the twin method and not to family studies. In addition, the document does not provide any citations that the EEA, which is counter intuitive, is correct. The NICE document also makes the assumption that if it is genetic then it must be a disease. However, a host of other traits have also been investigated and these studies have determined that MZs have a higher concordance than DZs. For instance, twin studies have shown a heritability for loneliness (Boomsma et al. 2005), the frequency of orgasm in women (Daeved et al., 2005), the results of the United States 2004 presidential election (Alford et al., 2005), perfectionism (Tozzi et al., 2004), and breakfast eating patterns (Keski-Rahkonen et al., 2004) (Cited in Joseph 2008). In 1990, Bouchard stated: “For almost every behavioural trait so far investigated, from reaction time to religiosity an important fraction of the variation among people turns out to be associated with genetic variation. This fact need no longer be subject to debate.” Yet, if all our traits have a genetic basis then the genetic evidence of a trait does not automatically lead to “it’s a disease” declarations. What many ADHD researchers seem to be saying is, that by implicating genetics in the behavioural trait of attention, this is somehow evidence of a disease. If Bouchard is correct, and all our traits have a strong basis in genetics, then can individuals exhibiting extremes of other traits also fall into the diseased category? The slippery-slope analogy seems almost too obvious to mention here, and might seem trite, however this appears to be exactly the trap that the child psychiatry profession has fallen into regarding other conditions, for instance child-onset bipolar disorder. The NICE statement on ADHD should not be seen with blinders on, as their statements about what constitutes a “disease” will surely be revisited in the years ahead as they face other instances where traits can be classified as a disease in need of medication. NICE’s foray into ADHD is only the beginning.

1.4.6 Dickstein and colleagues completed a systematic meta-analysis of 16 neuroimaging studies that compared patterns of neuro activity in children and adults with ADHD and controls. The GDG’s position would be stronger if indeed there was a biological marker for ADHD, however to cite the Dickstein paper will be seen as a desperate grasp for evidence. Like much of the ADHD neuroimaging research, on the surface the Dickstein paper might appear to make the case that there is a visible organic pathology in the brains of children diagnosed with ADHD, however a more in-depth view of the
study reveals problems of experimental design that have plagued this entire body of research. The Dickstein paper is a meta-analysis of 16 ADHD imaging studies. Out of these sixteen studies, four were used for a comparison of ADHD non-medicated to controls – the most important comparison. Interestingly, Dickstein et al. do not mention that two out these four studies used the same ADHD subjects – the two studies were separate papers but came from the same research group. This is fairly obvious from reading the two studies, and was confirmed in an email to the lead author. E-mails to the corresponding author of the Dickstein paper asking for clarification have gone unanswered. Double counting subjects is problematic for a meta-analysis, especially since Dickstein et al. did not mention it in their paper. Furthermore, even in the Dickstein analysis for the most important comparison in the study which was the non-medicated ADHD to controls the majority of the differences were for the most part not significant. It seems highly problematic for the NICE review to not mention this in their review. Although positive findings on neuroimaging studies of psychiatric disorders, including ADHD, are usually given wide coverage in scientific publications and the mass media, the fact remains that this body of research has not provided support for a specific “biological basis” of ADHD. This is well noted by Baumeister and Hawkins (2001) who report, “inconsistencies among studies raise questions about the reliability of the findings” (p. 2). Writing, for instance, about the tendency for studies to find decreases in the size and activity of the frontal lobes, Baumeister and Hawkins summarize that: Even in this instance, however, the data are not compelling. The number of independent replications is small, and the validity of reported effects is compromised by a lack of statistical rigor. For example, several of the major functional imaging studies failed to employ standard statistical controls for multiple comparisons. This means that many of the reported findings are almost certainly spurious. Moreover, considering the likely existence of bias toward reporting and publishing positive results, the literature probably overestimates the occurrence of significant differences between subjects with ADHD and control subjects (p. 8, references omitted). In addition, virtually all researchers in this field acknowledge that no brain scan can currently detect anomalies in any given individual diagnosed with a primary mental disorder, nor can it help clinicians to confirm such a diagnose. For example, in his authoritative Handbook of Brain Imaging,
Bremmer (2005) states:
Unfortunately, we are not at a point where brain imaging can be used
routinely for the diagnosis of psychiatric conditions. ... We still do not
understand the patho-physiology or mechanisms of response to treatment
for most of these disorders... Most studies of psychiatric patients have found
that even when a particular finding characterized a patient group, there
remained as many as a third of patients who scored in the range of the
control subjects. (pp. 33-35).

Similarly, in the case of ADHD, Giedd et al. (2001) conclude unequivocally
that:
If a child has no symptoms of ADHD but a brain scan consistent with what is
found in groups of ADHD, treatment for ADHD is not indicated. Therefore,
at the time of this writing, clinical history remains the gold standard of
ADHD diagnosis. (p. 45).

The Dickstein paper was funded by NIMH. Of interest to the NICE
reviewers might be the 2003 paper by Sowell et al., also funded by NIMH.
The Sowell study, involving 27 ADHD and 46 normal control subjects,
reported that ADHD children had smaller frontal lobes compared to the
control subjects, but overall the ADHD subjects had more cortical grey
matter (Sowell, Thompson, Welcome, Henkenius, Toga, and Petersen 2003).
This study’s significance derives not necessarily from this result, but—as
with several previous ADHD neuroimaging studies—from important
comparisons that researchers could have made, but did not. One reason for
bringing this study to your attention is because of your own
acknowledgment in your previous reports about other conditions and
treatments (the SSRIs for instance) that seeing the published data is not the
same as seeing all the data, because the pharmaceutical companies do not
publish all their studies. The same holds true for research into basic science
topics, although in this case it is government funded organizations that will
not release data.

As in an earlier, similar paper by Castellanos et al. (2002), some of the ADHD
subjects in the Sowell study were apparently medication-naïve. I say
“apparently” because specific descriptions were not provided: “15 of the 27
patients were taking stimulant medication at the time of imaging” (p. 1705).
It is unclear how to categorize the remaining twelve patients. Did they have a
history of medication use prior to the start of the study, and then stop taking their medication for 48 hours, or some other arbitrary time period before imaging. It is surprising that a study published in *Lancet* could be so vague about one of the most important variables in the study. Conclusions based on a comparison of normal control subjects to medication-naive ADHD subjects would be very different than conclusions based on a comparison of control subjects to ADHD subjects with varying durations of medication exposure or undergoing abrupt withdrawal.

The issue becomes considerably more muddled and confusing due to a brief concluding discussion by Sowell et al. (2003) of the potential role of stimulant medication on their findings. The authors first appropriately acknowledged that, since 55% of their ADHD children were taking stimulants, “the effects of stimulant drugs could have confounded our findings of abnormal brain morphology in children with [ADHD]” (p. 1705). The simplest way to properly evaluate this confounding effect would have been to compare the 15 medicated ADHD children with the 12 unmedicated ADHD children. However, Sowell et al. chose to not make that comparison: “We did not directly compare brain morphology across groups of patients on and off drugs because the sample size was considerably compromised when taking lifetime history of stimulant drugs into account” (p.1705). The authors further explained that this comparison, between unmedicated and medicated, is not needed because a prior study by Castellanos et al. (2002) suggested that medications do not affect brain size.

Sowell et al.’s methodological choice, and its justification, is both unconvincing and puzzling. First, although one can sympathize with their judgement that “taking lifetime history of stimulant medication into account” compromised their sample size, this judgement ignores that for thirty years ADHD neuroimaging researchers have deemed it perfectly acceptable to compare ADHD subjects and normal controls regardless of medication history. Indeed, virtually all the studies that Sowell et al. cite to contextualize their own study and interpret their results exemplify this practice. Thus it is difficult to see why Sowell et al. would feel that they should not compare medicated and unmedicated ADHD subjects. Clearly, just as they acknowledged limitations to their main study results, Sowell et al. could have reported the results of the more specific comparison with an acknowledgement of the appropriate limitations. Second, Sowell et al. cite Castellanos et al. to support the methodological choice of not comparing...
medicated and unmedicated ADHD subjects. But, third and most important, Sowell et al.’s data appear directly relevant to either support or refute the conclusions that Castellanos et al. (2002) drew from their comparison. In fact, the results of the Castellanos et al.’s comparison of brain volumes of medicated and unmedicated ADHD children were deemed worthy of a major press release by the NIMH concerning stimulant drugs’ effects on developing brains, yet the same comparison in the Sowell et al. study was considered insignificant and not even reportable. Sowell et al. would not supply the information about the most important comparison in the study, and a subsequent Freedom of Information Act Request to NIMH to release the information was denied. This was in spite of the fact that on their own web site NIMH encourages their grant recipients to share data. One could say that NIMH’s actions speak louder than their words. Given their own interest in the subject, possibly the NICE reviewers could request the data?

In June 2006, the *American Journal of Psychiatry* published three articles (Pliszka et al., 2006; Smith, Taylor, Brammer, Toone, & Rubia, 2006; Tamm, Menon, & Reiss, 2006) and an accompanying editorial about functional magnetic resonance imaging (Casey & Durston, 2006). The three studies conducted scans of children’s brains during a specified task, and, importantly, all three studies had a group of medication-naïve ADHD children. However, when considered together, the three studies implicated an inordinate number of different brain regions, with little replication of the regions between studies. In brief, Smith et al. (2006) implicated the frontal, parietal, and temporal lobes, along with the striatum. Pliszka et al. (2006) implicated the anterior cingulate cortex and the left ventrolateral prefrontal cortex. Tamm et al. (2006) implicated the parietal lobes, the right precuneus, and the thalamus. One could almost ask: What area of the brain is not implicated?

The accompanying editorial by Casey and Durston (2006) acknowledges these disparate findings, yet instead of looking at them as problematic for the ADHD neuroimaging field, they attempt to place the disparate findings within a theoretical construct that cognitive deficits in ADHD are due to a deficit in inhibitory control. They state: “Identification of core processes involved in a disorder can move a field from a disparate set of data-driven findings to a more theoretically coherent collection of studies” (p. 957). Does Casey and Durston’s model provide a solid base for ADHD
researchers to move forward, or is their explanation of these “disparate findings” an attempt at salvaging a lack of reproducibility within the ADHD neuroimaging field? The model as proposed by Casey and Durston is that, “basic learning systems are important in signaling top-down systems to adjust behaviour when predicted outcomes are violated.” This appears to be little more than a very general statement about learning. As a general statement it is hard to argue with it, because it is so broad and all-encompassing that it makes room for almost every conceivable finding. But it does little to explain how upwards of 10-15% of the population has a disease. One test for whether a theory is too broad, is to ask: What empirical findings would negate the theory? Casey and Durston have not proposed any findings that would negate their theory, and, indeed, it is hard to imagine any that would negate it. For instance, in Figure 1 their article, Casey and Durston hypothesize the involvement of the prefrontal cortex, the basal ganglia, the parietal cortex, and the cerebellum in ADHD. Yet none of the three accompanying studies even suggested that the cerebellum was involved. Bringing the cerebellum into the picture without elaboration is also problematic because as Furman notes: “…of the five studies that examined total cerebellar volume, four are listed as showing an association of ADHD with decreased volume, while three do not.” And, missing from Casey and Durston’s schematic is the thalamus, which one study did implicate. Moreover, two of the studies were contradictory: Pliszka et al. found greater activity in ADHD subjects than controls in the inferior prefrontal cortex (p. 1059), while Smith et al. found less activity (underactivation) in the mesial and front-parietal-temporal brain regions during the go/no go and switch tasks for the ADHD children. Yet, interestingly, while the imaging data for the ADHD children differed in these two studies, there was no difference in performance on the specified tasks between the ADHD children and controls. None of these issues are raised by Casey and Durston, and we are unsure how they could be fitted into the proposed model.

Perhaps the most significant aspect of putting forth such a highly theoretical model of ADHD is that Casey and Durston are implicitly acknowledging that the more practical aspect of developing an imaging scan as a diagnostic tool is becoming more and more unlikely.

A recent study by Volkow et al. (2007) utilized PET and compared dopamine transporter levels in 20 never medicated adults to 25 controls, and found that
Dopamine transporter levels were not positively correlated with the disease. In the NICE document, to your credit, you have few positive statements about this research, but on the other hand you do not come right out and acknowledge this. For instance, Volkow, in much more direct terms than NICE, has commented: “...it should be noted that the imaging studies are still not definitive because of the discrepancies in the findings...” The necessary and definitive test to confirm the suggestion that ADHD children have a neuroanatomic pathology consists of using an appropriate brain scan to detect a difference between a “typical” unmedicated ADHD child as found in the classroom, and a “normal” child. There is virtual unanimity that this cannot be accomplished at present. Experiments with highly selective patient and control groups are, at best, only preliminary studies, and the findings of these studies must be called into question. Ruling out the effects of psychotropic medication is merely one of the tasks confronting researchers conducting neuroimaging research with ADHD patients. Even if the field accomplishes this task, however, several other important tasks remain. One of these will involve trying to make sense of findings of brain abnormalities or differences among some individuals diagnosed with ADHD. In October 2005, for example, the New York Times published an article by Benedict Carey entitled “Can Brain Scans See Depression?” It contained interviews with prominent psychiatrists and child psychiatrists, many of whom have authored ADHD imaging papers. The Times article was notable for both its candor and frank assessment of the psychiatric neuroimaging field: “Yet, for a variety of reasons, the hopes and claims for brain imaging in psychiatry have far outpaced the science, experts say.” And in the words of Paul Wolpe, a professor of psychiatry and sociology: “The thing for people to understand is that right now the only thing imaging can tell you is whether you have a brain tumor.” A recent imaging study found a difference between the brains of conservatives and liberals. Does this difference equate to a disease?

(sonuga barke), timing (Tannock, smith), non executive memory (Rhodes and Coghill) and as noted variability also contribute – and may actually prove to be more important than exec functions.

On the other hand the statement “Recently it has emerged that the strongest and most consistent association with ADHD is for intra-individual variability (Klein et al., 2006).” is way to strong as it relies on only one study. It would be possible to make a similar argument could be made for a range of different neuropsychological functions based on other comparative studies.

<td>Limitations. When discussing the effect of stimulants on people not diagnosed with ADHD, regarding the Rapoport study, you state, “there were limited published data on the effects of stimulants in people who do not have ADHD.” This is an incredible statement as it seems to be saying that we do not know the effect of stimulants on normal people? Underlying any discussion of ADHD, (except for possibly the NICE document) and what every neuroscience researcher is aware of, is the understanding that the most straightforward experiment in all of neuroscience is the one seeking to determine if stimulant medication works, at least if one defines ‘works’ as a short-term improvement in attention span. Whether the subjects are male or female, whether they are preschoolers or geriatrics, whether they are diagnosed with ADHD or not, and whether the medication is provided by a doctor or a friend, it has been known for 75 years that stimulants improve...</td>

</tbody>
</table>
anyone’s and everyone’s ability to pay attention. The GDG sidesteps the issue of the fact that the stimulants such as methylphenidate (Ritalin) have a universal effect by stating that they are going to discuss the treatment of ADHD in a subsequent document. (However, even this is problematic because the document brings up the Rapoport study at one point). Talking about treatment with stimulants in a future document is fine, but this does not justify, in the current document, while it might be convenient, ignoring the universal effect of the stimulants on the CNS – as this does relate to the disease concept Unfortunately much of press still falls back on so-called “paradoxical effect” that sees stimulants only effecting ADHD children. Rapoport’s study shows this is false. Coffee drinkers also know this is false. Apparently one of the few organizations to not acknowledged this fact is the GDG.

Also regarding the Rapoport study, you state, “The very small numbers used in this study and lack of further similar studies means that considerable caution must be taken in drawing firm conclusions.”

Again, your double standard is evident. The NICE review suggests “considerable caution” when drawing conclusions about a study looking at the effect of amphetamines on the normal brain. Yet, just one page before in the review, there seems to be no hesitation or “caution” in your interpretation of the genetic studies, which have not discovered any ADHD genes, or the imaging studies, which are unable to distinguish ADHD children from controls.

13 PR Margaret Alsop 1.6 It is felt that the evidence submitted by parents, carers and others caring for an individual diagnosed as having ADHD is clear evidence on the validity of ADHD. There seems to be clear indication that the evidence submitted by professionals and those within the GDG that echoes that of parents, carers and individuals themselves. No references suggested. Comment taken into consideration.

37 CC David Coghill 1.6 The comment that “In adults the profile of symptoms may alter with a relative persistence of inattentive symptoms compared to hyperactive-impulsive symptoms.” Does not really match up with the evidence described in section 1.4.5 where it is suggested that evidence for this is weak and that relative to controls levels of overactivity stay high. Here would be a good place to dispel this notion of a true reduction in overactivity problems as one of the ADHD myths. No references suggested. Comment taken into consideration.

38 CC David Coghill 1.6 “There was no evidence of a need to apply a different concept of ADHD to No references Comment addressed,
children and adults. However age-related changes in the presentation are recognised.”
Could be expanded to add
There was no evidence of a need to apply a different concept of ADHD to children and adults. However age-related changes in the presentation are recognised. These changes are not yet reflected within the various diagnostic criteria.

| 83 | PR | Jonathan Leo | 1.6 | Position Statement on the Validity of ADHD. “There is evidence of both genetic and environmental influences in the aetiology of ADHD. …Contemporary research suggests that environmental risks are likely to interact with genetic factors…” Why is that whenever environmental influences are brought up that you feel the need to drop genetics into the discussion? When you say “contemporary research suggests that environmental risks are likely to interact with genetic factors” what recent research are you referring to? You are making it sound like the ADHD genetic researchers have recently uncovered this startling fact. However, the fact that genes interact with the environment has been known for years. According to Robert Sapolsky, “Genes influence behaviour, the environment influences behaviour, and genes and environment interact – this view is one of the great scientific clichés of the 20th century.” Commenting on the usefulness of the “vulnerability - stress theory of mental disorders” that any potential harmful environmental influences only operate on those with faulty genes, Mary Boyle points out that the theory is an important mechanism for managing the potential threat posed to biological psychiatrists whenever non-biological conditions are implicated in the etiology of psychological stress:

The usefulness of the hypothesis lies partly in its lack of specificity - since the nature of the claimed vulnerability has never been discovered, anything can count as an instance of it. Its usefulness also lies in its seeming reasonableness (who could deny that biological and psychological or social factors interact?) and its inclusiveness (it encompasses both the biological and social - surely better than focusing on only one?) while at the same time it firmly maintains the primacy of biology, not least through word order, and potentially de-emphasizes the environment by making it look as if the

see section 5.12.
"stress" part of the vulnerability-stress model consists of ordinary stresses which most of us would cope with, but which overwhelm only "vulnerable" people. We are thus excused from examining too closely either the events themselves or their meaning to the "vulnerable" person (Boyle, 2002).

Your document seems to be the perfect example of what Boyle is referring to. You maintain the primacy of biology with your wording, but as Boyle points out, the driving force behind your wording is not "contemporary research," that has discovered an ADHD gene, but is the contrast between the genetic studies, that have failed to find a specific ADHD gene or even a gene of modest effect, and studies implicating environmental factors. If you had discovered a gene, then you would not be talking about the vulnerability-stress hypothesis. Again, take the example of foster care homes where an inordinate number of children are diagnosed with ADHD (and other conditions). Clearly this data points to environmental influences on ADHD – no matter what genes a child is born with.

As the data from Nicky Hart shows, there appears to be a strong role for socioeconomic stratat. If we follow your logic, then the increased prevalence of children with smaller brains and less electrical activity (according to the current concept of ADHD) in the lower socioeconomic strata must be qualified with the statement that, their smaller brains are due to faulty genes being influenced by the environment.

88 PR Jonathan Leo 1.6 Position Statement on Validity of ADHD. “ADHD is distinguished from the normal range partly by the number and severity of symptoms and partly by the association with significant levels of impairment.”

Your statement points out why the diagnosis varies so much from one country to another, from one doctor’s practice to another, from one school to another, and from one household to another. Take the 2004 guidelines on the diagnosis of ADHD from the American Academy of Pediatricians. Take item #2 on their questionnaire as an example:

2) Six (or more) of the following symptoms of hyperactivity-impulsivity have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

- Hyperactivity
  - a) Often fidgets with hands or feet or squirms in seat
b) Often leaves seat in classroom or in other situations in which remaining seated is expected

c) Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)

d) Often has difficulty playing or engaging in leisure activities quietly

e) Is often “on the go” or often acts as if “driven by a motor”

f) Often talks excessively

Note that every item on the list uses the term “often,” a very unscientific term. How does one quantify “often.” Since “often” is in the eye of the beholder and can vary from one doctor’s office to the next it is easy to see how this document has little teeth to it. Apparently as long as one adult decides that the child “often” fidgets, then the child can be labelled and medicated. It is easy to see how a parent who does not get a diagnosis from one doctor can simply go to another doctor with different ideas about what “often” means. As an example of how the general public sees through a document like this take this example provided by the late Kevin McCready (2002):

In an episode of “The Sopranos,” the popular and critically acclaimed HBO series about a New Jersey mobster and his family, the primary character, Tony Soprano, is called into a meeting with school officials, including the school psychologist. Tony is told that his son has been determined to “have” ADHD. He asks how this has been determined and is told there is a set of criteria, which the psychologist then begins to itemize. The third criterion on the list is “tends to fidget.” The poorly educated, psychologically unsophisticated, working class gangster looks at directly at the psychologist….and asks simply in his earthy “jersey” accent: “What constitutes a fidget?” There may be little to admire about a man who makes his living illegally, but at least he ‘gets it.”

It is easy to see how guidelines that use the word “often” mean very little. Is NICE going to develop more stringent guidelines?

<p>| 39 | CC | David Coghll | 1.7.1 | The term “medical treatment” should be replaced by “pharmacological treatment” or “drug treatment” | No references suggested. | Comment addressed, see section 5.12. |</p>

The current GDG believes that children with ADHD have an organic brain deficiency, resulting from a genetic defect that in the future, once the technology is available, will be detected by a brain scan. However nowhere in the document has NICE answered the controversial question of: How many children have this defect? The obvious problem being that as the percentage of children taking Ritalin escalates, the harder it is to make the case that they have a disease. If, as in some school districts, upwards of 17% of the boys are prescribed Ritalin, this would suggest that the boundaries for normalcy have become narrower. As often happens after statistics documenting the increasing use of stimulants for younger and younger children make the headlines, many of the opinion leaders in the psychiatry community state that there is a problem with “over-prescribing” or “misdiagnosis,” yet none of these leaders, or any of the major psychiatric organizations, have issued guidelines on how to identify this large group of “misdiagnosed” children, nor have they clarified what they consider to be improper uses of prescribed stimulant medication (Johnson, 2006; Nakamura, 2002). No matter where NICE draws the line between normal and ADHD, whether it classifies 2%, 5% or 7% as having the disease, there will, by definition, be children who are inappropriately taking stimulant medication. Based on what criteria will NICE decide who these children misdiagnosed children are? For instance, if according to NICE 7% of British children have ADHD then what if 10% are taking medication? How will doctors identify the 3% of misdiagnosed children?

The dilemma for medical professionals who want to go beyond simply talking about misdiagnosed children and to actually identifying these children is that, without an objective biological marker demarcating the line between the “correctly” and “incorrectly” diagnosed, the sole criterion for determining the appropriateness of stimulant treatment comes down to: Are the adults in the child’s life satisfied with the medication’s effect? Presumably there are not many parents unhappy with the medication’s effects, who still continue to medicate their children. None of the medical professionals who talk about misdiagnosis have ever elaborated on how they plan to tell all these parents of misdiagnosed children that they should not be medicating their children, even though the medication is doing exactly what...
the medical community says it should be doing. As an example of the forces at work in the diagnosis of an individual child with ADHD, take a case study in the journal, *Pediatrics*. In 1999, the editors elicited commentaries from several prominent physicians about the case of a teenage boy who had been taking Ritalin for several years. The editors saw the boy’s scenario as an interesting case, worthy of commentary from a group of prominent child psychiatrists. But in an ironic twist of fate, they have unintentionally provided a much more interesting case study. From a sociological point of view the subject of the case was not the boy, but, instead, was the doctors and the editors. The case provides an excellent example of: 1) how a major determination in the diagnosis of ADHD is adult satisfaction, 2) how the medical community fully supports the use of stimulant medication as a performance enhancing drug, 3) how the same mindset that approves of using one psychotropic drug easily leads to the use of multiple medications, and 4) how the main stream medical journals have given little attention to the ethical implications of controlling and altering children to meet the demands of our contemporary educational/cultural system.

The 15-year old boy announced to his parents and his pediatrician that he wanted to stop taking his medication: “I don’t need it…I’m fine…I don’t see why I should take it.” He purposefully did not take the medication for a few weeks and he said he could not tell the difference…. However, his parents observed that his test results, when off the medication, were below his standard scores…. They also noted that he was more distractible and less attentive when doing his homework during that time (Cohen & Leo, 2002).

As stated by the physicians, the most important variable in determining whether this boy should keep taking his medication was the parental satisfaction with the medication, and the subsequent commentaries all focused on how to convince the boy to continue taking his medication. The boy’s wishes were not something to be listened to, but rather something to be managed, whether through dialogue or with another medication. As an example of polypharmaceuticals for children one of the commentators even suggested that the boy’s reluctance to keep taking his Ritalin suggested this was a sign that he needed another medication. Thus the boy, who wants to go off his one medication, would instead get two medications. None of the
commentators in the *Pediatrics* article contemplated that the boy’s wishes might be legitimate, but more importantly, as a sign of how one sided the issue has become in the medical community, the editors did not give space to a single commentator who questioned the ethics of giving a medication to improve grades.

As an example of who the experts in America are diagnosing with ADHD take this example from the Department of Psychiatry at New York University: “Sarah chooses to sit in the back of the classroom and much of the time she’s doodling in her notebook or staring out of the window. She seldom completes assignments and often forgets to bring the right book to class. Her desk is a mess and she generally can’t find what she is looking for. Then she gets weepy and says that nobody understands her.” This fourteen-year old girl is crying out “Please Understand Me.” The New York University experts’ response is to label her with ADHD. Medication will surely follow. Examples like this and the others I have cited, which come from those who strongly believe that ADHD is biological, are just more examples of how little science is involved in the ADHD diagnosis.

---

86 PR Jonathan Leo 1.7.1 “The GDG wish to stress that the role of important genetic influences does not exclude an important role for environmental influences since individual differences in genetic risk factors are likely to alter the sensitivity of an individual to environmental risks” This is confusing because earlier in the document the only environmental influences that you mentioned were prenatal exposure to drugs such as nicotine. What environmental influences are you referring to here? “Furthermore, the extent to which there are genetic influences has no direct bearing on the choice of treatment approaches since both medical and psychosocial interventions could be important in improving treatment outcomes.” Let's be honest here, the idea that ADHD is due to genetics is one of the most common reasons cited by the pharmaceutical companies and the psychiatric profession as evidence that ADHD is a biological disease – like diabetes. And diseases are treated with medications. Your statement is is even going against much of modern day psychiatry. According to Nancy Andreasen, in *The Broken Brain*, the biological model of mental illness can be summed up as follows: “1) The major psychiatric illnesses are diseases, 2) These diseases are caused principally by biological factors and most of these reside in the brain[,] and 4) The treatment of these diseases emphasizes the use of somatic therapies.” As another example of this type of thinking, take the recent comments by

Stephen Faraone in *Science*. In a discussion of “ADHD genes” he stated: “My hope is that once we’ve discovered those genes, we’ll be able to do a prospective study of kids at high versus low genetic risk. That’s when you’ll see environmental factors at work.” But certainly one can still see environmental factors at work in children without knowing their genotype. Yet, even more confusing is Faraone’s next comment. According to the reporter, “Eventually, he (Faraone) adds, environmental changes could play an important role in treating some ADHD patients” (Brown, 2003, p. 160). Eventually? Why do we need to wait? Why not implement the changes right now? Changing the environment is exactly what many people opposed to stimulants have been saying for years. Faraone’s take on the etiology of ADHD is strikingly similar to Thom Hartman’s view. Both believe that ADHD is a biological, hereditary trait (Hartmann, 1996). Where they differ is that Faraone, and other biological psychiatrists, see these children as dysfunctional, with a genetic defect in need of medication. The other group sees the children as having different genes, at one end of the spectrum, and that what is needed is a different environment (Hartmann, 1996). One purpose of the genetic studies, which the pharmaceutical companies, and the psychiatry profession, have propagated, is to imply that it’s genetic that drugs are needed. For instance, Faraone states: “Many parents are reluctant for their children to take psychotropic medication and others find it difficult to maintain the prescribed regimes. These problems are mitigated by discussing the genetic etiology of ADHD…” (Faraone, 1996, p. 598). If you are going to acknowledge that knowing about genetics has nothing to do with treatment than you should be ready to answer the general public and politicians when they ask: Then why are you doing this research? If knowing about genetics has no benefit to the patient, then one possibility for this line of research is to justify current practices. If ADHD does not have a strong genetic influence then giving a medication would be seen as very problematic, and would call into question the entire practice of medicating children with stimulants. If I were you I would delete this line about genetics and treatment.

You state “The quality of the evidence included in this review was variable and lacked any ‘gold standard’ because no diagnostic tests for ADHD have been developed or tested.” I suggest you be clear what you mean by “gold standard.” I think you mean a laboratory test of some sort. Although I’m probably in the minority, I think that the DSM-IV diagnosis of ADHD as No reference suggested. Comment addressed, see section 5.3.
made by a competent health professional is a pretty good gold standard inasmuch as it is reproducible with high reliability and has clinical implications. The inter-rater reliability of the ADHD diagnosis is not much worse than, for example, many accepted “gold standard” diagnoses made by radiologists.

89 | PR | Jonathan Leo | 1.8 | Evidence Summary
---|---|---|---
In your summary, after 22 pages of discussion about the evidence, you do not cite any direct evidence that ADHD results from a biological, hereditary defect. However you do not come right out and acknowledge this lack of evidence. The 1998 National Institutes of Health conference was much more direct when it said, “there are no data to indicate that ADHD is due to a brain malfunction.”

87 | PR | Jonathan Leo | 1.9 | “ADHD should be considered in all age groups (children adolescents, and adults), with symptom criteria adjusted for age appropriate changes in behaviour.” And also in 1.6, “There was no evidence of a need to apply a different concept of ADHD to children and adults.” There is an important point to be mentioned here that the NICE document ignores. Allowing adults, who can make their own decisions, to take stimulants is one matter, however it is an entirely separate matter when it comes to children. The ethical questions surrounding the use of Ritalin are becoming more significant as once-medicated children are now reaching adulthood.
According to a recent survey in the *LA Times*, a significant number of these adults are deciding to discontinue their medication (Healy, 2006b). The *Times* article quotes a 27-year old girl who reflects back on the years she was medicated, “It was kind of weirdly amazing….You get excited about monotonous work, honestly. Like, translating Spanish becomes totally fun... The thing is, it works. But why are we forcing people to be in that position that they should like something that they wouldn’t ordinarily” (Healy, 2006a). In just three short sentences this 27-year old girl goes right to the heart of the ethical dilemma of stimulant medication: Is it right to medicate people so that they do well in school. How is it that a lay person can go right to the heart of the issue while a committee of physicians with years of training can produce a document that ignores this key point? Why are questions like this not raised by academicians in medical journals, or by the GDG?

40 | CC | David Coghill | 1.9.1.1 | I felt that these were rather weakly described and a bit “fluffy” for want of a No references Comment addressed,
better word. It is really saying you should use the diagnostic criteria, you should actually count the symptoms you should be clear about impairment and you should consider ADHD diagnosis in all ages. I think it just needs some rewording to make it snappier. Also it could benefit from starting off with a very clear and strong statement saying that the diagnostic categories of ADHD and hyperkinetic disorder are considered valid and should be used. This is a very important message to clinicians, the public, the government (the press) etc.

1. CC Edmund Sonuga-Barke General This seems a very accurate and sensible document.

No references suggested. Comment taken into consideration.

2. CC Russell Schachar General I read the document with great interest and think that it is a solid contribution to the ongoing debate about ADHD/HKD. Given that the document is based on a review of reviews, it is not altogether easy to judge how the summary statements were reached, but they look appropriate.

No references suggested. Comment taken into consideration.

3. CC Geoff Kewley General I felt the review was a reasonable summary of discussion and have nothing else to add.

No references suggested. Comment taken into consideration.

4. PR Margaret Alsop General We are concerned with processes preceding and following diagnosis rather than diagnosis. The concept of ADHD is multi-faceted, therefore no individual discipline is likely to be competent to identify, assess and intervene alone. As such diagnosis becomes mechanical feature in a holistic process involving a range of professionals. A child psychiatrist or paediatrician should normally make the formal diagnosis. However, a diagnosis should only be considered valid if it is made on the basis of evidence that a particular agency is pertinent, that agency should be involved as appropriate. Medical practitioners also have a significant role to play in diagnosis and assessment in order to rule out physical factors which may lead to the symptoms similar to those of ADHD.

No references suggested. Comment addressed, see section 5.15.

5. PR Margaret Alsop General If these guidelines are intended to be accessible to professionals and parents from a range of disciplines who might first identify, or have concerns about, problems that may or may not result in an ADHD diagnosis. Their first efforts are likely to be of a broadly psychosocial nature (i.e. References suggested: Cooper (1997) Asked reviewer for full Comment taken into consideration.
behavioural/cognitive and educational interventions). Currently different professionals use different terminology to describe the phenomenon of ADHD (e.g. hyperkinetic disorder, behavioural problems). The use of different terms is not helpful to professionals, children, young people, adults or their families: therefore an attempt should be made in this document to be consistent in the use of terms that have been selected for their clarity and acceptability to a wide range of professionals. There are significant differences, sometimes of an ideological nature between different professional groups (Cooper, 1997; Hughes, 1999; Maras & Redmayne 1997). These differences can be exaggerated through training and practice and are often reflected in different professional perceptions and views of ADHD. Differences can sometimes result in confusion, misunderstandings and conflict and may have an adverse influence on the effectiveness of multi-disciplinary/agency working. However, there is also much common ground among professionals, especially in terms of sought after outcomes of intervention. ADHD by its very nature demands a multi-agency response, and provide an opportunity for medical, educational, psychological, social care and other professionals to work together.

6 PR Margaret Alsop General

We note that there is no reference made in relation to Transition between CAMHS into the Adult CMHT. There is clear evidence to indicate that a high percentage of those diagnosed as ADHD within childhood will not have any appropriate transitional plan in place, therefore it is important that an appropriate multi-agency response for transitional arrangements are identified.

(Social Exclusion Unit—Transitions Young Adults with Complex Needs)

12 PR Margaret Alsop General

The following statistics provides an overview of the numbers of children facing particular risk factors out of a total population of children in England of 12 million:

A In 2000, 2.7 million children lived in low
B Up to 75,000 children may be missing from school rolls
C Around 10 per cent of children aged 5 to 15 have a mental disorder of sufficient severity to cause them distress or to have considerable effect on the way they live and 20 per cent of children suffer from mental health problems
D 1 in 9 children run away from home for at least a night
E 1 in 10 families in England and Wales report incidences of domestic

No references suggested. Comment addressed, see NICE guideline 'Transition to adult services'.
violence in a year
F In 2000 there were 91,400 conceptions to girls aged under 20
G At the end of September 2001 there were approximately 5,400 households
with children in Bed and Breakfast accommodation
H There are approximately 300,000 children with disabilities in England,
110,000 of these are severely disabled.
I 26,800 Children and young people are on the child protection register
J 58,900 Children and young people are in public care
K 11,000 Young people aged 15-20 are in young offenders institutions.
Our concerns being, how many of these include those with ADHD or
possible ADHD?
*Figures released by the Children’s and Young Persons Unit on 6th September 2002. www.cypu.gov.uk*

| 14 | PR | Margaret Alsop | General | That the assessment, diagnosis and treatment for ADHD should be delivered
throughout the Lifespan, services delivery should be multi-agency, multi-
model and incorporate professionals from many services such as: Health,
Education, Social Care, Behaviour Support, Parenting Programmes, Adult
Community Mental Health, Community Care, Prison Health Care providers,
Housing, Employment agencies and those within the Criminal Justice
System. Our belief is that the term EBD (Emotional and Behavioural
Difficulties) should not be used in relation to service delivery for those
already diagnosed as having ADHD. Within many services the term used for
those with ADHD is described as having EBD, therefore access to a full
multi-agency approach may not be forthcoming. We understand that this
request may be out of the remit of the GDG and NICE but would still
therefore like to request it for inclusion and consideration. | No references suggested. | Comment taken into consideration. |

| 15 | PR | Margaret Alsop | General | Not being qualified nor trained in medicine, I do not consider it appropriate
for contributions from non – medically trained individuals to be included. I
can only go on experiences as a parent carer of a young adult (25yrs) his
having been un-medicatied for the first 14 years of his life and as to how
medications have now turned his life around and made him feel totally
inclusive to society and not another statistic within our penal system or
another fatality of drug abuse/overdose. | No references suggested. | Comment taken into consideration. |

| 16 | PR | Margaret Alsop | General | It is felt that the assessments for ADHD in children should be conducted
through a ‘Core diagnostic’ team, this way it is multi-agency, multi-model
and will rule out/include any other underlying difficulties such as ASD, LD, | No references suggested. | Comment addressed, see section 5.15. |
Dyslexia, etc, etc. During my own experiences, those diagnosed ADHD as children have received a dual diagnosis of ADHD and ASD in later adolescence or adulthood.

Diagnostic Criteria beyond the unexplained “ensure that a transparent, structured approach was taken” nor is it evident whether any other systematic approach or framework was considered. However, even with these criteria, the interpretation of the GDG that the evidence they present is sufficient to support the validity of ADHD using these criteria is open to question:

77 CC Sami Timimi General There is clear evidence in the document that the GDG has displayed unacceptable bias in its preferred paradigm for analysing the literature, in its selection of literature and in its interpretation of the literature they selected. The fact that most of the academic members of the GDG have previously published papers with the chair of the group and that the group does not include any members with a more critical stance, strengthens the impression that the levels of bias result from conflicts of interest that are seriously unethical. The conclusions are thus not valid and could lead to serious deficiencies in practice and provide poor protection for patients, possibly exposing many more children to significant harm. The document should not be accepted. The GDG should be dismantled, a new chair appointed and a new GDG convened with a more equitable balance of opinion reflected in its membership.

79 PR Jonathan Leo General Take a trait – any trait, either physical or behavioural. Given normal biological variability, if the trait is measured and subsequently plotted on a graph there will be a spectrum. Some are tall and some are short, some have long legs and some have short legs, or some have a longer attention span than others. Variability of a trait is not proof of a disease. Take a drug’s effect. There are certain drugs that have an effect on human traits. Alli, a new diet drug, will help people lose weight – no matter what their weight to begin with. There are also drugs that have an effect on an individual’s behaviour, no matter what their behaviour to begin with. Take the stimulants, for example: Response to a drug with a universal effect, like the stimulants, is not proof of a disease. (See the GDG comments page 17 section 1.5 limitations). These are the two most common reasons cited as evidence for a biological basis of ADHD. The dilemma for NICE is to go beyond this. As it is stands now, NICE’s conclusion that the ADHD diagnosis is valid is primarily based on the flawed premise that variability of a trait is proof of a disease. Even your own “Evidence Summary,” basically says it is a trait, which in your opinion should be called a disease, at one end

of the spectrum. In the summary you do not (or cannot) cite a single scientific study or even an area of study confirming that ADHD is primarily a problem of biology.

If traits can be called diseases then where does this stop? A recent Op-Ed article in the New York Times addresses the problem of pathologizing traits:

It may seem baffling, even bizarre, that ordinary shyness could assume the dimension of a mental disease. But if a youngster is reserved, the odds are high that a psychiatrist will diagnose social anxiety disorder and recommend treatment. How much credence should we give the diagnosis? Shyness is so common among American children that 42 percent exhibit it. And, according to one major study, the trait increases with age. By the time they reach college, up to 51 percent of men and 43 percent of women describe themselves as shy or introverted. Among graduate students, half of men and 48 percent of women do. Psychiatrists say that at least one in eight of these people needs medical attention (Lane, September 23, 2007).

In the future will NICE have a committee deciding if “Is Shyness a valid diagnosis?” According to the logic of the current document that identifying a trait is somehow proof of a disease the answer would appear to be “Yes.”

90  PR  Jonathan Leo  General  Conclusion: The NICE document provides no new insight into the diagnosis of ADHD. It has systematically ignored one side of the debate and has simply summarized the views of those involved with the ongoing medication of children. The flaws are neither subtle nor minor, nor can they be rectified with editing. The entire approach of the panel is flawed. I am not privy to the makeup of the panel but it appears that the panel had no members with a broad societal view of the ADHD diagnosis – if it did, then they were ignored. In all your discussions you seem to have one standard for biology and one for the environment. Marginal imaging studies, that compared medicated ADHD children to controls, and genetic studies, which have not found an ADHD gene, are given credence, while you cannot even cite a study linking the environment to ADHD. The other side of the debate, that variability of a trait, and the universal effect of stimulants, are not good evidence for justifying the belief that, upwards of 10% to 15% to of the world’s children have an organic brain defect, is simply not presented. Likewise the ethics surrounding the diagnosis are ignored in the NICE document. If the NICE statement on ADHD is approved no one should be surprised when five years from now more British children are admitted to medication.

being prescribed stimulants. In no way should the current NICE document be considered a fair and all encompassing view of the ADHD phenomena. On the surface, it is a document couched in the language of science, but when one looks deeper at the scientific studies there is little evidence to support the disease concept of ADHD.
