

# Breast cancer (early and locally advanced): diagnosis and treatment

## Evidence Review

February 2009

Developed for NICE by the National Collaborating Centre for Cancer

©2009 National Collaborating Centre for Cancer

This guideline was partially updated in July 2018. The sections that are no longer current are marked as 'Updated 2018' and grey shaded. Please see <https://www.nice.org.uk/guidance/ng101> for the updated evidence reviews.

## Table Of Contents

<b>Chapter 2 – Initial assessment, investigation and staging</b> .....	<b>4</b>
2.1 What is the role of breast magnetic resonance imaging (MRI) in the pre-operative staging of patients with biopsy proven ductal carcinoma in situ (DCIS) or invasive breast cancer? .....	4
2.2 What is the role of pre-treatment ultrasound assessment in staging the axilla?..	77
2.3 What are the effective strategies to manage psychological distress in patients with early stage breast cancer? .....	132
<b>Chapter 3 – Operable breast cancer</b> .....	<b>206</b>
3.1 What is the optimal tumour-free tissue margin to achieve in patients who undergo wide local excision for (DCIS)? .....	206
3.2 What is the role of mastectomy in patients with localised Pagets disease of the nipple?.....	256
3.3 In patients with invasive breast cancer or DCIS when is sentinel lymph node biopsy justified as a staging procedure? .....	308
3.4 What are the indications for completion axillary clearance when the axilla has been found by biopsy to contain metastasis?.....	497
3.5 What is the prognostic significance of small metastatic deposits in sentinel nodes?.....	548
3.6 When is it appropriate to perform immediate breast reconstructive surgery? ....	599
<b>Chapter 4 – Post-operative and adjuvant therapy planning</b> .....	<b>686</b>
4.1 Does progesterone receptor status add further, useful information to that of oestrogen receptor status in patients with invasive breast cancer?.....	686
4.2 What are the indications for adjuvant chemotherapy in patients with early invasive breast cancer? .....	700
4.3 What is the optimal time interval from completion of definitive surgery to commencement of adjuvant therapy?.....	711
<b>Chapter 5 – Adjuvant systemic therapy</b> .....	<b>769</b>
5.1 In premenopausal patients with breast cancer, what are the benefits of adjuvant ovarian suppression/ablation?.....	769
5.2.1 What is the role of aromatase inhibitors (AIs) as adjuvant therapy in post-menopausal women with hormone receptor positive breast cancer?.....	836
5.2.2 Which subgroups of post menopausal breast cancer patients should receive Aromatase Inhibitors as adjuvant therapy?.....	836
5.3 Is there an indication for the use of tamoxifen after excision of pure DCIS? .....	964
5.4.1 Update of NICE Technology Appraisal 109 – Docetaxel for the Adjuvant Treatment of Early Node-Positive Breast Cancer.....	996
5.4.2 Update of NICE Technology Appraisal 108 – Paclitaxel for the Adjuvant Treatment of Early-Positive Breast Cancer.....	996
5.5 Update of Technology Appraisal 107 – Trastuzumab for the Adjuvant Treatment of Early Stage HER2- Positive Breast Cancer.....	1044
5.6 What are the indication for the measurement of bone mineral density in patients with invasive breast cancer who are on adjuvant hormonal therapy? .....	1118
5.7 What are the indications for the use of bisphosphonates in patients with early breast cancer? .....	1123
<b>Chapter 6 – Adjuvant radiotherapy</b> .....	<b>1166</b>

6.1 What are the indications for radiotherapy after breast conserving surgery? ....	1166
6.2 When should patients with DCIS who have undergone complete excision or wide local excision (WLE) be given radiotherapy?.....	1228
6.3 Which groups of patients should receive chest wall radiotherapy after mastectomy?.....	1294
6.4 What is the most effective radiotherapy dose fractionation regimen for patients receiving external beam radiotherapy after surgical excision of the breast?.....	1347
6.5 What are the indications for an external beam radiotherapy boost to the..... site of local excision after breast conserving surgery?.....	1423
6.6 What are the indications for radiotherapy to the supraclavicular fossa, internal mammary chain and axilla?.....	1484
<b>Chapter 7 – Primary systemic therapy .....</b>	<b>1565</b>
7.1 What is the role of primary medical treatment in patients with early, invasive breast cancer? .....	1565
7.2 For patients with inflammatory or locally advanced breast cancer who are treated with primary cytotoxic chemotherapy, what is the role of surgery and/or radiotherapy? .....	1636
<b>Chapter 8 - Complications of local treatment, menopausal symptoms and psychological support .....</b>	<b>1710</b>
8.1 What strategies are effective in preventing lymphoedema in patients with breast cancer? .....	1710
8.2 What strategies are effective in reducing arm and shoulder mobility problems after breast cancer surgery?.....	1772
8.3 What treatments are effective and safe for use to treat patients with menopausal symptoms and invasive breast cancer or DCIS? .....	1828
<b>Chapter 9 – Follow-up .....</b>	<b>1906</b>
9.1 What is the role of breast imaging modalities in the follow-up of patients with invasive breast cancer and in patients with DCIS?.....	1906
9.2 What is the role of follow-up in patients who have been treated for breast cancer? .....	1969
<b>APPENDIX A – Search strategies .....</b>	<b>2009</b>
<b>APPENDIX B - Economic Plan .....</b>	<b>2073</b>

## Chapter 2 – Initial assessment, investigation and staging

### **2.1 What is the role of breast magnetic resonance imaging (MRI) in the pre-operative staging of patients with biopsy proven ductal carcinoma in situ (DCIS) or invasive breast cancer?**

#### **Short Summary**

##### *MRI for detecting DCIS*

Outcome data was identified from two case control studies and four case series, with a relatively high degree of consistency in results. However, data need to be interpreted with caution because of the limitations of the studies, low evidence levels and small sample sizes.

There is good evidence from retrospective case control studies that MRI can complement mammography in guiding surgical treatment of DCIS by providing better assessment to the extent of the lesion. 26/30 (86.7% sensitivity) lesions were detected by MRI as well as 8 lesions without mammographically detected microcalcification. In 7/30 cases MRI showed tumour extent accurately compared with mammography, and the combined diagnosis improved the accuracy of evaluating tumour extent. (Shiraishi, 2003).

The sensitivity of MRI for detecting DCIS is lower than that achieved for invasive breast cancer. However, contrast enhanced MRI can show foci of DCIS that are mammographically occult. The MRI technique is of complementary value for a better description of tumour size and detection of additional malignant lesions (Francescutti, 2002).

There is some evidence from case series that MRI is significantly more sensitive than mammography in DCIS detection. In women with known or suspected DCIS, MRI may have an important role in assessing the extent of disease in the breast (Menell, 2005).

##### *MRI for detecting invasive breast cancer*

The outcome data was identified from one systematic review, nine case control studies and 11 case series, with a relatively high degree of consistency in results.

Data need to be interpreted with caution because of the limitations of the studies, low evidence levels and small sample sizes.

Studies consistently demonstrate moderate to high sensitivity (75-100%) and specificity (82-100%) for breast MRI in detecting multicentric tumour foci in fibroglandular or dense breasts (Blue Cross/Blue Shield-TEC Review, 2004 and Del *et al.* 2007). MRI will detect additional mammogram-occult foci greater than 2 cm from the index cancer in approximately 10% of women. These additional foci are similar to those detected by mammography and are therefore likely to be associated with an increased risk of local recurrence for breast conserving surgery (Schnall *et al.* 2005). In patients eligible for breast conserving surgery, MRI is more accurate than conventional imaging in the assessment of tumour extent in one out of four patients (23%) and had a significantly higher yield than mammography of confirmed invasive lobular cancers (Deurloo *et al.* 2006).

Patients who are likely to benefit from MRI are those with dense breasts on mammography, lobular carcinoma and occult primary tumour. In non-fatty breasts ultrasound and MRI were more sensitive than mammography for invasive cancer, but both MRI and ultrasound involved a risk of overestimation of tumour extent. Contrast enhanced MRI has the lowest false-negative rate in detecting invasive lobular carcinoma and has the highest accuracy in measuring the size of the invasive lobular carcinoma (Boetes *et al.* 2004). MRI has been shown to detect occult invasive breast cancers with the sensitivity of 97%-100%. However, intraductal component of breast cancer is more accurately detected by ultrasound than MRI. MRI provided superior correlation between tumour size and pathology. Combined mammography, clinical examination and MRI was more sensitive than any other individual test or routine triad (Chung *et al.* 2005).

Axillary lymph nodes can be evaluated as part of an MRI-mammography study without substantial increase in examination time, and provide information about the localisation of possible metastatic lymph nodes. Using dynamic contrast enhanced imaging an 83% sensitivity and a 90% specificity for the presence of lymph node metastases was found with the chosen threshold of abnormal signal intensity increase. There was a poor correlation with metastases (sensitivity 63% and specificity 80%) when the size and shape of the axillary lymph nodes in MRI were used as criteria. These results are comparable to computerised tomography (CT) examinations of the axilla but are poorer than the results from ultrasound examination. Axillary lymph nodes showed contrast enhancement in both axillary lymph node dissection (ALND)-positive and ALND-negative patients, but enhancement was stronger and more rapid in patients with metastases (Kvistad *et al.* 2004).

The evidence about when the decision to change treatment (which was based on MRI/rates of mastectomy/procedures initiated by MRI investigation) reported that between 2% and 15% of patients otherwise eligible for breast conserving surgery who have had an MRI as part of their staging workup, would have a multicentric tumour not found by conventional preoperative staging workups. These percentages may be higher for patients with DCIS or invasive lobular cancer. Patients' treatment was changed to mastectomy based on MRI findings in 7% of the patients. In anticipation of breast conserving surgery or no surgery after mammography and clinical examination in 96 breasts, additional tumour was found by MRI in 30 cases (Blue Cross/Blue Shield-TEC Review, 2004; Bremner *et al.* 2007; Del *et al.* 2007).

Breast MRI is accurate in staging extent of disease in the breasts of patients with histological grade 3 tumours. In 10 patients with histological grade 1 tumours, the MRI findings overestimated their disease. In 11/115 patients, the primary tumour or a second tumour was only seen by MRI. In 170 patients MRI detected 96% multifocal disease and 95% of multicentric disease, whereas mammography detected 37% and 18% respectively and ultrasound detected 41% and 9% respectively. All bilateral breast cancers were seen on MRI. Both mammography and ultrasound detected 56%. Additional malignant foci detected on MRI identified unsuspected multifocal, multicentric or bilateral breast cancer resulting in necessary changes in treatment (Schelfout *et al.* 2004).

The evidence about tumour recurrence showed that preoperative MRI of the breast is effective in patients with histopathologically verified breast cancer, for local staging. The ipsilateral breast tumour recurrence is significantly higher in women with breast conserving

surgery and no staging with MRI. Metachronous contralateral carcinoma has occurred significantly more in patients without preoperative MRI staging (Fischer *et al.* 2004).

**Evidence Summary**

**Invasive Breast Cancer:**

The body of evidence for this topics consists of one systematic review, 9 case control studies and 11 observational studies - case series, with a relatively high degree of consistency in results.

All studies had comparable patient groups, good quality evidence was found comparing listed interventions.

Data needs to be interpreted with caution due to the limitations of the studies, low evidence levels and small sample sizes.

Studies consistently demonstrate moderate to high sensitivity (75-100%) and specificity (82-100%) for breast MRI in detecting multicentric tumour foci in fibroglandular or dense breasts.

Axillary lymph nodes can be evaluated as a part of an MR-mammography study without substantial increase in examination time, and provide information about the localisation of possible metastatic lymph nodes.

Patients' treatment was changed to mastectomy based on MRI findings in 7% of the patients.

**Sensitivity and Specificity (improved detection)**

There is strong evidence from systematic review that MRI of the breast has a better sensitivity for identifying multicentric breast tumours compared to the current presurgical evaluation. Approximately 2% to 15% of women who appear eligible for BCT would have multicentric disease detected on MRI and might be considered for mastectomy instead of BCT. These percentages of multicentric disease appear somewhat higher among subgroups of patients with either ductal carcinoma in situ (20-28%) or infiltrating lobular carcinoma (17-40%). Studies consistently demonstrate moderate to high sensitivity (75-100%) and specificity (82-100%) for breast MRI in detecting multicentric tumour foci. Positive predictive values (PPV) range from 50% to 100%, although the 3 most representative studies found a PPV for MRI of 67% to 100%. (Blue Cross/Blue Shield-TEC Review, 2004).

There is consistently good evidence from prospective cohort studies that preoperative MRI in patients eligible for BCT is more accurate than conventional imaging in the assessment of tumour extent in one out of four patients (23%). Patients <58 years old with irregular lesion margins at mammography and discrepancy in tumour extent by more than 10 mm between ultrasonography and mammography had a 3.2 X higher chance of accurate assessment at MRI (positive predictive value 50%, negative predictive value 84%,  $p=0.0002$ ). (Deurloo *et al.* 2006).

Consideration needs to be given to integration of breast MRI into the pre-treatment evaluation of women seeking BCT. MRI had a significantly higher yield of confirmed cancer ILs than mammography (0.18 (95%CI: 0.142-0.214) for MRI versus 0.072 (95%CI: 0.050-0.100) for mammography). The cancer ILs detected by MRI alone appeared to be similar to those detected by mammography with respect to size and histology. The percentage of biopsies of ILs that resulted in a cancer diagnosis was similar between the modalities (MRI 0.72 (95%CI: 0.6-0.81); Mammography 0.85 (95%CI: 0.62-0.96)). The results demonstrate that MRI will detect additional mammogram occult foci greater than 2 cm from the index cancer in approx. 10% of women. These additional foci are similar to those detected by mammography and are therefore likely to be associated with an increased risk of local recurrence for BCT. (Schnall *et al.*, 2005).

There is further evidence that in non-fatty breasts US and MR imaging were more sensitive than mammography for invasive cancer, but both MR imaging and US involved risk of overestimation of tumour extent. Combined mammography, clinical examination and MR imaging were more sensitive than any of other individual test or combination of tests. Mammographic sensitivity decreased from 100% in fatty breasts to 45% in extremely dense breasts. Mammographic sensitivity was highest for invasive ductal carcinoma (IDC) in 81% of cases versus 34% of cases of invasive lobular carcinoma (ILC) ( $p<0.001$ ) and 55% in ductal carcinoma in situ (DCIS) ( $p<0.01$ ) .

US showed higher sensitivity than mammography in IDC depicting 94% of cases, and for ILC 86% of cases ( $p<0.01$ ) and DCIS respectively, 47% ( $p<0.01$ ). MR showed higher sensitivity than mammography for all tumour types ( $p<0.01$ ) and higher sensitivity than US for DCIS – 89% of cases ( $p<0.01$ ) and depicting 95% cases of IDC and 96% of ILC cases. Additional tumour was detected in 18% of breasts by US and 30 at MR. Extent was overestimated in 12% at US and 29% at MR. Combined mammography, clinical examination, US, and MR detected additional tumour in 12% breasts and led to an overestimation of extent in 6%. US showed no detection benefit after MR imaging. (Berg *et al.*, 2004).

Specificity and sensitivity for incidentally detected lesions in the ipsilateral or contralateral breast as reported in a large retrospective cohort study found that lesions in a different quadrant from the main lesion, are smaller than 10 mm in diameter, and show persistent enhancement on MR imaging suggest benign lesions. Therefore, patients with such lesions could avoid unnecessary surgical procedures unless lesions are proved to be malignant by cytology or biopsy. Lesions of over 10 mm tended to be malignant (11/16 ; 69%), whereas those equal or less than 5 mm tended to be benign (17.5; 71%;  $p < 0.05$ ). Lesions in the same quadrant as the main lesion tended to be malignant (20/27.5; 73%), whereas those in a different quadrant tended to be benign (17.5/20.5; 85%;  $p < 0.001$ ). Lesions with early peak of enhancement tended to be malignant (20/25; 80%), whereas those with persistent enhancement tended to be benign (20/23; 87%;  $p < 0.001$ ). (Hidetake *et al.*, 2006).

The intraductal component of breast cancer is more accurately detected by US than MRI according to evidence from a retrospective cohort study. However, when US and MRI were used to diagnose the Intraductal component the results correlated well with histopathological findings. Sensitivity, Specificity and Accuracy were 57.1%, 84.2% and 78.7% respectively for US and 50%, 89.5% and 65.9% for MRI. When both US and MRI were used Sensitivity, Specificity and Accuracy were 75%, 84.2% and 78.7% respectively. (Sundararajan *et al.*, 2006).

Good evidence regarding the sensitivity and specificity of MRI in the detection of multiple malignant foci in fibroglandular or dense breasts comes from a prospective case control study. According to this study, breast MRI is more sensitive than mammography (MX) for the detection of multiple malignant foci in fibroglandular or dense breast. Mammography missed larger and more invasive cancer foci than MRI. A relative low PPV is a problem for both techniques. Of 99 breasts , pathologic findings revealed 52 unifocal, 29 multifocal and 18 multicentric cancers for a total of 188 malignant foci (158 invasive and 30 in situ). Overall sensitivity was 66% (124/188) for mammography and 81% (152/188) for MRI ( $p < 0.001$ ) in favour of MRI. Sensitivity for invasive foci was 72% for mammography and 89 % for MRI ( $p < 0.001$ ) in favour of MRI. Sensitivity for in situ foci was 37% for mammography and 40 % for MRI ( $p > 0.05$ ) no significant difference. Malignant foci missed by mammography: 64; MRI 36, with median diameters of 8 mm for MX and 5 mm for MRI ( $p = 0.033$ ) in favour of MRI. Overall Positive Predictive Value (PPV) was 76% for MMG and 68% for MRI, not significant. In breasts with fatty patterns sensitivity was 75% for MMG and 80% for MRI, not significant; PPV 75% and 65% respectively, not significant. In breasts with fibroglandular or dense patterns sensitivity was 60% for MX and 81% for MRI, ( $p < 0.001$ ) in favour of MRI and PPV was 78% and 71% respectively, not significant. (Sardanelli *et al.*, 2004).

There is good evidence that MRI provided superior correlation between tumour size and pathology (Spearman correlation coefficient between tumour size on ultrasound and MRI with pathology was .19 ( $p = .5$ ) and .88 ( $p < 0.001$ ) respectively. (Kepple *et al.*, 2005).

Lower quality evidence shows that, in patients with ILC, MRI has a higher sensitivity than other imaging modalities and is able to accurately delineate multifocal disease not evident on conventional imaging, and is therefore a useful tool for accurate staging prior to surgery. MRI identified all the patients with subsequently histologically proven multifocal disease, with PPV

of 100% and NPV of 55.6%. Management was changed in 24% of the cases following MRI. (Kneeshaw *et al.*, 2003).

This evidence is corroborated by further retrospective case series which shows that in comparison with US and MX contrast enhanced MR has the lowest false-negative rate in detecting ILC and has the highest accuracy in measuring the size of the ILC. MR could play a key role in the pre-operative work-up for accurate tumour size determination. (Boetes *et al.*, 2004).

Also, mammography alone is not enough in detecting, and especially in the staging of ILC. Differences between Radiologists, proved to be responsible for the non-detections of ILCs on mammography or treatment delay. The understaging of ILC by mammography can have a serious influence on the clinical management of patients with ILC. 35% to 37% were understaged, the largest differences between radiologists were found in the breast imaging reporting and data system (BIRADS) classification and staging performance. Compared to the pathological findings, Radiologist 1 staged 60% correct, overstaged 3% and understaged 37% in Session A and similar percentages in Session B. Radiologist 2 staged 60% correct, overstaged 5% and understaged 35% in Session A and respectively 52%, 0%, 48% in Session B. Radiologist 1 differed in 17% patients between two sessions, Radiologist 2 in 21%. Intra-observer variation for staging was  $k=0.66$  and  $k=0.70$ , respectively for both Radiologists. The  $k$  value for interobserver agreement was 0.46 and 0.65 comparing Sessions A and B. In the BIRADS classification, Radiologist 1 differed in 26% of patients between the two sessions and Radiologist 2 in 21% of patients. Comparing the results of both Radiologists from Session A and B resulted in 29% and 31% differences respectively. The  $k$  value for intra-observer variation was 0.42 and 0.68 respectively. Interobserver agreement was  $k=0.45$  and 0.50 comparing the BIRADS classification for Sessions A and B respectively. (Veltman *et al.*, 2006).

Further lower quality evidence from case series suggests that MRI is more accurate than US and clinical examination, both of which underestimated tumour size. MRI and mammography are more accurate in estimating tumour size. MRI detected 21 of the 22 ILCs while mammography and US detected 16 and 20 respectively. Clinical examination detected 19 tumours. There was a significant difference in clinical and histological size ( $p=0.0038$ ) with clinical examination underestimating tumour size in 63% of patients. There was no significant difference between mammographic and histological size ( $p=0.3894$ ). There was a significant difference between US and histological size ( $p=0.0003$ ), with US underestimating size in 90% of patients. There was no significant difference between MRI and histological size ( $p=0.6288$ ). (Francis *et al.*, 2001).

MRI may play an important role in the evaluation of patients with ILC, which is often difficult to diagnose on clinical examination and conventional imaging and more likely occur in multiple sites and in both breasts. However, false-negative MR findings do occur in a small percentage of ILC. MR findings of unifocal, multifocal, single quadrant and multi quadrant disease were correlated with other imaging techniques and compared with histological findings. Most ILC presented on MRI as a single speculated/irregular, inhomogeneous mass (pattern 1,  $n=12$ ) or as a dominant lesion surrounded by multiple small enhancing foci (pattern 2,  $n=8$ ). Multiple small enhancing foci with interconnecting enhancing strands (pattern 3) and an architectural distortion (pattern 4) were both described in three cases. There was one case

of a focal area of inhomogeneous enhancement (pattern 5) and one normal MR examination (pattern 6). Unifocal and multifocal lesions were identified on MRI in four patients with normal conventional imaging. In nine women, multiple additional lesions or more extensive multiquadrant disease were correctly identified only on MRI. ( Schelfout, 2004).

### **Axillary Node Staging**

There is good evidence that axillary lymph nodes can be evaluated as a part of an MR-mammography study without substantial increase in examination time, and provide the surgeon with knowledge about the localisation of possible metastatic lymph nodes. Using dynamic contrast enhanced imaging, a 83% sensitivity and a 90% specificity for the presence of lymph node metastases was found with the chosen threshold of abnormal signal intensity increase. When using a signal intensity increase in the lymph nodes of >100% during the first postcontrast image as a threshold for malignancy, 57/65 patients were correctly classified (sensitivity 83%, specificity 90%, accuracy 88%). These results were not improved when lymph node size and morphology were used as additional criteria. When combining enhancement patterns (signal intensity increase) and morphological criteria of the tumour to improve specificity of the method, the sensitivity decreased to 65%, without significant increase in specificity. Using the size and shape of the axillary lymph nodes in MR images as a criteria correlated poorly to the presence of metastases, with a sensitivity of 63% and a specificity of 80%. These results are comparable to CT examinations of the axilla but are poorer than the results from ultrasound examination. Clinical evaluation had a very low sensitivity of 25%, and was found to be an inaccurate method for detection of axillary lymph nodes metastases. Axillary lymph nodes showed contrast enhancement in both ALND-positive and ALND-negative patients, but enhancement was stronger and more rapid in patients with metastases, and on average reached a peak value during the first 57s after contrast injection. Axillary lymph nodes can be evaluated as a part of an MR-mammography study without substantial increase in examination time, and provide the surgeon with knowledge about the localisation of possible metastatic lymph nodes. (Kvistad *et al.*, 2004).

There is also fairly good evidence to suggest the feasibility of semi automated, non-invasive nodal cancer staging using a nonparticle enhanced lymphotropic magnetic resonance (LMRI) technique. Nanoparticles traced by MRI displayed an abnormal pattern when there was metastases in the nodes and a computer software recognises this abnormality. Unique magnetic tissue parameters were found, which accurately distinguished metastatic from normal nodes with an overall sensitivity of 98% and specificity of 92%. The parameters can be applied to data sets in a semi automated fashion and used for 3D reconstruction of complete nodal anatomy for different primary cancers. (Harishinghani *et al.*, 2004).

### **Incidence of Decision to Change Treatment Based on MRI / Rates of Mastectomy / Procedures Provoked by MRI**

There is strong evidence that the moderate specificity and relatively low PPV of MRI findings underscore the importance of performing image-guided biopsy of such lesions to confirm malignancy before committing the patient to mastectomy. If presurgical biopsy of multicentric foci is not performed, there is the distinct possibility of performing mastectomy when, in fact, no multicentric disease exists and there would be no possible long-term benefit to the patient. Between 2% and 15% of patients otherwise eligible for BCT who have had an MRI as part of their staging workup, would have multicentric tumour not found by conventional preoperative staging workups. These percentages may be higher for patients with DCIS or Infiltrating

Lobular Carcinoma. Patients' treatment was changed to mastectomy based on MRI findings in 7% of the patients. Of the total 13 patients who underwent mastectomy because of MRI findings, it appears that at least 2 of these were the result of false-positive MRI findings that were presumably not confirmed by preoperative MRI-guided biopsy. Potential benefits of breast conservation surgery are lower using MRI information to guide surgical treatment. Some studies point out that there is a harm of performing mastectomy for false-positive MRI findings when preoperative biopsy is not used for confirmation. There is strong evidence from systematic reviews comparing outcomes of mastectomy versus BCT for early stage breast cancer, that there is no significant difference in overall or disease-free survival during intermediate or long-term follow-up. (Blue Cross/Blue Shield-TEC Review, 2004).

There is good evidence from prospective cohort studies that, in anticipation of BCT or no surgery after mammography and clinical examination in 96 breasts, additional tumour was found by MRI in 30 cases, which altered surgical approach. (Berg *et al.*, 2004).

There is good evidence from a retrospective cohort study that Breast MRI does change surgical management by detecting additional malignancies. Breast MRI is accurate in staging extent of disease in the breast in patients with High-grade (HG) tumours. The size of the tumour on MRI correlated with the pathologic size for HG tumours (HG  $R=0.76$  vs. LG  $R=0.45$ ,  $p=0.033$ ). Mastectomy was performed in 53 patients. In 10 patients with LG tumours, the MRI findings overestimated their disease. In 11 out of 115 patients, the primary tumour or a second tumour was only seen by MRI. (Blair *et al.*, 2006).

This concurs with evidence from a large prospective case control study that pre-operative MRI is an important adjunct to conventional imaging in loco-regional staging of breast cancer and a useful tool in treatment planning. In 170 patients MRI detected 96% of multifocal disease and 95% of multicentric disease, whereas MX detected 37% and 18% respectively and US detected 41% and 9% respectively. All bilateral breast cancers were seen on MRI. Both MX and US detected 56%. Findings of more extensive disease and unsuspected multiple foci were identified on MRI only. Additional malignant foci detected on MRI identified unsuspected multifocal, multicentric or bilateral breast cancer resulting in necessary changes in therapeutic strategy (60 of the 204 patients). Nine unnecessary wider excisions and 3 unnecessary FNA/core biopsies were performed because of MRI overestimation of number or size of malignant lesions. Correlation between histopathology and MRI was far better than MX and US, in diameter of malignant lesions. The PPV was best for MRI ( $R^2: 0.56$ ). The predictions of MX and US were similar (0.37 and 0.35 respectively). (Schelfout *et al.*, 2004).

MRI has been shown to detect occult invasive breast cancers with the sensitivity of 97%-100%. Mammography and ultrasonography does not accurately assess the extent of DCIS which results in a high re-operation rate. Breast MRI can improve surgical planning in women with DCIS, improving the adequacy of initial treatment while reducing re-operation. In the study of 54 patients with predominantly DCIS, MRI altered surgical management in 26% of patients; unilateral changed to bilateral mastectomy (5); lumpectomy or re-excision to mastectomy (3); unilateral lumpectomy or mastectomy had additional biopsies for lesions in the ipsilateral or contralateral breast (6). There were 8 true-positives and 7 false-positives; sensitivity 86%, PPV 84%; MRI changed the surgical management to more appropriate therapy in 15% of patients, avoiding additional surgery while 11% underwent negative surgical interventions. (Chung *et al.*, 2005).

Further evidence from a retrospective case series shows that patients who desire Breast Conserving Therapy (BCT) should undergo MRI mammography before biopsy of a category 4/5 mammogram or immediately after a positive FNA biopsy result of a palpable mass. Prebiopsy or preoperative MRI mammography changed surgical management in 13/27 (48%) patients with breast cancer by discovering multicentric cancers or more extensive cancer. 9/27 patients with positive FNA biopsy results of palpable masses underwent preoperative MRI; 6/9 patients ipsilateral multicentric cancers or more extensive cancer was discovered that necessitated mastectomy rather than breast conservation. 18/27 patients had a category 4/5 mammograms. 10 of these patients had stereotactic biopsies followed by MRI; 4/10 had changes on the MRIs that required mastectomy rather than breast conservation. 8/27 patients had MRI before stereotactic biopsy; 3/8 patients had MRI abnormalities that required mastectomy. One patient had contralateral, multicentric cancers not seen on conventional mammography, necessitating bilateral mastectomies. (Bagley *et al.* , 2004).

Lower quality evidence shows that breast MRI is useful in diagnosis, staging and surgical management of ILC. Enhancement at MRI was seen for all 35 cancers. It was focal for 24 patients, regional for 10 and diffuse for 1. Malignancy was shown in 33 patients. For 11 patients, the MRI staging was positive finding 8 new cancers. MRI had an impact on the management of 11 patients (33%). MRI was beneficial in 8 of 11 patients (confirmed original BCT management in 3 cases, conversion to mastectomy in 3 cases, contralateral lumpectomy in 2 cases).MRI caused benign lesions to undergo biopsy in 3 patients (overestimated). (Fabre Demard *et al.*, 2005).

### **Other Reported Outcomes - Tumour Recurrence**

There is good evidence from a large retrospective cohort study that preoperative MR of the breast is recommended in patients with histopathologically verified breast cancer, for local staging. The in-breast tumour recurrence is significantly higher ( $p < 0.001$ ) in women with BCT and no staging with MRI. All cases had a conformity of histology and tumour localisation between primary index and tumour recurrence. Metachronous contralateral carcinoma has occurred significantly more in patients without pre-operative MRI staging. Tumour recurrence was detected between 6 and 45 months after surgical treatment. Contralateral cancer was detected 14 to 52 months after surgical treatment. (Fischer *et al.*, 2004).

### **DCIS:**

#### **Evidence Summary**

The outcomes of interest reported are Sensitivity and Specificity and incidence of decision to change treatment based on MRI, rates of mastectomy provoked by MRI and procedures provoked by MRI.

All studies had comparable patient groups, good quality evidence was found comparing listed interventions. The studies were designed to address comparatively Mammography (MX), Ultrasonography (US), Clinical Examination (CE), Magnetic Resonance Imaging (MRI) vs. Histopathological findings in women with newly diagnosed Ductal Carcinoma In Situ (DCIS)

The outcomes of interest reported are Sensitivity and Specificity and incidence of decision to change treatment based on MRI, rates of mastectomy provoked by MRI and procedures

provoked by MRI. No study was found that addressed cost effectiveness or health economics. Some studies mentioned cost effectiveness but not in an assessable evidence level.

There is a high degree of consistency, with all studies reporting similar findings.

The sensitivity of MRI for DCIS detection is lower than that achieved for invasive breast cancer.

There is some evidence from case series that MRI is significantly more sensitive than mammography in DCIS detection. In women with known or suspected DCIS, MRI may have an important role in assessing the extent of disease in the breast.

Tumour size measured at MRI did correlate with histopathologic size, but in contrast to mammography MRI tended to overestimate the tumour extent.

### **Sensitivity and Specificity (improved detection)**

There is good evidence from retrospective case control studies that MRI can complement mammography in guiding surgical treatment of DCIS by providing better assessment to the extent of the lesion. 26/30 (86.7% sensitivity) were detected through the MRI as well as 8 lesions without mammographically detected microcalcification. In 7/30 cases MRI showed tumour extent accurately compared with mammography, and the combined diagnosis improved the accuracy of evaluating tumour extent. (Shiraishi *et al.*, 2003).

Intensity-modulated parametric mapping technique for breast MRI resulted in the highest detection rate for the DCIS cases. Furthermore, the parametric mapping technique identified all intermediate and high-grade DCIS lesions, suggesting that a negative MRI using the parametric mapping technique may exclude intermediate and high-grade DCIS. With the use of a kinetic curve shape analysis, MRI classified 7/14 lesions (50%) as suspicious, including four with initial-rapid/late-washout and three initial-rapid / late-plateau. Using morphologic criteria, MRI classified 10/14 (71%) as suspicious., with the most prominent morphologic feature being a regional enhancement pattern. Using the intensity modulated parametric mapping technique, MRI classified 12/14 cases (86%) as suspicious. Parametric mapping identified all intermediate and high-grade DCIS lesions. (Mariano *et al.*, 2005).

There is also fairly good evidence that there are features that help differentiate high-grade DCIS from invasive carcinoma on MRI. High-grade DCIS is significantly more likely to show focal branching pattern ( $p=0.003$ ) or to have an irregular contour ( $p=0.003$ ) compared with invasive disease. All though of marginal statistical significance, DCIS lesions are more likely to have a lower morphological score than invasive carcinoma ( $p=0.006$ ), whilst the latter is more likely to show ring enhancement ( $p=0.007$ ). (Groves *et al.*, 2005).

The sensitivity of MRI for DCIS detection is lower than that achieved for invasive breast cancer. However, contrast enhanced MRI can depict foci of DCIS that are mammographically occult. The MRI technique is of complementary value for a better description of tumour size and detection of additional malignant lesions. On MRI, 21/22 (95%) DCIS lesions showed contrast enhancement. 14/15 (93%) pure DCIS lesions demonstrated respectively a low (3), undeterminate (5), and strong (6) enhancement. Morphologically, the enhancing lesion was focal in 7, segmental in 4 and with linear branching in 3 cases. Wash out was found in 4

cases, plateau curve in 8 and Type I curve in 2 cases. Multifocality was present in 5 cases. All DCIS with associated microinvasion demonstrated contrast enhancement: 1/7 cases showed a low enhancement, 2/7 showed an indeterminate enhancement and 4/7 showed a strong enhancement. Morphologically, the enhancing lesion was focal in 3/9, segmental in 5 and with linear branching in 1 case. The wash out was demonstrated in 3/7 cases, plateau curve in 3 and Type 1 curve in 1 case. Multifocality was present in 3 cases. (Francescutti *et al.*, 2002).

There is some evidence from case series that MRI is significantly more sensitive than mammography in DCIS detection. In women with known or suspected DCIS, MRI may have an important role in assessing the extent of disease in the breast. Of 33 breasts involved, DCIS was discovered by MRI alone in 21 (64%), by both MRI and mammography in 8 (24%) and by mammography alone in 1 (3%), DCIS found at mastectomy without findings of mammography or MRI in 3 breasts (9%). MRI had significantly higher sensitivity than mammography for DCIS detection (29/33 = 88% vs. 9/33 = 27%;  $p < 0.00001$ ). Multiple sites of disease were present in 5 breasts, better demonstrated with MRI in 3, mammography in 1, and equally by both in 1. The predominant enhancement pattern of DCIS on MRI was linear / ductal in 18/29 breasts (62%); mammography found calcifications associated with DCIS in 8/9 (89%). The nuclear grade of DCIS found with MRI and mammography was similar; size of lesion was larger on MRI; breast density did not impact results. (Menel *et al.*, 2005).

Both DCIS and DCIS with small invasive carcinoma can be adequately visualised on MRI. Tumour size measured at MRI did correlate with histopathologic size, but in contrast to mammography MRI tended to overestimate the tumour extent. Mammographic rate of detection for DCIS was 84/52 (90%) and for DCIS with small invasive carcinoma 10/12 (83%). MRI revealed 1 false negative case and the rate of detection for DCIS was 16/17 (94%). Correlation of mammographic size with histopathologic size was  $r = .44$  ( $p < .01$ ) and  $r = .49$  ( $p < .03$ ) for MRI. Mammography underestimated the lesion size by 5 mm or more in 47%, whereas with MRI size was adequately assessed in 43% and overestimated in 38%. (van der Velden *et al.*, 2006).

#### **Incidence of Decision to Change Treatment Based on MRI / Rates of Mastectomy / Procedures Provoked by MRI**

No study was found that addressed incidence of decision to change treatment, provoke additional procedures or determine a change in the rates of mastectomy based on MRI for DCIS.

## Evidence Tables – Invasive Breast Cancer

<p>Magnetic Resonance Imaging of the Breast for Preoperative Evaluation in Patients with Localized Breast Cancer: Blue Cross and Blue Shield Association 2004: Technology Evaluation Center (Tec) Assessment Programme Volume 18, No.8, 2004.</p>
<p><b>Design:</b> Systematic Review Evidence Level 1++</p>
<p><b>Country:</b> International</p>
<p><b>Inclusion criteria:</b> Diagnostic performance of MRI: articles pertaining to use of Contrast Enhanced MRI in humans for staging breast cancer, evaluating the effectiveness of preoperative MRI for early stage breast cancer (I or II), Trials on modified radical mastectomy vs. breast conservation therapy with respect to local recurrence, distant recurrence, or survival. Clinical outcomes relating to treatment decisions: study population followed prospectively, randomized and controlled, study effect on survival, local recurrence or distant recurrence, standard preoperative staging evaluation</p>
<p><b>Exclusion criteria</b> Single case reports</p>
<p><b>Population:</b> Patients with clinically localised early invasive breast cancer who have not yet received definitive surgery, considered eligible for breast conservation therapy (BCT) and who would prefer BCT instead of mastectomy.</p>
<p><b>Interventions:</b> Breast MRI as an adjunct to conventional preoperative staging evaluation (eg. Mammography, physical exam, and possibly ultrasound) to determine the extent of tumour in the breast when conventional staging has deemed the patient eligible for BCT. The reference standard for determining the diagnostic performance of preoperative evaluation for identification of multicentric disease is histopathologic assessment.</p>
<p><b>Outcomes:</b> The health outcomes considered in this assessment are survival, breast cancer recurrence, breast conservation, disease-free survival (incorporating the overall risk of recurrence) and locoregional recurrence (within the ipsilateral breast, chest wall, local lymph nodes or skin at the surgical site)</p>
<p><b>Results</b></p> <p><b><u>Sensitivity (improved detection)</u></b></p> <p>There is strong evidence that MRI of the breast has a better sensitivity for identifying multicentric breast tumours compared to the current presurgical evaluation. Approximately 2% to 15% of women who appear eligible for BCT would have multicentric disease detected on MRI and might be considered for mastectomy instead of BCT. These percentages of multicentric disease appear somewhat higher among subgroups of patients with either ductal carcinoma in situ (20-28%) or infiltrating lobular carcinoma (17-40%). Studies consistently demonstrate moderate to high sensitivity (75-100%) and specificity (82-100%) for breast MRI in detecting multicentric tumour foci. Positive predictive values (PPV) range from 50% to 100%, although the 3 most representative studies found a PPV for MRI of 67% to 100%.</p> <p><b><u>Incidence of Decision to Change Treatment Based on MRI</u></b></p> <p>Between 2% and 15% of patients otherwise eligible for BCT who have had an MRI as part of their staging workup, would have multicentric tumour not found by conventional preoperative staging workups. These percentages may be higher for patients with DCIS or Infiltrating Lobular Carcinoma.</p> <p>Patients' treatment was changed to mastectomy based on MRI findings in 7% of the patients. Of the total 13 patients who underwent mastectomy because of MRI findings, it appears that at least 2 of these were the result of false-positive MRI findings that were presumably not</p>

confirmed by preoperative MRI-guided biopsy. Potential benefits of breast conservation surgery are lower using MRI information to guide surgical treatment. Some studies point out that there is a harm of performing mastectomy for false-positive MRI findings when preoperative biopsy is not used for confirmation.

There is strong evidence from systematic reviews comparing outcomes of mastectomy versus BCT for early stage breast cancer, that there is no significant difference in overall or disease-free survival during intermediate or long-term follow-up.

**Procedure Provoked by MRI**

There is strong evidence that the moderate specificity and relatively low PPV of MRI findings underscore the importance of performing image-guided biopsy of such lesions to confirm malignancy before committing the patient to mastectomy. If presurgical biopsy of multicentric foci is not performed, there is the distinct possibility of performing mastectomy when, in fact, no multicentric disease exists and there would be no possible long-term benefit to the patient.

<b>OUTCOME INTEREST</b>	<b>OF</b>	<b>No. Studies</b>	<b>COMPARISON</b>	<b>RESULT</b>
<b><u>Sensitivity (improved detection)</u></b>		18 (n=1401)	MRI vs. current presurgical evaluation	MRI of the breast has a better sensitivity for identifying multicentric breast tumours
			Sensitivity	Moderate to high (75-100%)
			Specificity	82-100%
			Positive Predictive Values	50-100%
<b><u>Incidence of Decision to Change Treatment Based on MRI</u></b>				2% to 15% of BCT patients with multicentric breast tumours detected only on MRI

**General comments**

**Design:** Prospective Cohort Study Evidence Level 2++

**Country:** Netherlands

**Setting:** Hospital

**Inclusion criteria:** Patients with early breast cancer, identified through fine needle aspiration or core biopsy, eligible for BCT based on clinical examination and conventional imaging. All patients underwent mammography and ultrasonography.

**Exclusion criteria** Not reported

**Population:** 165 patients with 166 malignant tumours (one patient with a bilateral tumour confirmed at MRI)  
Mean age was 55 years (range 28-86yrs).

<u>Density at Mammography</u>	<b>N</b>	<b>%</b>	<u>Suspicious Abnormality</u>	<b>N</b>	<b>%</b>
Almost entirely fat	10	6%	at mammography	158	95%
Scattered fibroglandular tissue	65	39%	at ultrasonography	159	96%
Heterogeneously dense	79	48%			
Extremely dense	12	7%	<b><u>Histological Type</u></b>		
			Invasive Ductal Carcinoma	138	83%
<b><u>Non-measurable</u></b>			Invasive Lobular Carcinoma	25	15%
at least one of two	31	19%	Ductal Carcinoma In Situ	3	2%
both mammography & ultrasonography	3	2%	Tumour negative axillary lymph nodes	132	80%
only at mammography	18	11%	Tumour positive axillary lymph nodes	33	20%
only at ultrasonography	10	6%	Tumour negative axilla	92	55%
			Tumour positive axilla	74	45%
<b><u>Interventions</u></b>					
BCT	135	81%			
Mastectomy	31	19%			
Sentinel Node Procedure	132	80%			
Lymph Node Dissection	32	20%			

**Interventions:** Pre-operative Breast MRI.

**Outcomes:** Correlation between imaging (Breast MRI) and pathology.  
Assessment of complimentary value of MRI where conventional imaging underestimated or overestimated tumour extent (by more than 10 mm compared with histology) and MRI assessed the extent accurately.

**Results**

There is good evidence that preoperative MRI in patients eligible for BCT is more accurate than conventional imaging in the assessment of tumour extent in one out of four patients (23%). Patients <58 years old with irregular lesion margins at mammography and discrepancy in tumour extent by more than 10 mm between ultrasonography and mammography had a 3.2 X higher chance of accurate assessment at MRI (positive predictive value 50%, negative

predictive value 84%, p=0.0002).

**Complimentary value of MRI to determine tumour extent**

<b>Estimate</b>	<b>Conventional imaging</b>		<b>MRI</b>	
Correct	117	(70%)	150	90%
Overestimate	7	(4%)	6	4%
Underestimate	42	(25%)	10	6%

**Tumour extent measured at conventional imaging and at MRI**

<b>Conventional imaging</b>	<b>MRI</b>			
	Correct	Underestimation	Overestimation	Total
Correct	111	2	4	117
Underestimation	33	8	1	42
Overestimation	6	0	1	7
Total	150	10	6	166

**Tumour extent measured at conventional imaging and at MRI**

(lesions eligible for BCT measurable at both mammography and ultrasonography)

<b>Conventional imaging</b>	<b>MRI</b>			
	Correct	Underestimation	Overestimation	Total
Correct	93	2	4	99
Underestimation	25	7	0	32
Overestimation	3	0	1	4
Total	121	9	5	135

**General comments**

Schnall, M.D., Blume, J., Bluemke, D.A., Deangelis, G.A., Debruhi, N., Harms, S., Heywang-Korbrunner, S.H., Hylton, N., Kuhl, C.K., Pisano, E.D., Causer, P., Schnitt, S.J., Smazal, S.F., Stelling, C.B., Lehman, C., Weatherall, P.T., Gatsonis, C. MRI Detection of Distinct Incidental Cancer in Women with Primary Breast Cancer Studied in IBMC 6883, Journal of surgical Oncology, no 92 pp. 32-38, 2005

**Design:** Prospective Cohort Study Evidence Level 2++

**Country:** International

**Setting:** Hospital

**Inclusion criteria:** women presenting with a suspicious or highly suspicious imaging finding on conventional imaging (BiRads 4 and 5) or suspicious clinical findings requiring biopsy, in whom the index lesion diagnosis was established to be cancer.

**Exclusion criteria**

**Population:** 426 women

<b>Characteristics:</b>		<b>Histology</b>	
Age:	52±11	Invasive ductal (NOS)	59.6%
Family history of breast CA	39.7%	DCIS	14.3%
Index lesion size (mean)	24.7±1.3 mm	Invasive lobular	7.3%
Index lesion (median)	18 mm	Mixed lobular/ductal	11.7%
Index lesion palpable	51.4%	Tubular carcinoma	2.1%
Index lesion visible on mammography	88.5%	Colloid carcinoma	1.4%
		Other	3.6%

**Interventions:** Pre-operative Breast MRI.

**Outcomes:** Findings of incidental lesions; comparison of suspicious ILs on MRI with those on biopsy; mammography density detected by mammography or MRI only; characteristics of most advanced lesions.

**Results:** There is good evidence that consideration needs to be given to integration of breast MRI into the pre-treatment evaluation of women seeking breast conservation therapy (BCT). MRI had a significantly higher yield of confirmed cancer ILs than mammography (0.18 (95%CI: 0.142-0.214) for MRI versus 0.072 (95%CI: 0.050-0.100) for mammography). The cancer ILs detected by MRI alone appeared to be similar to those detected by mammography with respect to size and histology. The percentage of biopsies of ILs that resulted in a cancer diagnosis was similar between the modalities (MRI 0.72 (95%CI: 0.6-0.81); Mammography 0.85 (95%CI: 0.62-0.96)). The results demonstrate that MRI will detect additional mammogram occult foci greater than 2 cm from the index cancer in approx. 10% of women. These additional foci are similar to those detected by mammography and are therefore likely to be associated with an increased risk of local recurrence for BCT.

**Findings of Incidental Lesions**

<b>Findings by:</b>	<b>mammography</b>	<b>MRI</b>	<b>MRI only</b>
Women with complete scans	417	423	423
Women with at least one IL	41 (9.8%)	129 (30.5%)	101 (23.9%)

Women with at least one suspicious IL	36(8.6%)	103 (24.3%)	83 (19.6%)
Women with at least one suspicious IL+ pathology data	20 (4.8%)	78 (18.4%)	61 (14.4%)
Percent verified by pathology	55.5% (20/36)	75.7% (78/103)	73.5% (61/83)
Women with verified cancer IL	17	56	41
Percent of cancer IL in biopsied women	85% (17/20)	72.8 (56/78)	67.2% (41/61)

**Comparison of the population with suspicious IL on MRI with those who underwent biopsy**

	<b>Suspicious IL</b>	<b>Suspicious IL with biopsy</b>	<b>Suspicious IL with missing biopsy</b>
Number of women	103	78	25
Age (mean, SD)	54.3 (11) years	54.5 (11) years	53.4 (10) years
Post menopausal (%of total; %missing of total)	48 (46.6%; 0%)	35 (44.9%; 0%)	13 (52%; 0%)
Family history of breast CA (%of total; %missing of total)	38 (36.9%; 0%)	28 (35.9%; 0%)	10 (40%; 0%)

**General comments**

Berg, W.A., Gutierrez, L., NessAiver, M.S., Carter W.B., Bhargavan, M., Lewis, R.S., Ioffe, O.B. Diagnostic Accuracy of Mammography, Clinical Examination, US, and MR Imaging in Preoperative Assessment of Breast Cancer. Radiology, No. 233, pp. 830-849, 2004

**Design:** Prospective Cohort Study Evidence Level 2++

**Country:** USA

**Setting:** Hospital

**Inclusion criteria:** women older than 18 with newly diagnosed invasive breast cancer by means of core biopsy and-or high clinical or mammographic suspicion of invasive breast cancer.

**Exclusion criteria:** women unwilling or unable to consent or unable to undergo MR because of a pacemaker, aneurism clip or metallic foreign body; patients who have undergone open biopsy before mammography, US and MR.

**Population:** a cohort of 111 consecutive women,. Median size of foci 18 mm (range 2-107) Mean age 48.7, median age 48, range 26-81years). Lesions proved malignant in 110 patients (99.1%) with 177 malignant foci (73% palpable)

**Interventions:** assess the accuracy of mammography, clinical examination, US, and MR imaging in preoperative assessment of breast cancer.

**Outcomes:** sensitivity in tumour detection, correlated with histopathological findings

**Results:**

There is good evidence that in non-fatty breasts US and MR imaging were more sensitive than mammography for invasive cancer, but both MR imaging and US involved risk of overestimation of tumour extent. Combined mammography, clinical examination and MR imaging were more sensitive than any of other individual test or combination of tests. Mammographic sensitivity decreased from 100% in fatty breasts to 45% in extremely dense breasts.

Mammographic sensitivity was highest for invasive ductal carcinoma (IDC) in 81% of cases versus 34% of cases of invasive lobular carcinoma (ILC) ( $p<0.001$ ) and 55% in ductal carcinoma in situ (DCIS) ( $p<0.01$ ).

US showed higher sensitivity than mammography in IDC depicting 94% of cases, and for ILC 86% of cases ( $p<0.01$ ) and DCIS respectively, 47% ( $p<0.01$ ).

MR showed higher sensitivity than mammography for all tumour types ( $p<0.01$ ) and higher sensitivity than US for DCIS – 89% of cases ( $p<0.01$ ) and depicting 95% cases of IDC and 96% of ILC cases.

In anticipation of BCT or no surgery after mammography and clinical examination in 96 breasts, additional tumour was found in 30, which altered surgical approach.

Additional tumour was detected in 18% of breasts by US and 30 at MR. Extent was overestimated in 12% at US and 29% at MR.

Combined mammography, clinical examination, US, and MR detected additional tumour in 12% breasts and led to an overestimation of extent in 6%.

US showed no detection benefit after MR imaging.

**Diagnostic performance in 258 proven lesions (177 malignancies and 81 benign lesions)**

Modality	Sensitivity	Specificity	Positive predictive value	Accuracy
----------	-------------	-------------	---------------------------	----------

Mammography	120/177 (67.8%)	61/81 (75%)	120/140 (85.7%)	181/258 (70.2%)
MMG and clinical examination	137/177 (77.4%)	58/81 (72%)	173/160 (85.6%)	195/258 (75.6%)
Clinical examination	89/177 (50.3%)	75/81 (92%)	89/95 (94%)	164/258 (63.6%)
US	147/177 (83.0%)	28/81 (34%)	147/200 (73.5%)	175/258 (67.8%)
MMG and US	162/177 (91.5%)	19/81 (23%)	162/244 (72.3%)	181/258 (70.2%)
MMG, clinical examination and US	165/177 (93.2%)	18/81 (22%)	165/228 (72.4%)	183/258 (70.9%)

**General comments**

Fischer, U., Zachariae, O, Baum, F., von Heyden, D., Funke, M., Liersch. The Influence of Preoperative MRI of the Breasts on Recurrence Rate in Patients with Breast Cancer. Eur. Radiol. 14: 1725-1731, 2004

**Design:** Retrospective Cohort Study Evidence Level 2++

**Country:** Germany

**Setting:** Hospital

**Inclusion criteria:** patients with histologically verified breast cancer; age >18, <78, interval between imaging and surgery <4 weeks; histopathology verified R0 resection with tumour free section ≥1 mm; standardised surgical approach; standardised adjuvant radiation therapy after BCT and adjuvant systemic therapy (hormonal/chemotherapy)

**Exclusion criteria:** haematogenous metastases of the breast carcinoma; other concomitant diseases; incomplete data

**Population:** 346 patients:

Arm A – n = 121 - patients (124 lesions) with preoperative contrast-enhanced MRI before surgery

Arm B – n = 225- patients (227 lesions) without preoperative MRI before surgery

Characteristics	Arm A	Arm B
<b>Mean age</b>	<b>55.2 (27-74)</b>	<b>57.1(29-77)</b>
<b>Histology</b>		
IDC	69.4%	75.3%
IL	9.7%	10.6%
DCIS	12.1%	3.5%
Other entities	8.8%	10.6%
<b>Lymph nodes</b>		
Negative	61.2%	54.2%
Positive	38.8%	45.8%
<b>Tumour size</b>		
pT1	63.3%	47.6%
pT2	28.9%	32.0%
pT3/4		20.4%
<b>Grading</b>		
G1	4.0%	2.6%
G2	79.0%	63.9%
G3	12.9%	27.8%
G4	4.0%	5.7%

**Interventions:** evaluate the benefit of preoperative MRI

**Outcomes:** in-breast tumour recurrence rate; contralateral carcinoma detected;

**Results:** There is good evidence that preoperative MR of the breast is recommended in patients with histopathologically verified breast cancer, for local staging. The in-breast tumour recurrence is significantly higher (p<0.001) in women with BCT and no staging with MRI. All cases had a conformity of histology and tumour localisation between primary index and tumour recurrence. Metachronous contralateral carcinoma has occurred significantly more in patients without pre-operative MRI staging. Tumour recurrence was detected

between 6 and 45 months after surgical treatment. Contralateral cancer was detected 14 to 52 months after surgical treatment.

<b>Recurrence rate and treatment modality</b>	<b>Arm A</b>	<b>Arm B</b>
Number of patients with BCT	71.1%	62.3%
In breast tumour relapse	1%	6.5%
Number of patients with ME	28.9%	38.7%
Contralateral breast cancer within follow-up	1.7%	4.0%

**General comments**

Hidetake Yabuuchi, Toshiro Kuroiwa, Chie Kusumoto, Tatsuro Fukuya, Shinji Ohno, Yoichi Hachitanda; Incidentally Detected Lesions on Contrast-Enhanced MR Imaging in Candidates for Breast-Conserving Therapy: Correlation Between MR Findings and Histological Diagnosis; Journal of Magnetic Resonance Imaging, 23:486-492 (2006)

**Design:** Retrospective Cohort Study Evidence Level 2++

**Country:** International

**Setting:** Hospital

**Inclusion criteria:** A cohort of MR images of 299 female breast cancer patients between June 2000 and September 2002 in which the maximum diameter was equal to or less than 4cm without a wide ductal spread and/or multicentric cancers on mammography and conventional US.

**Exclusion criteria:** Lesions smaller than 3mm in maximum diameter, because such small lesions were less likely to be detected, even on repeat US. Multiple lesions diffusely distributed in the entire breast, because these are frequently seen in patients with fibrocystic changes or hormonal changes.

**Population:** Incidentally detected lesions 59 (20%); Histological diagnosis obtained in 48/59 (81%). Ages ranged from 27 to 77 years (mean 59 years)

<b>Histologic Type of the Main Lesion</b>	<b>N = 48</b>
Invasive ductal carcinoma	41
Ductal carcinoma in situ (DCIS)	3
Mucinous carcinoma	2
Invasive lobular carcinoma	1
Malignant phyllodes tumour	1

**Interventions:** Investigate the correlation between MR findings and the histological diagnosis of incidentally detected lesions in candidates for Breast Conserving Therapy (BCT)

**Outcomes:** MRI Characteristics of Incidentally Detected Lesions; Sensitivity and specificity of combination of size, enhancement and quadrant.

**Results:** Incidentally detected lesions that are found in a different quadrant from the main lesion, are smaller than 10 mm in diameter, and show persistent enhancement on MR imaging suggest benign lesions. Therefore, patients with such lesions should avoid unnecessary surgical procedures unless lesions are proved to be malignant by cytology or biopsy.

Lesions of over 10 mm tended to be malignant (11/16 ; 69%), whereas those equal or less than 5 mm tended to be benign (17.5; 71%;  $P < 0.05$ ). Lesions in the same quadrant as the main lesion tended to be malignant (20/27.5; 73%), whereas those in a different quadrant tended to be benign (17.5/20.5; 85%;  $P < 0.001$ ). Lesions with early peak of enhancement tended to be malignant (20/25; 80%), whereas those with persistent enhancement tended to be benign (20/23; 87%;  $P < 0.001$ ).

<b>Combination of size, enhancement and quadrant</b>	<b>Ratio of benignancy</b>	<b>Ratio of malignancy</b>
--	----------------------------	----------------------------

Different quadrant and persistent enhancement	12.5/13.5 (93%)	1/13.5 (7%)*
Different quadrant and early peak enhancement	5/7 (71%)	2/7 (29%)
Same quadrant and early peak enhancement	0/18 (0%)	18/18 (100%)*
Same quadrant and persistent enhancement	7/9 (78%)	2/9 (22%)
Different quadrant and size 3-5 mm	8/8 (100%)	0/8 (0%)*
Different quadrant and size over 10 mm	4.5/7.5 (60%)	3/7.5 (40%)
Same quadrant and size 3-5 mm	4/10 (40%)	6/10 (60%)
Same quadrant and size over 10 mm	0/8 (0%)	8/8 (100%)*
Early peak enhancement and size 3-5 mm	2/6 (23%)	4/6 (67%)
Early peak enhancement and size over 10 mm	1/11.5 (9%)	10.5/11.5 (91%)*
Persistent enhancement and size 3-5 mm	10/11 (91%)	1/11 (9%)*
Persistent enhancement and size over 10 mm	3/4 (75%)	1/4 (25%)
Same quadrant only	7.5/27.5 (27%)	20/27.5 (73%)
Different quadrant only	17.5/20.5 (85%)	3/20.5 (15%)
Early peak enhancement only	5/25 (20%)	20/25 (80%)
Persistent enhancement only	20/23 (87%)	3/23 (13%)
Size of 3-5 mm only	12/17 (71%)	5/17 (29%)
Size of over 10 mm only	5/16 (31%)	11/16 (69%)

<b>General comments</b>				

Blair, S., McElroy, M., Middleton, M.S., Comstock, C., Wolfson, T., Kamrava, M., Wallace, A., Mortimer, J., "The Efficacy of Breast MRI in Predicting Breast Conservation Therapy", Journal of Surgical Oncology, No.94, pp220-225, 2006

**Design:** Retrospective Cohort Study Evidence Level 2++

**Country:** USA

**Setting:** Hospital

**Inclusion criteria:** Patients with early breast cancer, identified through routine imaging mammogram or ultrasound or were palpable on physical exam and had pathological assessment of tumour specimens, who underwent bilateral breast MRI and subsequent definitive surgical treatment

**Exclusion criteria:**

**Population**

115 consecutive patients, high-grade tumours n=40, low-grade tumours n=75

<b>Clinicopathologic Feature</b>	<b>Incidence</b>	
Age	Mean 52 years	(Range 31-78 yrs)
Menopausal Status	64 (56%) pre-menopausal	51 (44%) post-menopausal
Grade	40 (35%) high	75 (65%) low
ER/PR	64 (56%) positive	51 (44%) negative
Her 2 neu	11 (10%) positive	104 (90%) negative
Histology	108 (94%) ductal	7 (6%) lobular

<b>Reasons for MRI:</b>	<b>N = 85</b>
Evaluation of lobular carcinoma	6
Part of a Protocol for Neoadjuvant therapy	26
Indeterminate findings on mammogram	53

**Interventions:** MRI breast

**Outcomes:** Correlation of breast MRI and pathology

**Results:** There is good evidence that Breast MRI does change surgical management by detecting additional malignancies. Breast MRI is accurate in staging extent of disease in the breast in patients with High-grade (HG) tumours. The size of the tumour on MRI correlated with the pathologic size for HG tumours (HG R=0.76 vs. LG R=0.45, P=0.033). Mastectomy was performed in 53 patients. In 10 patients with LG tumours, the MRI findings overestimated their disease. In 11 out of 115 patients, the primary tumour or a second tumour was only seen by MRI.

<b>Correlation of Breast MRI and Pathology</b>		<b>Spearman rho</b>	<b>P=Value</b>
Measurement of tumour on MRI and Pathologic of total amount of tumour		0.51	>0.001
Size by MRI and total tumour size	Previous	0.50	0.005

	Chemotherapy		
	Previous Excision	0.53	0.003
Pre-operative MRI measurement and pathologic measurement	HG tumours	0.73	<0.0001

**Reasons for Mastectomy:** Positive predictive value of 47%

<b>Patient Reasons</b>	<b>N = 19</b>	<b>Imaging Reasons</b>	<b>N = 34</b>
Patient choice	8	Residual disease on MRI after excision	3
Family history	3	Multi-centric disease on MRI	8

Blair et al. (present series)	115	All tumours	0.51	0.05

**General comments**

Sundararajan, S., Tohno, E., Kamma, H., Ueno, E., Minami, M. Detection of Intraductal Component around Invasive Breast Cancer Using Ultrasound: Correlation with MRI and Histopathological Findings. Radiation Medicine, Vol. 24, No. 2, pp. 108-114, 2006

**Design:** Retrospective Cohort Study Evidence Level 2++  
**Country:** Japan  
**Setting:** Hospital

**Inclusion criteria:** Patients with invasive breast cancer, with Intraductal component identified through fine needle aspiration or core biopsy, mammography (and ultrasonography (US))

**Exclusion criteria:** DCIS and non-mass forming tumours

**Population:** 47 patients with invasive breast cancer who had undergone a complete US examination for Intraductal component and mass-forming tumours. Age range: 29 to 81 (median age 52 years), T1 (n=27) T2 (n=20)

**Interventions:** Pre-operative Breast MRI

**Outcomes:** Efficacy of US in the detection of Intraductal component in comparison with MRI and histopathological findings

**Results:** There is good evidence that US examination depicted the Intraductal component of breast cancer more accurately than MRI. However, when US and MRI were used to diagnose the Intraductal component the results correlated well with histopathological findings.

Sensitivity, Specificity and Accuracy were 57.1%, 84.2% and 78.7% respectively for US and 50%, 89.5% and 65.9% for MRI. When both US and MRI were used Sensitivity, Specificity and Accuracy were 75%, 84.2% and 78.7% respectively.

**Histopathological classification (HP) of Intraductal component and correlation with US and MRI**

Contrast –enhanced MR Imaging of Breast Lesions and Effect on Treatment. The Journal of Cancer Surgery, EJSO, :30, 501-507, 2004

**Design:** Prospective Case Control Study Evidence Level 2++

**Country:** Belgium

**Setting:** Hospital

**Inclusion criteria:** women under 80 years old, with a suspect breast lesion found on clinical examination (CE) and/or Mammography (MX) and/or ultrasonography (US) and if biopsy was indicated.

**Exclusion criteria:**

**Population** 204 consecutive women, age range 21-79 (mean 56.6 years)

pathological examination	invasive cancers	215
	pure DCIS foci	41
	benign lesions	76
positive family history		61%
positive histopathological examination		170
lesions detected on CE and/or MX and/or US and/or MRI:		332
	positive on CE (invasive +DCIS)	139
	positive on MX	173
	positive on US	160
	positive on MRI	247
index lesions	invasive carcinoma	204
	low grade	72
	intermediate grade	41
	high grade	34
	pure DCIS	20
	low grade	4
	intermediate grade	3
	high grade	13
	benign lesion	37
malignant lesions	palpable	123
	detected on MX	149
	detected on US	133
	detected on MRI	161
	MRI only (additional foci)	55

**Interventions:** MRI breast

**Outcomes:** Sensitivity of MRI vs. MX; Correlation; Effect on staging; Changes in therapeutic strategy.

**Results:** There is good evidence that pre-operative MRI is an important adjunct to conventional imaging in loco-regional staging of breast cancer and a useful tool in treatment planning. In 170 patients MRI detected 96% of multifocal disease and 95% of multicentric disease, whereas MX detected 37% and 18% respectively and US detected 41% and 9% respectively. All bilateral breast cancers were seen on MRI. Both MX and US detected 56%. Findings of more extensive disease and unsuspected multiple foci were identified on MRI only. Additional malignant foci detected on MRI identified unsuspected multifocal, multicentric or bilateral breast cancer resulting in necessary changes in therapeutic strategy (60 of the 204 patients). Nine unnecessary wider excisions and 3 unnecessary FNA/core biopsies were performed because of MRI overestimation of number or size of malignant lesions. Correlation between histopathology and MRI was far better than MX and US, in diameter of malignant lesions. The PPV was best for MRI ( $R^2$ : 0.56). The predictions of MX and US were similar (0.37 and 0.35 respectively).

**Additional lesions and subgroup characterisation:**

Multifocal (MF), multicentric (MC) and bilateral (Bil) breast cancer;  
 Histopathologic diagnosis (HPD), mammography (MX), ultrasound (US), magnetic resonance imaging (MRI)

	HPD	MX	US	MRI

**Interventions:** MRI breast

**Outcomes:** Correlation of breast MRI and pathology; Sensitivity of MRI versus Mammography

**Results:** There is good evidence that Breast MRI is more sensitive than mammography (MMG) for the detection of multiple malignant foci in fibroglandular or dense breast. Mammography missed larger and more invasive cancer foci than MRI. A relative low PPV is a problem for both techniques. Of 99 breasts, pathologic findings revealed 52 unifocal, 29 multifocal and 18 multicentric cancers for a total of 188 malignant foci (158 invasive and 30 in situ).

Overall sensitivity was 66% (124/188) for mammography and 81% (152/188) for MRI (p< 0.001) in favour of MRI

Sensitivity for invasive foci was 72% for mammography and 89% for MRI (p< 0.001) in favour of MRI

Sensitivity for in situ foci was 37% for mammography and 40 % for MRI (p>0.05) no significant difference

Malignant foci missed by mammography: 64; MRI 36, with median diameters of 8 mm for MMG and 5 mm for MRI (p=0.033) in favour of MRI

Overall Positive Predictive Value (PPV) was 76% for MMG and 68% for MRI, not significant.

In breasts with fatty patterns sensitivity was 75% for MMG and 80% for MRI, not significant; PPV 75% and 65% respectively, not significant.

In breasts with fibroglandular or dense patterns sensitivity was 60% for MMG and 81% for MRI, (p<0.001) in favour of MRI and PPV was 78% and 71% respectively, not significant.

**Focus by focus analysis of diagnostic performance of Mammography and dynamic MRI in Pathology controlled study (n=99 breasts)**

Features	Mamography	MRI	p

**Interventions:** Comparison of change in management in patients with pure DCIS and DCIS with invasive cancer

**Outcomes:** Change in management

**Results:** MRI has been shown to detect occult invasive breast cancers with the sensitivity of 97%-100%. Mammography and ultrasonography does not accurately assess the extent of DCIS which results in a high re-operation rate. Breast MRI can improve surgical planning in women with DCIS, improving the adequacy of initial treatment while reducing re-operation. In the study of 54 patients with predominantly DCIS, MRI altered surgical management in 26% of patients; unilateral changed to bilateral mastectomy (5); lumpectomy or re-excision to mastectomy (3); unilateral lumpectomy or mastectomy had additional biopsies for lesions in the ipsilateral or contralateral breast (6).

There were 8 true-positives and 7 false-positives; sensitivity 86%, PPV 84%; MRI changed the surgical management to more appropriate therapy in 15% of patients, avoiding additional surgery while 11% underwent negative surgical interventions.

**General comments**

Bagley, F.H., The Role of Magnetic Resonance Imaging Mammography in the Surgical Management of the Index Breast Cancer; Arch Surg, Vol 139, pp 380-383, (2004)

**Design:** Retrospective Case Series Evidence Level 3

**Country:** USA

**Setting:** Hospital

**Inclusion criteria:** Patients with breast cancer who underwent prebiopsy or preoperative MRI mammography

**Exclusion criteria:**

**Population:** 27 patients, age not reported

**Interventions:** Surgical management of breast cancer

**Outcomes:** Change in surgical management prompted by findings on MRI mammography

**Results:** There is good evidence that patients who desire Breast Conserving Therapy (BCT) should undergo MRI mammography before biopsy of a category 4/5 mammogram or immediately after a positive FNA biopsy result of a palpable mass.

Prebiopsy or preoperative MRI mammography changed surgical management in 13/27 (48%) patients with breast cancer by discovering multicentric cancers or more extensive cancer. 9/27 patients with positive FNA biopsy results of palpable masses underwent preoperative MRI; 6/9 patients ipsilateral multicentric cancers or more extensive cancer was discovered that necessitated mastectomy rather than breast conservation. 18/27 patients had a category 4/5 mammograms. 10 of these patients had stereotactic biopsies followed by MRI; 4/10 had changes on the MRIs that required mastectomy rather than breast conservation. 8/27 patients had MRI before stereotactic biopsy; 3/8 patients had MRI abnormalities that required mastectomy. One patient had contralateral, multicentric cancers not seen on conventional mammography, necessitating bilateral mastectomies.

**Ability of MRI to Detect Multicentricity Compared with the Single Index Cancer, and to Predict Size, Compared with Mammography and/or Clinical Examination**

Group	No. of Patients	No. of Patients		
		Multicentricity	Increased Size	Agreement
Positive FNA	9	3	3	3
Positive stereotactic biopsy	10	2	2	6
Category 4/5 mammogram	8	1	2	5
<b>Total</b>	<b>27</b>	<b>6</b>	<b>7</b>	<b>14</b>

**Accuracy of MR Imaging Compared with Pathological Findings**

	Multicentricity Cancers	No. of	Larger Cancer than Mammogram or Examination, No. of

Group			Cancers	
	MR Imaging Predicted	Pathologically Confirmed	MR Imaging Predicted	Pathologically Confirmed
Positive FNA	8	8	6	6
Positive stereotactic biopsy	4	4	8	8
Category 4/5 mammogram	2	2	7	4
<b>Total</b>	<b>14</b>	<b>14</b>	<b>21</b>	<b>18</b>

**General comments:** Confounders not accounted for as there is no report on Age, HRT, Menopause, etc.

Kneeshaw, P.J., Turnbull, L.W., Smith, A., Drew, P.J. Dynamic Contrast-Enhanced Magnetic Resonance Imaging Aids the Surgical Management of Invasive Lobular Breast Cancer. European Journal of Surgical Oncology, 29:32-37, 2003

**Design:** Retrospective Case Series Evidence Level 3

**Country:** UK

**Setting:** Hospital

**Inclusion criteria:** patients with ILC from the BASO database who had undergone triple assessment and had the size of tumour and multifocality recorded according to mammogram, ultrasound and clinical examination and has undergone MRI. Final histological diagnosis and tumour diameter was obtained from the histology report.

**Exclusion criteria:**

**Population:** 21 patients with ILC, mean age 57 years (range 43-72 years).

12 patients had concurrent LCIS

4 patients had concurrent DCIS

No other characteristics reported

**Interventions:** evaluating the efficacy of current imaging modalities compared with MRI in the evaluation of ILC

**Outcomes:** correlation of tumour size and detection sensitivity between modalities, altered surgical management

**Results:** There is some evidence that MRI has a higher sensitivity than other imaging modalities and is able to accurately delineate multifocal disease not evident on conventional imaging, and is therefore a useful tool for accurate staging prior to surgery for ILC.

MRI identified all the patients with subsequently histologically proven multifocal disease, with PPV of 100% and NPV of 55.6%. Management was changed in 24% of the cases following MRI.

**Sensitivity of each modality  
the detection of ILC**

**Sensitivity and specificity of each modality  
for detection of multifocal ILC**

Modality	Sensitivity		Sensitivity	Specificity	PPV	NPV	Accuracy

**Design:** Retrospective Case Series Evidence Level 3

**Country:** France

**Setting:** Hospital

**Inclusion criteria:** Surgically treated patient with pure Invasive Lobular Carcinoma (ILC)

**Exclusion criteria:**

**Population:** 35 patients, mean age 55 years (range 38-76 years).

<b>Mammographic abnormalities:</b>	Opacity 45%
	Asymmetrical Density 55%

**Interventions:** Breast MRI

**Outcomes:** Regional staging

**Results:** Breast MRI is useful in diagnosis, staging and surgical management of ILC.

Enhancement at MRI was seen for all 35 cancers. It was focal for 24 patients, regional for 10 and diffuse for 1. Malignancy was shown in 33 patients. For 11 patients, the MRI staging was positive finding 8 new cancers.

MRI had an impact on the management of 11 patients (33%). MRI was beneficial in 8 of 11 patients (confirmed original BCT management in 3 cases, conversion to mastectomy in 3 cases, contralateral lumpectomy in 2 cases).MRI caused benign lesions to undergo biopsy in 3 patients (overestimated).

Boetes, C., Veltman, J., Van Die, L., Bult, P., Wobbes, T., Barentsz, J, O., The Role of MRI in Invasive Lobular Carcinoma. Breast Cancer Research and Treatment; 86; pp31-37; 2004

**Design:** Retrospective Case Series Evidence Level 3

**Country:** Holland

**Setting:** Hospital

**Inclusion criteria:** Surgically treated patient with pure Invasive Lobular Carcinoma (ILC), with available pre-operative imaging measurements (MX), US and MRI

**Exclusion criteria:**

**Population:** 34 patients, mean age 55 years (range 35-78 years).  
Mean tumour size at pathological examination 4.9 cm (range 1 to 15 cm)  
Intervention: 26 patients underwent mastectomy : 10 patients had BCT  
Axillary lymph node involvement - 56% of patients

**Interventions:** Retrospectively re-evaluate imaging measurements for tumour detection and size; findings compared with pathology.

**Outcomes:**

MR detection and measurement of tumour size, compared to MX and US in patients with ILC.

**Results:** There is some evidence that of the three imaging modalities contrast enhanced MR has the lowest false-negative rate in detecting ILC and has the highest accuracy in measuring the size of the ILC. MR could play a key role in the pre-operative work-up for accurate tumour size determination

	<b><u>MX</u></b>	<b><u>US</u></b>	<b><u>MRI</u></b>
False-negative scores	14%	3%	0%
Underestimated	56%	53%	14%
Correctly estimated	33%	47%	75%
Overestimated	17%	0%	11%

The correlation coefficients for mammography were respectively  $r = 0.34$  ( $p < 0.05$ ) and  $r = 0.27$  ( $p < 0.05$ ) for both radiologists, for ultrasound  $r = 0.24$  ( $p < 0.05$ ) and for MRI  $r = 0.81$  ( $p < 0.01$ ).

**General comments:** Imaging measurements on MX, US and MR vs. pathology measurements are presented in scatter diagrams - any extraction of figures would be highly speculative.

Veltman, J., Boetes, C., Van Die, L., Bult, P., Blickman, J, G., Barentsz, J, O., Mammographic Detection and Staging of Invasive Lobular Carcinoma. Journal of Clinical Imaging; 30; pp94-98; 2006

**Design:** Retrospective Case Series Evidence Level 3

**Country:** Holland

**Setting:** Hospital

**Inclusion criteria:** Surgically treated patient with pure Invasive Lobular Carcinoma (ILC)

**Exclusion criteria:**

**Population:** 42 patients, mean age 64 years (range 44-85 years).  
 Mean tumour size at pathological examination 33 mm (range 3-110 mm)  
 Intervention: 27 patients underwent mastectomy : 15 patients had BCT  
 Staging: T1 - 20 patients; T2 - 13 patients; T3 - 9 patients

**Interventions:** Evaluate mammography in detecting and staging of ILC.

**Outcomes:** Evaluate mammography in detecting and staging of ILC.

**Results:** There is some evidence that mammography alone is not enough in detecting, and especially in the staging of ILC. Differences between Radiologists, proved to be responsible for the non-detections of ILCs on mammography or treatment delay. The understaging of ILC by mammography can have a serious influence on the clinical management of patients with ILC. 35% to 37% were understaged, the largest differences between radiologists were found in the breast imaging reporting and data system (BIRADS) classification and staging performance.

Compared to the pathological findings, Radiologist 1 staged 60% correct, overstaged 3% and understaged 37% in Session A and similar percentages in Session B. Radiologist 2 staged 60% correct, overstaged 5% and understaged 35% in Session A and respectively 52%, 0%, 48% in Session B. Radiologist 1 differed in 17% patients between two sessions, Radiologist 2 in 21%. Intra-observer variation for staging was  $k=0.66$  and  $k=0.70$ , respectively for both Radiologists. The  $k$  value for interobserver agreement was 0.46 and 0.65 comparing Sessions A and B. In the BIRADS classification, Radiologist 1 differed in 26% of patients between the two sessions and Radiologist 2 in 21% of patients. Comparing the results of both Radiologists from Session A and B resulted in 29% and 31% differences respectively. The  $k$  value for intra-observer variation was 0.42 and 0.68 respectively. Interobserver agreement was  $k=0.45$  and 0.50 comparing the BIRADS classification for Sessions A and B respectively.

**Staging Results**

**General comments**

Francis, A., England, D.W., Rowlands, D.C., Wadley, M., Walker, C., Bradley, S.A.. The diagnosis of invasive lobular breast carcinoma. Does MRI have a role? *The Breast*, 10:38-40, 2001

**Design:** Retrospective Case Series Evidence Level 3

**Country:** UK

**Setting:** Hospital

**Inclusion criteria:** invasive lobular carcinoma diagnosed by core biopsy

**Exclusion criteria:**

**Population:** 22 patients, characteristics not reported

**Interventions:** comparison between clinical, ultrasound scan, mammographic imaging and MRI

**Outcomes**

**Results:** There is some evidence that MRI is more accurate than US and clinical examination, both of which underestimated tumour size. MRI and mammography are more accurate in estimating tumour size.

MRI detected 21 of the 22 ILCs while mammography and US detected 16 and 20 respectively. Clinical examination detected 19 tumours.

There was a significant difference in clinical and histological size ( $p=0.0038$ ) with clinical examination underestimating tumour size in 63% of patients.

There was no significant difference between mammographic and histological size ( $p=0.3894$ ).

There was a significant difference between US and histological size ( $p=0.0003$ ), with US underestimating size in 90% of patients.

There was no significant difference between MRI and histological size ( $p=0.6288$ )

**General comments:** study too small to have statistical power. Population characteristics

(age, tumour stage, etc) not reported.

Schelfout, K., Van Goethem, M., Kersschot, E., Verslegers, I., Biltjes, I., Leyman, P., Colpaert, C., Thienpont, L., Van den Haute, J., Gillardin, J, P., Tjalma, W., Buytaert, Ph., Schepper, A. De., Preoperative Breast MRI in Patients with Invasive Lobular Breast Cancer. Eur Radiol: 14: pp1209-1216, 2004

**Design:** Retrospective Case Report Evidence Level 3

**Country:** Belgium

**Setting:** Hospital

**Inclusion criteria:** Patients who had been diagnosed with Infiltrative Lobular Carcinoma (ILC) +/- LCIS (Lobular Carcinoma in situ) and who had undergone preoperative MR imaging of the breast and had all original pathology, imaging and clinical examination reports available for review.

**Exclusion criteria:** Associated ductal carcinoma

**Population:** 26 women, age range 41-74 (mean 56.9 years)

**Interventions:** MRI

**Outcomes:** Use of MRI in preoperative staging of ILC and detection of multifocal/multicentric disease

**Results:** MRI may play an important role in the evaluation of patients with ILC, which is often difficult to diagnose on clinical examination and conventional imaging and more likely occur in multiple sites and in both breasts. However, false-negative MR findings do occur in a small percentage of ILC. MR findings of unifocal, multifocal, single quadrant and multi quadrant disease were correlated with other imaging techniques and compared with histological findings. Most ILC presented on MRI as a single speculated/irregular, inhomogeneous mass (pattern 1,  $n=12$ ) or as a dominant lesion surrounded by multiple small enhancing foci (pattern 2,  $n=8$ ). Multiple small enhancing foci with interconnecting enhancing strands (pattern 3) and an architectural distortion (pattern 4) were both described in three cases. There was one case of a focal area of inhomogeneous enhancement (pattern 5) and one normal MR examination (pattern 6). Unifocal and multifocal lesions were identified on MRI in four patients with normal conventional imaging. In nine women, multiple additional lesions or more extensive multiquadrant disease were correctly identified only on MRI.

Kvistad, K.A., Rydland, J., Smethurst, H.-B., Lundgren, S., Fjosne, H.E., Haraldseth, O. Axillary Lymph Node Metastases In Breast Cancer: Preoperative Detection with Dynamic Contrast-Enhanced MRI. *Eur. Radiol*, 10: 1464-1471, 2004

**Design:** Prospective Case Control Evidence Level 2++

**Country:** Norway

**Setting:** Hospital

**Inclusion criteria:** patients with invasive breast cancer to be treated with axillary node dissection

**Exclusion criteria:**

**Population:** 65 patients with level I and II axillary node dissection; mean age 59.4 (range 38-79)

<u>Characteristics</u>	<u>n=</u>	<u>Histology</u>	<u>n=</u>	<u>Tumour staging</u>	<u>n=</u>
Premenopausal	18	Invasive ductal carcinoma	54	T1a	0
Postmenopausal	47	Invasive lobular carcinoma	3	T1b	13
		Mucinous carcinoma	4	T1c	25
<b>Intervention</b>	<b>n=</b>	Tubular carcinoma	2	T2	20
Mastectomy	45	Undifferentiated adenocarcinoma	2	T3 and T4	7
Wide local incision	20				

**Interventions:** evaluating the value of MRI in axillary node staging

**Outcomes:** sensitivity, specificity, accuracy

**Results:** There is good evidence that axillary lymph nodes can be evaluated as a part of an MR-mammography study without substantial increase in examination time, and provide the surgeon with knowledge about the localisation of possible metastatic lymph nodes. Using dynamic contrast enhanced imaging, a 83% sensitivity and a 90% specificity for the presence of lymph node metastases was found with the chosen threshold of abnormal signal intensity increase.

When using a signal intensity increase in the lymph nodes of >100% during the first postcontrast image as a threshold for malignancy, 57/65 patients were correctly classified (sensitivity 83%, specificity 90%, accuracy 88%).

These results were not improved when lymph node size and morphology were used as additional criteria.

When combining enhancement patterns (signal intensity increase) and morphological criteria of the tumour to improve specificity of the method, the sensitivity decreased to 65%, without significant increase in specificity.

Using the size and shape of the axillary lymph nodes in MR images as a criteria correlated poorly to the presence of metastases, with a sensitivity of 63% and a specificity of 80%.

These results are comparable to CT examinations of the axilla but are poorer than the results from ultrasound examination.

Clinical evaluation had a very low sensitivity of 25%, and was found to be an inaccurate method for

detection of axillary lymph nodes metastases.

Axillary lymph nodes showed contrast enhancement in both ALND-positive and ALND- negative patients, but enhancement was stronger and more rapid in patients with metastases, and on average reached a peak value during the first 57s after contrast injection.

Axillary lymph nodes can be evaluated as a part of an MR-mammography study without substantial increase in examination time, and provide the surgeon with knowledge about the localisation of possible metastatic lymph nodes.

**Comparison of Results of clinical assessment and MRI of axillary lymph nodes**

Parameter	Clinical assessment	Abnormal SI increase	Abnormal SI increase and positive washout sign	Lymph node size >0.5 cm and abnormal morphology	Abnormal SI increase and size >0.5 cm and abnormal morphology
True positive	6	20	17	15	15
True negative	40	37	37	33	38
False positive	1	4	4	8	3
False negative	18	4	7	9	9
Sensitivity (%)	25	83	71	63	63
Specificity (%)	98	90	90	80	93

**Results of patients with at least one axillary lymph node corresponding to the assigned short-axis diameters as measured on the MR images and related to the histopathological axillary lymph node (ALND)**

	Lymph node size ≤0.5 cm	Lymph node size ≤0.5 cm and ≤1.0 cm	Lymph node size ≤0.5 cm and ≤1.0 cm and abnormal morphology	Lymph node size ≤1.0 cm and ≤2.0 cm	Lymph node size ≤1.0 cm and ≤2.0 cm and abnormal morphology	Lymph node size ≤2.0 cm	Lymph node size ≤2.0 cm and abnormal morphology
<b>ALND-positive patients (n=24)</b>	22	15	12	5	5	2	2
<b>ALND-negative patients (n=41)</b>	41	15	8	1	1	0	0

Harishinghani, M. G., Weissleder, R.; Sensitive, Noninvasive Detection of Lymph Node Metastases. Plos Medicine; Vol 1; Issue 3; pp 202-209; 2004

**Design:** Prospective Case Control Study Evidence Level 2-

**Country:** USA

**Setting:** Hospital

**Inclusion criteria:** Histologically validated lymph nodes from patients with primary cancers

**Exclusion criteria:**

**Population:** Test dataset/lymph nodes histologically validated (n=216) prospective cases, from 34 patients with primary cancers; Learning dataset / lymph nodes with known histopathology (n=97) retrospective cases

<u>Parameter</u>	<u>Learning dataset</u>	<u>Test dataset</u>
Patients (n)	37	34
Lymph nodes (n)	97	216
Malignant (n/%)	44 (45%)	46 (21%)
Benign (n/%)	53 (55%)	170 (79%)

	Breast	7
	Penile	4

**Interventions:** semi automated, non-invasive nodal cancer staging using a nonparticle enhanced lymphotropic magnetic resonance (LMRI) technique

**Outcomes:** accurate staging; magnetic tissue parameters of cancer metastases and normal unmatched lymph nodes

**Results:** There is fairly good evidence to suggest the feasibility of semi automated, non-invasive nodal cancer staging using a nonparticle enhanced lymphotropic magnetic resonance (LMRI) technique. Nanoparticles traced by MRI displayed an abnormal pattern when there was metastases in the nodes and a computer software recognises this abnormality. Unique magnetic tissue parameters were found, which accurately distinguished metastatic from normal nodes with an overall sensitivity of 98% and specificity of 92%. The parameters can be applied to data sets in a semi automated fashion and used for 3D reconstruction of complete nodal anatomy for different primary cancers.

**Discriminatory power of Imaging Parameters in Learning dataset**

<u>Analysis</u>	<u>Parameter</u>	<u>Sensitivity</u>	<u>Specificity</u>	<u>PPV</u>	<u>NPV</u>
Visual analysis	Short axis >10	59.0	81.1	72.2	70.4

	mm				
	Round > 8 mm	43.1	73.5	57.7	60.9

	$\delta$ SNR <4.2	52.2	94.3	88.4	70.4
	$\delta$ LNM <0.031	79.1	83.0	79.1	83.0
	$\delta$ T2* <34.9ms	86.4	92.5	90.5	89.1
Semiautomated (post only)	SNR >2.1	95.5	84.9	84.0	95.7
	LNM ratio	97.7	73.6	75.4	97.5
	T2*	93.2	94.3	93.2	94.3
	Pixel variance	97.7	90.6	89.6	98.0
	T2* and variance	97.7	94.3	93.5	98.0

**General comments:** very small study, only 7 of the histologically proven malignancies (lymph nodes) came from breast cancer patients all in the test dataset.

## Evidence Tables- DCIS

Shiraishi, A., Kurosaki, Y., Maehara, T., Suzuki, M., Kurosumi, M.; Extension of Ductal Carcinoma In Situ: Histopathological Association with MR Imaging and Mammography; Magnetic Resonance in Medical Sciences; Vol. 2; No. 4; pp159-163; 2003

**Design:** Retrospective Case Control Study Evidence Level 2++

**Country:** Japan

**Setting:** Hospital

**Inclusion criteria:** Women with DCIS and DCIS with microinvasion

**Exclusion criteria:**

**Population:** 30 women with 30 histologically verified lesions (12 pure DCIS; 18 DCIS with microinvasive foci);

Mean age: 49.8 years (range 34-70 years)

Treated with: 19 mastectomy; 11 BCT

**Interventions:** Evaluating capability of breast MRI and mammography in determining tumour extent and detectability of DCIS.

**Outcomes:** Correlation of MR, Mammography and Histopathological results; Sensitivity

**Results:** There is good evidence that MRI can complement mammography in guiding surgical treatment of DCIS by providing better assessment to the extent of the lesion. 26/30 (86.7% sensitivity) were detected through the MRI as well as 8 lesions without mammographically detected microcalcification. In 7/30 cases MRI showed tumour extent accurately compared with mammography, and the combined diagnosis improved the accuracy of evaluating tumour extent.

### Difference in Tumour Extent Between Imaging and Specimen

	0	≤ 10mm	11-20mm	≥ 21mm	≤ 10mm	11-20mm	≥ 21mm
	<b>underestimation</b>				<b>overestimation</b>		
MRI	2 (9.1%)	8 (36.4%)	3 (13.6%)	6 (27.3%)	3 (13.6%)	0	0
Mammography	1 (4.5%)	7 (31.8%)	3 (13.6%)	7 (31.8%)	3 (13.6%)	0	1 (4.5%)
MRI + Mammography	2 (9.1%)	8 (36.4%)	4 (18.2%)	3 (13.6%)	4 (18.2%)	0	1 (4.5%)

MRI + mammography: combined evaluation with MRI and mammography

### Difference in Size Divided by Actural Size of Specimen

	0-20%	21-40%	41-60%	61-80%	81-100%	100%<
MRI	12	3	4	1	2	0
Mammography	9	6	3	2	1	1

**General comments:**

Mariano, M.N., van den Bosch., M.A.A.J., Daniel, B.L., Nowels, K.W., Birdwell, R.L., Fong, K.J., Desmond, P.S., Plevritis, S., Stables, L.A., Zakhour, M., Herfkens, R.J., Ikeda, D.; Contrast-Enhanced MRI of Ductal Carcinoma In Situ: Characteristics of a New Intensity-Modulated Parametric mapping Technique Correlated with Histopathological Findings; Journal of Magnetic Resonance Imaging; Vol 22; pp520-526; 2005

**Design:** Retrospective Case Control Study Evidence Level 2++

**Country:** USA

**Setting:** Hospital

**Inclusion criteria:** Patients with pure DCIS on pathology who underwent conventional mammography and contrast-enhanced (CE) MRI using the intensity-modulated parametric mapping technique

**Exclusion criteria:** Concurrent microinvasion; LCIS; IDC; ILC or inflammatory carcinoma in the specimen

**Population:** 14 patients; Mean age 43 years (range 26-52 years)

**Interventions:** Intensity modulated parametric mapping MRI

**Outcomes:** Correlation with histopathological findings

**Results:** There is good evidence that intensity-modulated parametric mapping technique for breast MRI resulted in the highest detection rate for the DCIS cases. Furthermore, the parametric mapping technique identified all intermediate and high-grade DCIS lesions, suggesting that a negative MRI using the parametric mapping technique may exclude intermediate and high-grade DCIS.

With the use of a kinetic curve shape analysis, MRI classified 7/14 lesions (50%) as suspicious, including four with initial-rapid/late-washout and three initial-rapid / late-plateau. Using morphologic criteria, MRI classified 10/14 (71%) as suspicious., with the most prominent morphologic feature being a regional enhancement pattern. Using the intensity modulated parameteric mapping technique, MRI classified 12/14 cases (86%) as suspicious. Parametric mapping identified all intermediate and high-grade DCIS lesions.

**Detection Rate of 14 Pure DCIS Lesions by Mammography and Contrast-Enhanced MRI Criteria**

Modality	DCIS cases detected
Mammography	9/14 (64%)
MRI kinetic curve-only	7/14 (50%)
MRI morphology-only	10/14 (71%)
MRI parametric mapping technique	12/14 (86%)

**Detection Rate of 14 Pure DCIS Lesions Stratified by Nuclear Grade by Mammography and Contrast-Enhanced MRI**

	Low nuclear grade (n=4)	Intermediate nuclear grade (n=3)	High nuclear grade (n=7)

Mammogram suspicious	2 (50%)	2 (67%)	5 (71%)
MRI kinetic curves suspicious	2 (50%)	0 (0%)	5 (71%)
MRI morphology suspicious	1 (25%)	3 (100%)	6 (86%)
MRI parametric mapping suspicious*	2 (50%)	3 (100%)	7 (100%)

\* MRI parametric mapping identified all intermediate and high grade DCIS lesions

**Level of Periductal Lymphocytic Infiltration Stratified by Nuclear Grade in 14 Pure DCIS Lesions**

	<b>None infiltration (n=4)</b>	<b>Intermediate infiltration (n=5)</b>	<b>Moderate or intense infiltration (n=5)</b>
Low grade DCIS	2 (50%)	2 (40%)	0 (0%)
Intermediate grade DCIS	2 (50%)	1 (20%)	0 (0%)
High grade DCIS	0 (0%)	2 (40%)	5 (100%)

**General comments**

Francescutti, G.E., Londero, V., Berra, I., Del Frate, C., Zuiani, C., Bazzocchi, M.; Breast MRI of Ductal Carcinoma in situ: Is there MRI role? Radiol Oncol; Vol 36(4); pp305-312; 2002

**Design:** Retrospective Case Control Study Evidence Level 2+

**Country:** Italy

**Setting:** Hospital

**Inclusion criteria:** Women diagnosed with DCIS lesions who underwent contrast enhanced MRI within 7 days after mammographic examination

**Exclusion criteria:**

**Population:** 22 women - Mean age 53 (range 42-75 years)  
 Histological Diagnosis: Surgical Biopsy (n=6); Core Needle Biopsy (n=16)  
 DCIS (n=15); DCIS plus Microinvasive Component or Microfoci of IDC (n=7)

**Interventions:** Contrast enhanced MRI

**Outcomes: Sensitivity**

**Results:** There is fairly good evidence that the sensitivity of MRI for DCIS detection is lower than that achieved for invasive breast cancer; however, contrast enhanced MRI can depict foci of DCIS that are mammographically occult. The MRI technique is of complementary value for a better description of tumour size and detection of additional malignant lesions. On MRI, 21/22 (95%) DCIS lesions showed contrast enhancement. 14/15 (93%) pure DCIS lesions demonstrated respectively a low (3), undeterminate (5), and strong (6) enhancement. Morphologically, the enhancing lesion was focal in 7, segmental in 4 and with linear branching in 3 cases. Wash out was found in 4 cases, plateau curve in 8 and Type I curve in 2 cases. Multifocality was present in 5 cases.

All DCIS with associated microinvasion demonstrated contrast enhancement: 1/7 cases showed a low enhancement, 2/7 showed an indeterminate enhancement and 4/7 showed a strong enhancement. Morphologically, the enhancing lesion was focal in 3/9, segmental in 5 and with linear branching in 1 case. The wash out was demonstrated in 3/7 cases, plateau curve in 3 and Type 1 curve in 1 case. Multifocality was present in 3 cases.

All DCIS with associated microinvasion demonstrated contrast enhancement: 1/7 cases showed a low enhancement, 2/7 showed an indeterminate enhancement and 4/7 showed a strong enhancement. Morphologically, the enhancing lesion was focal in 3/9, segmental in 5 and with linear branching in 1 case. The wash out was demonstrated in 3/7 cases, plateau curve in 3 and Type 1 curve in 1 case. Multifocality was present in 3 cases.

**Enhancement rates in 14 DCIS and 7 DCIS with associated minimum invasion**

% of signal intensity increase	DCIS	DCIS+DCI	Total
<70%	3 (21%)	1 (14%)	19%
70%-140%	5 (36%)	2 (29%)	33%
>140%	6 (43%)	4 (57%)	48%
<b>Configuration</b>

Groves, A.M., Warren, R.M.L., Gogward, S., Rajan, P.S.,; Characterization of Pure High-grade DCIS on Magnetic Resonance Imaging Using the Evolving Breast MR Lexicon Terminology: Can it be differentiated from pure invasive disease? Magnetic Resonance Imaging; Vol. 23; pp733-738; 2005

**Design:** Retrospective Case Control Study Evidence Level 2+

**Country:**UK

**Setting:** Hospital

**Inclusion criteria:** Histologically proven pure high-grade DCIS

**Exclusion criteria:** Previous chemotherapy, inadequate MRI, all cases with mixed lesions (invasive and DCIS, including microinvasion) and one patient who was too breathless to undergo an adequate examination

**Population:** 26 patients (13 DCIS compared with 13 invasive carcinoma)

		<b>DCIS</b>	<b>Invasive</b>
<b>Mean Age</b>		56.2 years (range 34-74 years)	53 years (range 42-68 years)
<b>Grade</b>	1	0	3
	2	0	3
	3	13	7
<b>Size</b>	<9 mm	1	1
	10-20 mm	2	5
	>20 mm	10	7
<b>Mean Size</b>		37.3mm (range 6-89mm)	31mm (range 6-97mm)
<b>Unifocal</b>		13	11
<b>Multifocal</b>		0	2

**Interventions:** MRI

**Outcomes:** MRI characteristics of DCIS and invasive breast carcinoma

**Results:** There is fairly good evidence that there are features that help differentiate high-grade DCIS from invasive carcinoma on MRI. High-grade DCIS is significantly more likely to show focal branching pattern ( $p=0.003$ ) or to have an irregular contour ( $p=0.003$ ) compared with invasive disease. All though of marginal statistical significance, DCIS lesions are more likely to have a lower morphological score than invasive carcinoma ( $p=0.006$ ), whilst the latter is more likely to show ring enhancement ( $p=0.007$ ).

**Summary of MRI DCIS and Invasive Breast Carcinoma MRI Characteristics**

	<b>Age (years)</b>	<b>Size (mm)</b>	<b>Percentage Enhancement</b>	<b>Morphological Score</b>	<b>Total Score</b>

**Outcomes:** correlation coefficients to assesses differences in size between imaging and histopathologic examination

**Results:**

There is some evidence that DCIS and DCIS with small invasive carcinoma can be adequately visualised on MRI. Tumour size measured at MRI did correlate with histopathologic size, but in contrast to mammography MRI tended to overestimate the tumour extent.

Mammographic rate of detection for DCIS was 84/52 (90%) and for DCIS with small invasive carcinoma 10/12 (83%)

MRI revealed 1 false negative case and the rate of detection for DCIS was 16/17 (94%).

Correlation of mammographic size with histopathologic size was  $r = .44$  ( $p < .01$ ) and  $r = .49$  ( $p < .03$ ) for MRI. Mammography underestimated the lesion size by 5 mm or more in

47%, whereas with MRI size was adequately assessed in 43% and overestimated in 38%

**Mammographic Findings (n=64) and MRI findings (n=22)**

BiRads clasification	Mammography		MRI	
	%	N	%	N
Negative	11	7	5	1
Benign finding	1	1	0	0
Probably benign finding	16	10	9	2
Suspicious abnormality	50	32	81	18
Highly suggestive malignancy	16	10	5	1
Unknown	6	4	0	0

**General comments**

Menell, J.H., Morris, E.A, Dershaw, D.D., Abramson, A.F., Brogi, E., Liberman, L.,; Determination of the Presence and Extent of Pure Ductal Carcinoma In Situ by Mammography and Magnetic Resonance Imaging; The Breast Journal; Vol. 11; No. 6; 2005

**Design:** Retrospective Case Series Evidence Level 3

**Country:** USA

**Aim:** Hospital

**Inclusion criteria:** Patients with pure DCIS on pathology who underwent conventional mammography and contrast-enhanced (CE) MRI using the intensity-modulated parametric mapping technique:

**Exclusion criteria:**

**Population:** 32 women (33 breasts), 39 sites of pure DCIS; Mean age 53 years (range 34-79 years); no invasive or microinvasive tumour was found

**Interventions:** Contrast-Enhanced MRI

**Outcomes:** Correlation of presence and extent of pure DCIS by mammography and MRI

**Results:** There is some evidence that MRI is significantly more sensitive than mammography in DCIS detection. In women with known or suspected DCIS, MRI may have an important role in assessing the extent of disease in the breast. Of 33 breasts involved, DCIS was discovered by MRI alone in 21 (64%), by both MRI and mammography in 8 (24%) and by mammography alone in 1 (3%), DCIS found at mastectomy without findings of mammography or MRI in 3 breasts (9%). MRI had significantly higher sensitivity than mammography for DCIS detection (29/33 = 88% vs. 9/33 = 27%;  $p < 0.00001$ ). Multiple sites of disease were present in 5 breasts, better demonstrated with MRI in 3, mammography in 1, and equally by both in 1. The predominant enhancement pattern of DCIS on MRI was linear / ductal in 18/29 breasts (62%); mammography found calcifications associated with DCIS in 8/9 (89%). The nuclear grade of DCIS found with MRI and mammography was similar; size of lesion was larger on MRI; breast density did not impact results.

**Detection of any DCIS in 33 Breasts by Imaging Modality, MRI vs. Mammography**

	<b>MRI</b>	<b>Mammography</b>	<b>Neither</b>
Detection of DCIS	29 (88)	9 (27)	3 (9)
Detected only by	21 (64)	1 (3)

## Health Economic Summary

A single literature review was performed to assess the cost-effectiveness of breast MRI in the preoperative staging of invasive breast cancer patients and CDIS patients. From 100 references initially identified through the search, 25 were considered further, although only 9 papers were finally retrieved. In total, 8 papers were excluded: 3 were about screening (Baron et al 2005; Hailey et al 1997; Plevritis et al 2000), 3 did not include an economic analysis (Heiberg et al 1996; Hylton et al 1999; Pietan et al 1999), 1 assessed a study population different to that considered in the topic (Hrung et al 1999), 1 assessed thoracic X-ray as the main intervention, while MRI was used selectively across patients (Norum et al 2000). Only 1 study was finally included in the systematic review (Esserman et al 1999). The only included study (Esserman et al 1999)<sup>1</sup> was a partial economic evaluation (since only costs of MRI were reported). The study was conducted in USA and investigated the usefulness of conducting contrast-enhanced MRI compared to mammography to assess the extent of cancer in the breast before surgery. The study sample included patients with invasive breast cancer, DCIS, Paget's disease and others; therefore, there seemed to be considerably heterogeneity in terms of the type of patients considered at analysis. A small patient sample was considered (i.e. 57 patients in total). The usefulness of MRI was assessed prospectively in the diagnostic study, while the usefulness of mammographies were retrospectively reviewed. The mammography costs were not considered in the cost analysis. Overall, there were relevant limitations both in terms of the clinical and the cost analysis. Moreover, it is not clear whether the study sample, the clinical practice and the unit costs used in the study would be representative within a UK setting. Therefore, the usefulness of this study is very limited and uncertainty remains regarding whether MRI is a cost-effective strategy in the preoperative staging of EBC patients.

Evidence Table

### Economic evaluations

Esserman L et al. Utility of magnetic resonance imaging in the management of breast cancer: evidence for improved preoperative staging. <i>Journal of Clinical Oncology</i> , 1999. 17(1): p. 110-119.
--

#### **Design:**

##### Type of economic evaluation:

Partial economic evaluation (the costs of one of the interventions –mammography- were not included). The type of economic analysis was cost-effectiveness analysis (cost-consequences), with effectiveness derived from a single study and no modelling exercise conducted.

##### Clinical effectiveness:

It was derived from a diagnostic study, for which MRI was conducted prospectively and mammographies, when available, were reviewed retrospectively.

##### Cost estimation:

It considered the potential savings (in terms of surgical procedures –mastectomy, lumpectomy, reconstruction and implants- and radiation therapy) associated with better

---

<sup>1</sup> Note that a quality assessment was not undertaken for this paper for not being a full economic evaluation.

staging achieved with MRI. Some resource consumption derived from authors' assumptions based on their clinical experience, and unit costs from 1997 Medicare reimbursement fees. Resources used were not identified independently of costs. The price year was 1995.

**Country:** USA, **setting:** Hospital

**Inclusion criteria**

Patients with diagnosis of breast cancer (by fine needle aspiration for malignancy, core biopsy for DCIS or invasive breast cancer, or excisional biopsy with positive surgical margins) and planned surgical excision  
 Enrolment: June 1995 – September 1996

**Exclusion criteria**

Not stated

**Population**

57 patients, accounting for 58 diagnoses: 33 patients (57%) with invasive cancer (29 ductal, 2 lobular, 2 multiple histology); 9 patients (16%) with intraductal carcinoma (i.e. invasive cancer plus extensive DCIS) 7 patients (12%) with DCIS; 1 patient (2%) with Paget's; 8 patients (14%) with no residual disease or with LCIS only.

50 of them showed residual tumour at final pathology, and in 5 cases mammography was not repeated after initial biopsy. Final sample size: 45 patients with MRI and mammograms

**Interventions**

- Contrast-enhanced MRI (three-dimensional imaging technique TARGET, with General Electric 1.5 tesla Signa whole body imager) for local staging
- Mammography

The reference standard used in the study was pathologic size (the authors reported that the use of pathologic size as reference standard was somewhat arbitrary, even if blindly conducted for the study)

**Follow up** – It seems that from the moment of conducting the mammogram after initial biopsy to the moment the MRI and pathological results were available

**Results**

MRI was more accurate identifying the extent of disease and would lead to savings by identifying more accurately the type of surgery to undergo.

OUTCOME OF INTEREST*	MRI	Mammography	OVERALL RESULT
Correctly identified presence or absence of disease (number of cases)	55/58	Non stated	-
Accurate in predicting extent of disease (number of cases)	54/58	Non stated	-
False positive results	2/58	Non stated	-
False negative results	2/58	Non stated	-
Concordance with tumour pathology to identify malignancy	44/45 (98%)	38/45 (84%)	P = 0.03
Concordance with tumour pathology on tumour extent	43/44 (98%)	21/38 (55%)	P = 0.001

<b>(overall)</b>			
Concordance with tumour pathology on tumour extent for unifocal disease (invasive)	19/19 (100%)	10/14 (71%)	-
Concordance with tumour pathology on tumour extent for multifocal/multicentric disease	10/10 (100%)	4/9 (44%)	-
Concordance with tumour pathology on tumour extent for intraductal carcinoma	7/8 (88%)	4/8 (50%)	-
Concordance with tumour pathology on tumour extent for DCIS	6/6 (100%)	37 (43%)	-
Concordance with tumour pathology on tumour extent for Paget's disease	1/1 (100%)	21/38 (55%)	-
Cases for which MRI, but not clinical examination and mammography, identified disease too extensive for lumpectomy (i.e. change to mastectomy)	10 (17.54%)	-	-
Cases in which MRI would have changed surgical decision making by predicting successful breast conservation; number (%)	14 (24.56%)	-	-
Unit cost of MRI (charge per hour, \$1995; in 1998, 30 minutes were required per patient)	\$1,500	-	-
Total savings for the study sample by using MRI (\$1995)	\$102,659	-	-
* The most relevant outcomes have been reported in bold			

#### **Authors' conclusions –**

MRI was better than mammograms for both identification of malignancy (98% versus 84%;  $p = 0.03$ ), concordance on extent (98% versus 55%;  $p < 0.001$ ) and extent of disease in extensive intraductal carcinoma (88% versus 50%), and it has potential to lead to cost savings.

#### **General comments –**

In terms of the analysis of clinical effectiveness, the study was a diagnostic study that used prospective data to assess MRI and retrospective data to assess mastectomy. The investigator recording MRI measurements was blinded to mammographic results and pathology was independently reviewed in a blinded way. However, the sample size of the study was small, and included patients with invasive breast cancer, DCIS patients, patients with Paget's disease, etc. As the authors stated, the study was designed to gather information to assess MRI, and not to direct surgical therapy, therefore the

outcome 'potential impact of MRI on surgical decision making' may be of limited usefulness. The authors additionally highlighted, as potential barrier for the introduction of MRI, the difficulties in image interpretation and reader variability, although they mention that the type of technology used in the study (TARGET) helps reducing both problems. The authors mentioned that the study sample was likely to be representative of the patients seen within the community and at academic centres who are likely to benefit from MRI, although they may have referred to a USA setting. In terms of generalisability of the results, the study was conducted in USA (therefore the clinical practice may be different, and so resource use may differ from the UK, as will costs/prices). For these reasons, the study may not be generalisable/ applicable to the UK setting. There was not a direct comparison of the costs of MRI with those of mammography; therefore, the authors' conclusions are questionable. Given that the costs of the alternative of using mammograms were not considered in the study, nothing can be clearly concluded regarding the cost-effectiveness of MRI compared to mammograms.

## **2.2 What is the role of pre-treatment ultrasound assessment in staging the axilla?**

### **Short Summary**

The evidence for this topic comes from case series studies and one meta-analysis which pooled estimates.

Eight studies reported the proportion of cases in whom it was possible to visualise axillary lymph nodes on ultrasound. This proportion had a mean of 76% and median 81% but varied widely, with a range 35% to 99%. The remaining proportion represents patients for whom ultrasound does not add any information. (Altinyollar *et al.* 2005, Brancato *et al.* 2004, Damera *et al.* 2003, Deurloo *et al.* 2003, Dixon *et al.* 1992, Esen *et al.* 2005, Nori *et al.* 2005 and Podkrajsek *et al.* 2005).

The systematic review by Alvarez *et al.* (2006) performed a meta-analysis of staging outcomes for 'grey scale' axillary ultrasound based upon 16 case series studies. The meta-analysis provided pooled estimates of staging outcomes. When patients with palpable and non-palpable axillary lymph nodes were combined, lymph nodes that were suspicious on ultrasound based on their size (> 5mm); sensitivity was 69.2% and specificity was 75.2%. If lymph nodes were suspicious on ultrasound based on their morphology the sensitivity was 71.0% and specificity was 86.2%. Considering only studies of patients with non-palpable lymph nodes, ultrasound had reduced sensitivity (using the morphologic criterion for nodal involvement) and there was little change in specificity. When a meta-analysis including only patients in whom it was possible to obtain biopsy material by ultrasound were considered, the pooled sensitivity was 75.0% and the pooled specificity was 98.3%. In a meta-analysis of patients in whom ultrasound-guided biopsy was planned, and defining failure to find a node on ultrasound or failure to collect biopsy material as a negative screen was conducted, the effect of these classifications was to reduce the sensitivity of ultrasound compared to earlier values, with little change in its specificity.

From case series studies the staging performance of 'grey scale' ultrasound alone showed a mean sensitivity of 62%, a mean specificity of 87%, a positive predictive value of 86% and a negative predictive value of 71%. (Altinyollar *et al.* 2005, Bartonkova *et al.* 2006, Brancato *et al.* 2004, Chandawarkar *et al.* 1997, Esen *et al.* 2005, Heusinger *et al.* 2005, Lee *et al.* 1996, Hergan *et al.* 1996, Sato *et al.* 2004 and Van Rijk *et al.* 2006).

The staging performance of 'grey scale' ultrasound plus colour doppler ultrasound showed a mean sensitivity of 65%; a mean specificity of 89% a positive predictive value of 78% and a negative predictive value of 81%. (Couto *et al.* 2004, Dixon *et al.* 1992, Esen *et al.* 2005, Lee *et al.* 1996, Nori *et al.* 2005, Perre *et al.* 1996, Podkrajsek *et al.* 2005 and Walsh *et al.* 1994).

The staging performance of ultrasound guided fine needle aspiration cytology (FNAC) showed a mean sensitivity of 43%, a mean specificity of 100%, a positive predictive value of 99% and a negative predictive value of 72%. (Brancato *et al.* 2004, Damera *et al.* 2003, De Kanter *et al.* 2006, Deurloo *et al.* 2003, Lemos *et al.* 2005, Podkrajsek *et al.* 2005, Stewart *et al.* 2006 and Van Rijk *et al.* 2006). Ciatto *et al.* (2007) reported an overall sensitivity of 72.6% and specificity of 95.6% with a negative predictive value of 67.2% and a positive predictive value 96.6% when excluding inadequate results from analysis; including inadequate results as a negative gave a sensitivity of 64.6%, specificity of 95.7%, negative predictive value of 61.3% and a positive predictive value of 96.6%. Sahoo *et al.*

(2007) reported an overall sensitivity of 96% and specificity of 93%. Somasunder et al. (2006) reported an increase in sensitivity from T1 (35%) to T3/4 (78%) and specificity from T1 (96%) to T3/4 (100%). The likelihood of node FNAC being positive was linked with tumour stage (Ciatto *et al.* 2007; Somasunder *et al.* 2006). Ciatto *et al.* (2007) also reported a significant association with histological grade and number of nodes involved. Sahoo *et al.* (2007) reported that 40 (70%) patients with positive ultrasound FNAC were spared the additional step of SLNB while Somasunder *et al.* (2006) reported that 79 (47%) patients with positive ultrasound FNAC were spared SLNB.

**PICO**

Population	Intervention	Comparison	Outcomes
Patients with early invasive breast cancer who require staging of the axilla and staging procedure planned is less than an axillary clearance.	Ultrasound assessment of the axilla	No USS assessment	Diagnostic accuracy of nodal involvement
	Report results by subgroups: i) with concurrent core biopsy/FNAB ii) without concurrent core biopsy/FNAB if possible between FNAB and core biopsy	USS assessment but no FNAC/core biopsy  USS assessment including FNAC/core biopsy where appropriate.	Utility (operations prevented)  Changes to treatment strategy – particularly use of neoadjuvant chemotherapy  Unnecessary treatment  Cost effectiveness

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

**Evidence Summary**

The majority of the studies are set in the context of selecting patients for either axillary dissection, or less extensive surgery (most often SLNB) on the basis of US imaging and in some studies, US guided axillary biopsy.

The majority of studies (16) are of series of patients treated in Europe. Two series of patients were treated in Turkey, one series in Taiwan, and one series in Japan. One case series study appears to represent a US-Indian team of authors and the systematic review was undertaken in Spain.

Studies vary in terms of their choice of gold standard: either axillary clearance, axillary sample or SLNB.

Criteria for suspicious (i.e. disease positive) nodes on US also vary, but are usually based on the size of lymph nodes or more commonly, morphologic criteria and in the case of colour doppler US, vascular criteria.

The staging performance outcomes vary considerably across the studies, as evidenced by the demonstrated heterogeneity in the systematic review by Alvarez et al. (2006). In particular, the rate of visualising axillary nodes on US varies widely across the studies, and in fact, many authors do not report this rate in their series.

## Staging performance outcome measures

		Axillary nodal disease status attributed by Gold Standard		
		Present	Absent	
US imaging result	+	a	b	test positive a+b
	-	c	d	test negative c+d
		Axillary disease positive a+c	Axillary disease negative b+d	<b>Total</b>

Sensitivity =  $a/[a+c]$

1-sensitivity = false negative rate

Specificity =  $d/[b+d]$

1-specificity = false positive rate

Positive predictive value (PPV) =  $a/[a+b]$

Negative predictive value (NPV) =  $d/[c+d]$

### Visualisation of axillary nodes by US

Only 8 studies reported the proportion of cases<sup>2</sup> in whom it was possible to visualise axillary lymph nodes on US. This proportion had mean 76% and median 81% but varied widely, with range 35% to 99%. The complement of this proportion represents patients for whom US does not add any information.

[Altinyollar *et al.* 2005, Brancato *et al.* 2004, Damera *et al.* 2003, Deurloo *et al.* 2003, Dixon *et al.* 1992, Esen *et al.* 2005, Nori *et al.* 2005 and Podkrajsek *et al.* 2005]

The remaining studies do not report a rate of identification of axillary nodes on US, but some (for example, Sato *et al.* 2004) report staging outcomes for their entire, consecutive series of patients. This implies that either axillary nodes were identified in 100% of patients, or that failure to identify any nodes was considered to be a negative result by US, or that only patients with successfully visualised axillary nodes on US were analysed.

## Staging performance of axillary US

### Systematic review evidence

Of the 22 included studies, there was one systematic review that performed meta-analysis of staging outcomes for grey scale axillary US based upon 16 case series studies (Alvarez *et al.* 2006). The meta-analysis provided pooled estimates of staging outcomes as shown

---

<sup>2</sup> Some studies counted the number of axillae rather than patients, such that a patient with bilateral breast cancer underwent two imaging procedures, counted as two axillae.

below. For the majority of meta-analyses performed, there was significant statistical heterogeneity amongst individual study results.

**Meta-analysis of patients with palpable axillary nodes and patients with non-palpable axillary nodes combined (Alvarez et al. 2006):**

Nodal size criterion<sup>3</sup>:

Sensitivity = 69.2% [95% CI 63.4-74.6]

Specificity = 75.2% [95% CI 70.4-79.6]

Morphologic criterion<sup>4</sup>:

Sensitivity = 71.0% [95% CI 65.2-76.3]

Specificity = 86.2% [95% CI 82.6-89.3]

Therefore US using either criterion was associated with similar sensitivity, whereas US using the morphologic criterion had higher specificity.

**Meta-analysis of patients with non-palpable axillary nodes only (Alvarez et al. 2006):**

Considering only studies of patients with non-palpable nodes, US had reduced sensitivity to the above, when using the morphologic criterion for nodal involvement and there was little change in specificity:

Nodal size criterion:

Pooled sensitivity = 60.9% [95% CI 54.5%-67.1%]

Pooled specificity = 77.3% [95% CI 72.5%-81.6%]

Morphologic criterion:

Pooled sensitivity = 43.9% [95% CI 37.1%-50.8%]

Pooled specificity = 92.4 [95% CI 88.7%-95.2%]

**Meta-analysis of only patients in whom it was possible to obtain biopsy material by US (Alvarez et al. 2006):**

Pooled sensitivity = 75.0% [95% CI 70.3%-79.3%]

Pooled specificity = 98.3% [95% CI 96.2%-99.4%]

**Meta-analysis of patients in whom US guided biopsy was planned, but defining failure to find a node on US as a negative screen and failure to collect biopsy material as a negative screen (Alvarez et al. 2006):**

The effect of these classifications was to reduce the sensitivity of US compared to the above, with little change in its specificity:

Pooled sensitivity = 45.4% [95% CI 40.0%-50.9%]

Pooled specificity = 99.6% [95% CI 98.6%-100%]

**Other studies**

21 case series studies provide data in a similar format. These are as follows.

**Grey scale US alone**

---

<sup>3</sup> Where nodes are suspicious on US based on their size being >5mm.

<sup>4</sup> Where nodes are suspicious on US based on their morphology.

11 studies provided data on the staging performance of grey scale US alone, with summary statistics as follows:

	Sensitivity	Specificity	PPV	NPV
mean	62%	87%	86%	71%
median	64%	87%	87%	75%
Highest	81%	100%	100%	88%
lowest	35%	71%	74%	46%

[Altinyollar 2005, Bartonkova 2006, Brancato 2004, Chandawarkar 1997, Damera 2003\*, Esen 2005, Heusinger 2005, Lee 1996, Hergan 1996, Sato 2004 and Van Rijk 2006].

\* *This study was included in the systematic review by Alvarez et al. (2006).*

### **US including colour doppler**

8 studies provided data on the staging performance of grey scale US plus colour doppler US, with summary statistics as follows:

	Sensitivity	Specificity	PPV	NPV
mean	65%	89%	78%	81%
median	71%	92%	85%	81%
Highest	86%	100%	100%	90%
lowest	38%	71%	52%	73%

[Couto 2004, Dixon 1992, Esen 2005, Lee 1996, Nori 2005, Perre 1996, Podkrajsek 2005 and Walsh 1994].

Figure 1 illustrates the staging performance of grey scale US and combined grey scale US with colour doppler based on 17 series of patients.

**Figure 1**

**Grey scale plus colour doppler US series:**

Couto *et al.* 2004, Dixon *et al.* 1992, Esen *et al.* 2005, Lee *et al.* 1996, Nori *et al.* 2005, Perre *et al.* 1996, Podkrajsek *et al.* 2005, Walsh *et al.* 1994

**US plus FNAC**

8 studies provided data on the staging performance of US guided FNAC, with summary statistics as follows:

	Sensitivity	Specificity	PPV	NPV
mean	43%	100%	99%	72%
median	46%	100%	100%	73%
Highest	59%	100%	100%	85%
lowest	21%	98%	97%	63%

[Brancato 2004, Damera 2003\*, De Kanter 2006, Deurloo 2003\*, Lemos 2005, Podkrajsek 2005, Stewart 2006 and Van Rijk 2006].

\* These two studies were included in the systematic review by Alvarez *et al.* (2006).

Figure 2 illustrates the staging performance of combined US and FNAC based on 8 series of patients.

**UPDATE EVIDENCE**

Three observational studies reported on the sensitivity and specificity of US guided FNAC, two of these studies also reported on surgical management.

Ciatto *et al.* (2007) reported an overall sensitivity of 72.6% and specificity of 95.6% with NPV of 67.2% and PPV 96.6% when excluding inadequate results from analysis; including inadequate results as negative gave a sensitivity of 64.6%, specificity of 95.7%, NPC of 61.3% and PPV of 96.6%.

Sahoo *et al.* (2007) reported an overall sensitivity of 96% and specificity of 93%.

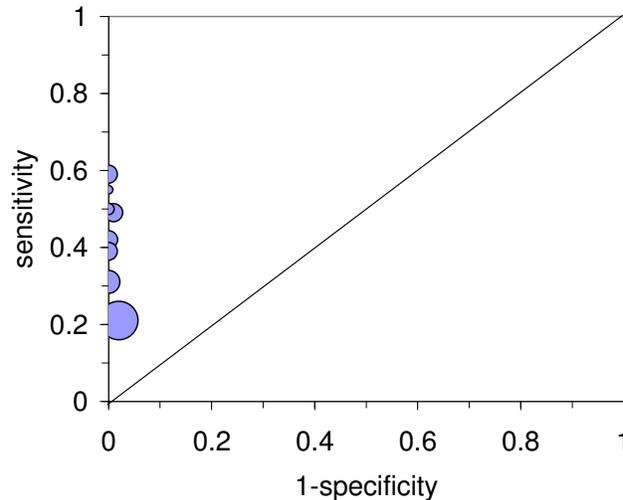

Evidence from two studies show that the likelihood of node FNAC being positive was linked with tumour stage (Ciatto *et al.* 2007; Somasunder *et al.* 2006). Ciatto *et al.* (2007) also reported a significant association with tumour grade ( $p < 0.00001$ ) and number of nodes involved ( $p < 0.001$ ). Somasunder *et al.* (2006) reported an increase in sensitivity from T1 (35%) to T3/4 (78%) and specificity from T1 (96%) to T3/4 (100%). No p values were given.

Sahoo *et al.* (2007) reported that 40 (70%) patients with positive US FNAC were spared the additional step of SLNB while Somasunder *et al.* (2006) reported that 79 (47%) patients with positive USFNAC were spared SLNB.

**Figure 2**

ROC curve for pre-operative detection of positive axillary nodes by combined US with FNAC (8 studies)

Circle area is proportional to the number of subjects in each study

Brancato 2004, Damera 2003, De Kanter 2006, Deurloo 2003, Lemos 2005\*, Podkrajsek 2005\*, Stewart 2006, Van Rijk 2006.

*\* Indicates two studies that used colour doppler US with biopsy. All other studies are of grey scale US.*

### **Avoidance of unwarranted surgical procedures**

In the study by Brancato et al. (2004) a post hoc analysis demonstrated that in a series of 155 patients, the use of axillary US with performance of FNAC in all visualised axillary nodes avoided 6 inappropriate axillary clearances (in patients with negative definitive axillary histology) and 5 of 34 inappropriate SLNB procedures (in patients with positive definitive axillary histology) that would have arisen without the use of US guided FNAC.

The same study also demonstrated that had FNAC only been performed in patients with suspicious nodes on US, then 6 inappropriate axillary clearances and 3 of 34 inappropriate SLNB procedures would have been avoided that would have arisen without the use of US guided FNAC.

### **Health economics**

Only one study provided any health economic information. The study by Brancato et al. (2004) calculated the cost of staging one patient by surgery alone, with no axillary US/FNAC, as EUR 104.

The use of US with FNAC performed in all cases with visualised nodes as per the study protocol resulted in a cost of EUR 103 to stage one patient.

The use of US with performance of FNAC only in cases with suspicious nodes on US resulted in a cost of EUR 90 to stage one patient.

## Evidence Tables

### Systematic review of diagnostic studies

Alvarez, Anorbe, Alcorta, Lopez, Alonso & Cortes . Role of sonography in the diagnosis of axillary lymph node metastases in breast cancer: a systematic review. [Review] [29 refs]. AJR American Journal of Roentgenology. 186[5]. 2006.

Design: Systematic review of diagnostic studies (diagnosis, screening), evidence level: 2+

Country: Spain, setting: Secondary care

#### **Inclusion criteria** Studies had to report on:

Patients with breast cancer;

US axilla performed before SLNB or axillary clearance;

US at 7MHz or higher;

Sonographic criteria for positivity or based upon US guided biopsy;

Axillary dissection or SLNB as gold standard;

Results expressed as sensitivity and specificity.

Also, for meta analysis, studies had to provide data from which numbers of true positive, true negative, false positive and false negative results could be determined.

**Exclusion criteria** See above.

**Interventions** Aim: to evaluate the role of US, with or without US guided biopsy, in staging the axilla.

**Outcomes** Pooled estimates of sensitivity and specificity for:

Studies of patients with palpable and non-palpable axillary nodes;

Studies of patients with non-palpable axillary nodes only;

Studies of only patients who underwent US guided axillary node biopsy.

Outcomes are reported in two further sub-groups:

1. Where nodes are suspicious on US based on their size >5mm;
2. Where nodes are suspicious on US based on their morphology.

**Follow up** Not reported.

**Results** Meta-analysis of patients with palpable axillary nodes and patients with non-palpable axillary nodes combined:

1. Nodal size criterion on US

Pooled sensitivity = 69.2% [95% CI 63.4-74.6]

Pooled specificity = 75.2% [95% CI 70.4-79.6]

2. Morphologic criterion on US

Pooled sensitivity = 71.0% [95% CI 65.2-76.3]

Pooled specificity = 86.2% [95% CI 82.6-89.3]

For these results, statistical heterogeneity was demonstrated for all but sensitivity in the setting (1.).

Meta-analysis of patients with non-palpable axillary nodes only:

1. Nodal size criterion on US

Pooled sensitivity = 60.9% [95% CI 54.5%-67.1%]

Pooled specificity = 77.3% [95% CI 72.5%-81.6%]

2. Morphologic criterion on US

Pooled sensitivity = 43.9% [95% CI 37.1%-50.8%]

Pooled specificity = 92.4 [95% CI 88.7%-95.2%]

Statistical heterogeneity was demonstrated for all of these results.

Meta-analysis of only patients in whom it was possible to obtain biopsy material by US:

Pooled sensitivity = 75.0% [95% CI 70.3%-79.3%]

Pooled specificity = 98.3% [95% CI 96.2%-99.4%]

Statistical heterogeneity was demonstrated for both of these results.

Meta-analysis of patients in whom US guided biopsy was planned, but defining failure to find a node on US as a negative screen and failure to collect biopsy material as a negative screen:

Pooled sensitivity = 45.4% [95% CI 40.0%-50.9%]

Pooled specificity = 99.6% [95% CI 98.6%-100%]

Statistical heterogeneity was demonstrated for both of these results.

**General comments** Literature search was performed on MEDLINE only, but studies written in four European languages were eligible for inclusion.

Of 367 possible studies, 31 articles were selected and 16 were finally included.

Quality assessment of studies was rigorous and included:

Prospective/retrospective design;

Whether patients were in consecutive series;

Choice of gold standard, and its criteria for node positivity;

US test criteria for node positivity;

Whether assessment of test or gold standard were blind.

All sensitivity and specificity values reported use a combination of axillary clearance or SLNB as gold standard.

Prospective case series

Altinyollar, Dingil & Berberoglu . Detection of infraclavicular lymph node metastases using ultrasonography in breast cancer. J Surg Oncol 92[4]. 2005.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Turkey, setting: Secondary care

**Inclusion criteria** 100 consecutive patients with invasive breast cancer of clinical stage I-II (n=79) and stage III (n=21).

**Exclusion criteria** None stated.

**Population** number of patients = 100, age range 23 to 76 years, median age = 47 years.

**Interventions** Aim: to evaluate the role of preoperative US in identifying axillary and infraclavicular lymph node metastases.

All patients underwent preoperative axillary/infraclavicular US and axillary clearance of levels I, II and III.

**Outcomes** Staging performance of US.

**Follow up** Not reported.

**Results** The mean no. of nodes retrieved by axillary clearance was 24.7 (range 11-39).

Staging performance of axillary ultrasound (all axillary nodes):  
Rate of detection of axillary nodes by US =  $77/100=77\%$ .

Sensitivity =  $49/62 = 79\%$  [95% CI 67%-87%]

Specificity =  $35/38 = 92\%$  [95% CI 79%-97%]

PPV =  $49/52 = 94\%$  [95% CI 84%-98%]

NPV =  $35/48 = 73\%$  [95% CI 59%-83%]

Staging performance of US for status of infraclavicular nodes only:

Sensitivity =  $19/40 = 48\%$  [95% CI 33%-63%]

Specificity =  $59/60 = 98\%$  [95% CI 91%-99.7%]

PPV =  $19/20 = 95\%$  [95% CI 76%-99%]

NPV =  $59/80 = 74\%$  [95% CI 63%-82%]

Upstaging:

79 patients had clinical stage I-II prior to US, and 21 patients stage III. Following US, respective values were 61 and 39 patients and on definitive histology, respective values were 51 and 49 patients.

**General comments** In 21 patients with clinical stage III disease, US was performed after neoadjuvant chemotherapy.

Criteria for suspicious nodes on US were one or more of the following

features:

disappearance of fatty hilus;  
ratio of short:long axis between 0.5-1.0;  
decreased echogenicity;  
eccentric cortical hypertrophy.

Gold standard for staging performance is axillary clearance. Calculation defines cases of nodes not identified by US as 'screened negative'.

Histology technique for axillary nodes: haematoxylin and eosin.

No reporting of blinding with regard to either test (US) or gold standard (axillary clearance) results.

Bartonkova, Schneiderova, Standara, Fait & Fabian . Sensitivity of ultrasound examination of axillary nodes in breast cancer. Ceska.Radiologie. 60[2]. 2006.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Czech Republic (sometimes also rendered as Czechia, setting: Secondary care

**Inclusion criteria** 196 consecutively treated patients with breast cancer.

**Exclusion criteria** Not known.

**Population** number of patients = 196.

**Interventions** Aim: to evaluate the role of US in assessing the status of axillary nodes.

Patients underwent axillary US plus definitive surgical staging.

**Outcomes** Staging performance of axillary US.

**Follow up** Not reported.

**Results** A mean of 8 axillary nodes were examined to provide definitive histology.

Staging performance of US in detecting axillary metastases:

Sensitivity =  $87/138 = 63\%$  [95% CI 55%-71%]

Specificity =  $43/58 = 74\%$  [95% CI 62%-84%]

PPV =  $87/102 = 85\%$  [95% CI 77%-91%]

NPV =  $43/94 = 46\%$  [95% CI 36%-56%]

**General comments** Article written in Czeck: data extracted from tabulated data in the paper plus English language abstract.

Results should be interpreted with caution since entire paper not read.

Staging data are based on the entire series of patients (n=196), who were a consecutive series.

Brancato, Zappa, Bricolo, Catarzi, Risso, Bonardi, Cariaggi, Bianchin, Bricolo, Rosselli Del, Cataliotti, Bianchi & Ciatto . Role of ultrasound-guided fine needle cytology of axillary lymph nodes in breast carcinoma staging. Radiol.Med (Torino) 108[4]. 2004.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Italy, setting: Secondary care

**Inclusion criteria** 159 consecutively treated patients with breast cancer. There were 4 cases of bilateral cancer making a total of 163 axillae but axillary surgery was omitted in four cases, leaving 159 axillae evaluable (155 patients).

**Exclusion criteria** None reported.

**Population** number of patients = 159, age range 23 to 89 years, mean age = 59 years.

**Interventions** Aim: to evaluate the efficacy US guided FNAC in the staging of breast cancer and in the reduction of inappropriate surgery i.e. SLNB where the axilla is positive, or axillary clearance where the axilla is negative.

All patients underwent grey scale US and FNAC was performed in all cases with nodes visualised on US.

**Outcomes** Staging performance of US alone and US guided FNAC;

Inappropriate surgery avoided through use of US guided FNAC.

Cost.

**Follow up** Not reported.

**Results** The rate of visualisation of axillary nodes on US was 133/159 = 83.6%.

Staging performance of US:

Sensitivity = 45/70 = 64% [95% CI 53%-75%]

Specificity = 77/89 = 87% [95% CI 78%-92%]

PPV = 45/57 = 79% [95% CI 67%-88%]

NPV = 77/102 = 75% [95% CI 66%-83%]

Staging performance of combined US and FNAC:

Sensitivity = 41/70 = 59% [95% CI 47%-69%]

Specificity = 89/89 = 100% [95% CI 96%-100%]

PPV = 41/41 = 100% [95% CI 91%-100%]

NPV = 89/118 = 75% [95% CI 67%-82%]

Avoidance of inappropriate operations in 155 evaluable patients:

1. At the time of the study, accepted practice at the centre was to not perform axillary US/FNAC and to perform axillary clearance in all cases of clinically palpable lymph nodes, and SLNB in non palpable cases. In the light of the study, accepted practice would have resulted in 6 inappropriate axillary

clearances and 34 inappropriate SLNBs.

2. The use of US and FNAC of all visualised nodes as per the study protocol avoided all 6 inappropriate axillary clearances and 5 of 34 inappropriate SLNBs.

3. In a post hoc analysis, if US were performed in all cases but FNAC only in cases with suspicious nodes on US, then all 6 inappropriate axillary clearances and 3 of 34 inappropriate SLNBs.

Cost:

1. The cost of staging one patient by accepted practice (no axillary US/FNAC) was EUR 104.

2. The use of US and FNAC of all visualised nodes as per the study protocol resulted in a cost of EUR 103 to stage one patient.

3. In a post hoc analysis, if US were performed in all cases but FNAC only in cases with suspicious nodes on US, then the cost of staging one patient was calculated as EUR 90.

The use of US and FNAC in cases (2) and (3) above was associated with no additional average cost per patient to avoid inappropriate surgery.

**General comments** On US, criteria for suspicious nodes were:  
enlargement/assymetry;  
increased echogenicity;  
irregular structure of the medulla;  
absence of hypechoic hilum;  
greater longitudinal diameter than transverse diameter.

Gold standard was either SLNB or axillary clearance (histological technique not reported).

Cytology smears from FNAC were reported 'in accordance with European Community recommendations'.

Blinding not reported.

Inappropriate procedures were defined as an axillary clearance in the case of negative histology or a SLNB in the case of positive histology.

95% CIs calculated using spreadsheet: acknowledgement to R Newcombe,

[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls).

Chandawarkar & Shinde . Preoperative diagnosis of carcinoma of the breast: Is a 'cost-cutter' algorithm tenable? J Surg Oncol 64[2]. 1997.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: US/India, setting: Secondary care

**Inclusion criteria** 109 patients prospectively recruited, with breast cancer of stage pT1-pT4, who were scheduled for radical mastectomy.

**Exclusion criteria** Not reported.

**Population** number of patients = 109, age range 23 to 69 years.

**Interventions** Aim: to assess the staging performance of palpation, US and mammography in patients with breast cancer.

All patients underwent preoperative clinical examination including palpation of the axilla, followed by US axilla and then mammography of the breast and axilla.

**Outcomes** Staging performance of palpation, US and mammography.

**Follow up** Not reported.

**Results** Staging performance of axillary mammography:

Sensitivity = 69%

Specificity = 67%

PPV = 86%

NPV = 43%

Staging performance of axillary US:

Sensitivity = 77%

Specificity = 71%

PPV = 88%

NPV = 52%

Staging performance of axillary palpation:

Sensitivity = 88%

Specificity = 85%

PPV = 94%

NPV = 72%

Staging performance of combined axillary mammography plus palpation:

Sensitivity = 90%

Specificity = 86%

PPV = 95%

NPV = 76%

Staging performance of combined axillary US plus palpation:

Sensitivity = 94%

Specificity = 90%

PPV = 98%

NPV = 82%

**General comments** No criteria reported for positive test result for palpation, US or mammography.

Gold standard was radical mastectomy; pathological technique not described; blinding not described.

Data provided in paper is insufficient to see details e.g. the numbers of patients with successful imaging, or to calculate confidence intervals.

Couto, Dias, Goncalo, Pinto & de Oliveira . Diagnostic value of ultrasound and color Doppler in identifying axillary lymph node metastases in patients with breast cancer. Eur J Gynaecol.Oncol 25[5]. 2004.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Portugal, setting: Secondary care

**Inclusion criteria** 55 patients with biopsy-proven breast cancer of stage T1-2, N0 with no indications for neoadjuvant treatment.  
One patient had bilateral breast cancer.

**Exclusion criteria** None reported.

**Population** number of patients = 55.

**Interventions** Aim: to evaluate the diagnostic ability of US and colour doppler to identify metastases in axillary lymph nodes.

All patients underwent US/doppler of the axilla and axillary dissection.

**Outcomes** Staging performance of US/doppler.

**Follow up** Not reported.

**Results** Staging performance of US/doppler:

Sensitivity =  $15/21 = 71\%$  [95% CI 50%-86%]

Specificity =  $25/35 = 71\%$  [95% CI 55%-84%]

PPV =  $15/25 = 60\%$  [95% CI 41%-77%]

NPV =  $25/31 = 81\%$  [95% CI 64%-91%]

**General comments** Criteria for suspicion of metastasis on US/doppler were:  
globular shape;  
irregular cortical thickening;  
loss of germinal echogenicity;  
intranodal hypoechogenic mass;  
increased vascularisation in the cortex;  
increased blood flow rates.

Authors describe 'prospective study' but do not state that the patients were a consecutive series. Definitive histology technique not described. No evidence presented of blinding of researchers.

Staging results are reported for 56 axillae in 55 patients.

95% CIs calculated using spreadsheet: acknowledgement to R Newcombe, Cardiff University:  
[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls).

Damera, Evans, Cornford, Wilson, Burrell, James, Pinder, Ellis, Lee & Macmillan . Diagnosis of axillary nodal metastases by ultrasound-guided core biopsy in primary operable breast cancer. Br J Cancer 89[7]. 2003.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** 166 patients with operable, invasive breast cancer.

**Exclusion criteria** Patients with definite locally advanced disease.

Study also excludes patients with suspicious nodes clinically or by imaging that were found to be non-malignant by biopsy or definitive surgery and also patients who did not proceed to definitive surgery.

**Population** number of patients = 166, age range 33 to 81 years.

**Interventions** Aim: to evaluate US guided core biopsy of abnormal axillary nodes in order to decide between axillary clearance or axillary sample/sentinel node biopsy.

Patients underwent US axilla. Patients with abnormal nodes on US underwent US guided core biopsy or FNA.

Patients with metastases detected by US plus core biopsy/FNA underwent axillary clearance to level III.

Patients with no metastases detected by US plus core biopsy/FNA underwent axillary sampling or SLNB.

**Outcomes** Diagnostic performance of US alone and US with core biopsy/FNA.

**Follow up** Not reported.

**Results** Rate of detection of nodes by US = 103/166 = 62%.

Nodes were suspicious on US in 54/103 = 52.4% of patients with nodes seen on US, and these 54 patients underwent US guided biopsy.

Staging performance of US:

Sensitivity = 55%

Specificity = 82%

PPV = 74%

NPV = 65%

Staging performance of US guided biopsy:

Sensitivity = 42%

Specificity = 100%

PPV = 100%

NPV = 74%

The sensitivity of 42% represents 27 patients out of all those with axillary

metastases eventually revealed by surgery (64), who could proceed straight to axillary clearance on the basis of US guided biopsy.

**General comments** Nodes defined as suspicious on US were those with a longitudinal axis: transverse axis of greater than 2 or a nodal cortex thicker than 2mm.

Staging results classify nodes that were not visualised as failures e.g. false negatives.

De Kanter, Menke-Pluijmers, Henzen-Logmans, van Geel, van Eijck, Wiggers & Eggermont . Reasons for failure to identify positive sentinel nodes in breast cancer patients with significant nodal involvement. Eur J Surg Oncol 32[5]. 2006.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Netherlands, the, setting: Secondary care

**Inclusion criteria** 161 clinically node-negative patients with breast cancer, due to undergo definitive surgery.

**Exclusion criteria** None reported, patients appear to be a consecutive series.

**Population** number of patients = 161, mean age = 56 years.

**Interventions** Aim: to investigate the incidence of cases where a falsely negative SLNB result occurs, and to explore explanatory factors.

All patients underwent US axilla with FNAC, followed by SLNB plus axillary clearance.

**Outcomes** Provides data to derive staging outcomes for US plus FNAC.

**Follow up** Not reported.

**Results** Staging performance of US with FNAC:

Sensitivity =  $31/79 = 39\%$  [95% CI 29%-50%]

Specificity =  $82/82 = 100\%$  [95% CI 96%-100%]

PPV =  $31/31 = 100\%$  [95% CI 89%-100%]

NPV =  $82/130 = 63\%$  [95% CI 55%-71%]

**General comments** Study primarily explores a hypothesis to explain cases of falsely negative SLNB, but provides sufficient data (in table 4) to derive staging performance of US with FNAC.

Gold standard: axillary clearance. All axillary nodes were examined using haematoxylin and eosin histology (and sentinel nodes with IHC).

Data present US/FNAC result as 'malignant'/'not malignant'. This indicates that any cases in which no nodes were seen on US would be classed as 'not malignant', pending the gold standard result.

No reporting of blinding.

95% CIs calculated using spreadsheet: acknowledgement to R Newcombe, Cardiff University:  
[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls).

Deurloo, Tanis, Gilhuijs, Muller, Kroger, Peterse, Rutgers, Valdes & Schultze Kool . Reduction in the number of sentinel lymph node procedures by preoperative ultrasonography of the axilla in breast cancer.[see comment]. Eur J Cancer 39[8]. 2003.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Netherlands, the, setting: Secondary care

**Inclusion criteria** 265 patients with breast cancer and clinically uninvolved axillary nodes, including 3 patients with bilateral breast cancer, hence data represent 268 axillary procedures.

**Exclusion criteria** Stated by inclusion criteria.

**Population** , age range 27 to 91 years, mean age = 56 years.

**Interventions** Aim: to evaluate the role of preoperative US plus FNAC in preventing unnecessary SLNB in patients with breast cancer.

Patients underwent US axilla. Patients with suspicious lymph nodes underwent FNAC. Patients with tumour cells detected by FNAC underwent axillary clearance.

Patients with no cancer cells detected by FNAC or in whom US revealed no lymph nodes underwent SLNB.

**Outcomes** Rate of prevention of SLNB by detecting axillary disease preoperatively.

Quantitative features on US to predict nodal involvement (data not shown)

Data permit calculation of staging performance of combined US and FNAC.

**Follow up** Not reported.

**Results** The success rate of US to detect axillary nodes was 93/268 = 34.7%.

Staging performance of combined US and FNAC:

Sensitivity = 37/121 = 30.6% [95% CI 23.1%-39.3%]

Specificity = 147/147 = 100% [95% CI 97.5%-100%]

PPV = 100% [95% CI 90.6%-100%]

NPV = 63.6% [95% CI 57.3%-70.0%]

Of all 268 cases, 37 (13.8%) were spared SLNB procedures.

**General comments** On US, nodes were considered suspicious if the cortex appeared atypical or if the smallest diameter was  $\geq 5$ mm.

Staging performance outcomes for combined US plus FNAC calculated by constructing the 2:2 table from the data provided; failure to find nodes by US, failure to perform FNAC or no cells found by FNAC all classed as negative [95% CIs provided by Cardiff University: R Newcombe, [http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls)].

Dixon, Walsh, Paterson & Chetty . Colour Doppler ultrasonography studies of benign and malignant breast lesions. Br J Surg 79[3]. 1992.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** Study included two groups:  
32 randomly selected patients with cytologically proven breast cancer;  
21 patients with cytologically proven benign breast mass (no data shown).

**Exclusion criteria** Not reported.

**Population** number of patients = 53, age range 15 to 71 years.

**Interventions** Aim: to evaluate the role of US with colour doppler imaging in illustrating primary breast cancer tumours and axillary nodal metastases.

32 patients with cytologically proven breast cancer underwent preoperative US with colour doppler of the breast (no data shown) and the axilla, followed by surgical axillary staging.

**Outcomes** Staging performance of US with colour doppler.

**Follow up** Not reported.

**Results** Axillary nodes were identified in 31 patients. Definitive histological assessment of the axilla was available for 29 patients.

Staging performance of US plus colour doppler:

Rate of detection of axillary nodes by US =  $31/32 = 97\%$ .

Sensitivity =  $9/12 = 75\%$  [95% CI 47%-91%]

Specificity =  $17/17 = 100\%$  [95% CI 82%-100%]

PPV =  $9/9 = 100\%$  [95% CI 70%-100%]

NPV =  $17/20 = 85\%$  [95% CI 64%-95%]

**General comments** Two groups in the study appear to be convenience samples, although data provided here for one series only.

Criteria for suspicious nodes on US and colour doppler:

For nodes seen on US, any clear-cut, persistent doppler signal in or immediately around the node.

Gold standard was either axillary clearance or axillary node sample. No details provided of histological methods. No evidence of blind assessment of results.

Staging results are reported for 29 patients with definitive histological data available (gold standard). Numbers involved are small. 2:2 table constructed from data provided in paper.

95% CIs calculated using spreadsheet: acknowledgement to R Newcombe,  
Cardiff University:

[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls)

Esen, Gurses, Yilmaz, Ilvan, Ulus, Celik, Farahmand & Calay . Gray scale and power Doppler US in the preoperative evaluation of axillary metastases in breast cancer patients with no palpable lymph nodes. Eur Radiol. 15[6]. 2005.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Turkey, setting: Secondary care

**Inclusion criteria** 85 consecutive patients with breast cancer and clinically non-palpable axillary nodes.

**Exclusion criteria** 2 patients were found to have benign disease by definitive surgery and were excluded from the analysis.

**Population** number of patients = 85, age range 30 to 78 years, mean age = 56 years.

**Interventions** Aim: to evaluate the staging performance of US with colour doppler imaging in patients with breast cancer and clinically negative axillary nodes.

All patients underwent US plus colour doppler of the axilla followed by axillary clearance to levels I and II.

**Outcomes** Staging performance of grey scale US and doppler imaging.

**Follow up** Not reported.

**Results** Rate of detection of axillary nodes by US = 82/83 = 98.8%.

Staging performance of grey scale US:

Sensitivity = 81%

Specificity = 94%

PPV = 93%

NPV = 85%

Staging performance of doppler US:

Sensitivity = 51%

Specificity = 97%

PPV = 94%

NPV = 69%

Staging performance of combined grey scale/doppler:

Sensitivity = 86%

Specificity = 94%

PPV = 91%

NPV = 90%

**General comments** Criteria for suspicious nodes on US/doppler:

Absence of echogenic hylum;

Diffuse/asymmetric thickening of the hypoechoic cortex;

Peripheral vascularisation.

No details provided for histological technique. No evidence of blinding.

Heusinger, Lohberg, Lux, Papadopoulos, Imhoff, Schulz-Wendtland, Beckmann & Fasching . Assessment of breast cancer tumor size depends on method, histopathology and tumor size itself\*. Breast Cancer Research & Treatment 94[1]. 2005.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Germany, setting: Secondary care

**Inclusion criteria** 486 patients with invasive breast cancer. Results reported are for those who underwent axillary US plus definitive histology, identified from a prospective, consecutive series of 503 patients.

**Exclusion criteria** Not reported.

**Population** number of patients = 486, mean age = 56 years.

**Interventions** Aim: to ascertain the value of axillary US in patients with invasive breast cancer.

All patients underwent US axilla and definitive axillary surgery.

**Outcomes** Staging performance of axillary US.

**Follow up** Not reported.

**Results** Staging performance of axillary US:

Sensitivity =  $64/156 = 41\%$  [95% CI 34%-49%]

Specificity =  $307/330 = 93\%$  [95% CI 90%-95%]

PPV =  $64/87 = 74\%$  [95% CI 63%-82%]

NPV =  $307/399 = 77\%$  [95% CI 73%-81%]

**General comments** Criteria for suspicious axillary nodes on US not reported. Definitive histology (gold standard) data is tabulated but no details are provided on surgical procedure nor histological technique.

No reporting of blinding.

Cardiff University:

[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls).

Lee, Lee, Su, Liu & Lee . Color Doppler ultrasound evaluation of axillary lymph node in patients with breast tumor. Journal of Medical Ultrasound 4[3]. 1996.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Taiwan (ROC), setting: Secondary care

**Inclusion criteria** 39 female patients with 41 breast cancer tumours.

**Exclusion criteria** Not reported.

**Population** number of patients = 39, age range 36 to 80 years, mean age = 52 years.

**Interventions** Aim: to evaluate the capability of colour doppler US to detect axillary nodal metastases in patients with breast cancer.

All patients underwent preoperative colour doppler US followed by axillary clearance of level I-III.

**Outcomes** Staging performance of colour doppler US.

**Follow up** Not reported.

**Results** Staging performance of grey scale US alone:

Sensitivity =  $14/18 = 78\%$  [95% CI 55%-91%]

Specificity =  $19/23 = 83\%$  [95% CI 63%-93%]

PPV =  $14/18 = 78\%$  [95% CI 55%-91%]

NPV =  $19/23 = 83\%$  [95% CI 63%-93%]

Staging performance of combined grey scale and colour doppler US:

Sensitivity =  $13/18 = 72\%$  [95% CI 49%-88%]

Specificity =  $22/23 = 96\%$  [95% CI 79%-99%]

PPV =  $13/14 = 93\%$  [95% CI 69%-99%]

NPV =  $22/27 = 81\%$  [95% CI 63%-92%]

**General comments** Study is limited by small series size.

40 primary tumours were malignant on definitive surgery, in 39 patients.

Diagnostic criteria on colour doppler US:

Any definable mass in the axilla was taken to be an axillary node. Any persistent colour doppler signal was recorded as a suspicious node.

Gold standard was axillary clearance; no details provided of histological technique. Blinding not reported.

2x2 contingency tables for grey scale US versus gold standard and combined grey scale with colour doppler versus gold standard provided. Staging outcomes are calculated with a total of 41 tumours, one of which was benign, with the effect of lowering the prevalence of axillary disease.

95% CIs calculated using spreadsheet: acknowledgement to R Newcombe, Cardiff University:

[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls)

Lemos, Dias, Goncalo, Pinto, Fernandes & Oliveira . Detection of axillary metastases in breast cancer patients using ultrasound and colour Doppler combined with fine needle aspiration cytology. Eur J Gynaecol.Oncol 26[2]. 2005.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Portugal, setting: Secondary care

**Inclusion criteria** 40 patients with biopsy-proven operable, invasive breast cancer of stage T1-2, N0.

**Exclusion criteria** Patients due to receive neoadjuvant chemotherapy.

**Population** , age range 38 to 85 years, mean age = 59 years.

**Interventions** Aim: to evaluate the staging performance of colour doppler US with FNAC in patients with invasive breast cancer.

All patients underwent US colour doppler of the axilla with FNAC performed on suspicious nodes.

**Outcomes** Staging performance of colour doppler US with FNAC.

**Follow up** Not reported.

**Results** Staging performance of combined greyscale, colour doppler US and FNAC:

Sensitivity = 55%

Specificity = 100%

PPV = 100%

NPV = 85%

**General comments** Criteria for suspicious nodes:

Grey scale US:

Globular shape;

Increased cortical thickness;

Hypoechoic germinal centre;

Presence of 'nodes within the lymph node'.

Doppler:

Increased flow globally or peripherally;

High velocity flow.

Gold standard was histological findings of axillary clearance. Histological technique not reported.

Study is limited by small series size.

Nori, Bazzocchi, Boeri, Vanzi, Nori, Mangialavori, Distante, Masi, Simoncini & Londero . Role of axillary lymph node ultrasound and large core biopsy in the preoperative assessment of patients selected for sentinel node biopsy. Radiol.Med (Torino) 109[4]. 2005.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Italy, setting: Secondary care

**Inclusion criteria** 117 women scheduled for breast conserving surgery and SLNB.

**Exclusion criteria** Clinically involved axillary nodes;  
Multifocal breast cancer;  
Pregnancy;  
Previous breast surgery/excisional biopsy.

Of 117 eligible patients in the series, 15 were excluded, 6 due to benign pathology and 9 due to failure to visualise a minimum of 4 axillary nodes on US. Therefore staging outcomes are based on 102 patients.

**Population** number of patients = 102, age range 29 to 88 years, mean age = 54 years.

**Interventions** Aim: to evaluate the staging performance of axillary US with US guided core biopsy in patients with breast cancer scheduled for SLNB.

All patients underwent US axilla (including colour doppler in an undisclosed number of patients). US guided core biopsy was planned in patients with suspicious nodes on US.

**Outcomes** Staging performance of US guided core biopsy.

**Follow up** Not reported.

**Results** The rate of visualisation of axillary nodes on US (based on 4 exclusions noted above) was 113/117 = 96.6%.

Staging performance of US alone:

Sensitivity = 13/34 = 38% [95% CI 24%-55%]

Specificity = 56/68 = 82% [95% CI 72%-90%]

PPV = 13/25 = 52% [95% CI 34%-70%]

NPV = 56/77 = 73% [95% CI 62%-81%]

Core biopsy:

Core biopsy was indicated in 25 patients with suspicious nodes on US. 11 patients underwent core biopsy and core biopsy was omitted in 14 patients due to deep nodes or nodes close to blood vessels. Compared to definitive histology, core biopsy results were truly positive in 8 patients, truly negative in 2 patients and falsely negative in 1 patient.

**General comments** In some cases colour doppler US was used to avoid puncture of large blood vessels when performing core biopsy. In other cases core biopsy was not performed due to risk of bleeding. Colour doppler was also used in some cases for diagnostic purposes, but was not investigated per

se. Use of doppler may enhance the performance of grey scale US in this study.

Criteria for suspicious nodes on grey scale US:

globular morphology;

disappearance of hilar fat hyperechogenicity;

eccentric focal thickening/denting of cortex.

Criteria for suspicious nodes on colour doppler US (used selectively):

peripheral vascularisation;

focal absence of vascularisation;

displacement of intranodal vessels.

Definitive histology results are reported, but not the technique used. Paper implies that gold standard was either SLNB or axillary dissection as indicated by US or core biopsy, but not stated absolutely. No reporting of blinding.

95% CIs calculated using spreadsheet: acknowledgement to R Newcombe,  
Cardiff University:

[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls).

Perre, Koot, De, Weits & Leguit . Colour Doppler ultrasonography in the diagnosis of axillary lymph node metastases in breast cancer. Breast 5[1]. 1996.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Netherlands, the, setting: Secondary care

**Inclusion criteria** 98 consecutive patients with breast cancer.

**Exclusion criteria** None stated.

**Population** number of patients = 98.

**Interventions** Aim: to determine the value of colour doppler US in the preoperative detection of axillary metastases in patients with breast cancer.

All patients underwent colour doppler US.

**Outcomes** Staging performance of colour doppler US.

**Follow up** Not reported.

**Results** Staging performance of colour doppler US for the whole series (n=100):

Sensitivity =  $16/32 = 50\%$  [95% CI 34%-66%]

Specificity =  $56/68 = 82\%$  [95% CI 72%-90%]

PPV =  $16/28 = 57\%$  [95% CI 39%-73%]

NPV =  $56/72 = 78\%$  [95% CI 67%-86%]

Staging performance of colour doppler US for patients who underwent prior breast surgery (n=26):

Sensitivity =  $1/3 = 33\%$  [95% CI 6%-79%]

Specificity =  $20/23 = 87\%$  [95% CI 68%-95%]

PPV =  $1/4 = 25\%$  [95% CI 5%-70%]

NPV =  $20/22 = 91\%$  [95% CI 72%-97%]

Staging performance of colour doppler US for patients who did not undergo prior breast surgery (n=74):

Sensitivity =  $15/29 = 52\%$  [95% CI 34%-69%]

Specificity =  $36/45 = 80\%$  [95% CI 66%-89%]

PPV =  $15/24 = 63\%$  [95% CI 43%-79%]

NPV =  $36/50 = 72\%$  [95% CI 58%-83%]

**General comments** Data are presented for 100 axillae in 98 patients.

Criteria for suspicious lymph nodes:

Nodes visualised on grey scale US were studied with colour doppler US, and peripheral flow was regarded as malignant (central flow benign).

Gold standard: axillary clearance. Histological technique not reported. Blinding not reported.

26 patients underwent breast surgery (but not axillary clearance) prior to axillary US. Results are also provided for these patients separately. Sub

group analysis results in small numbers (and wide confidence intervals).

For calculation of outcomes, authors classified equivocal colour doppler US findings (n=5) as negative (whether proven false negative or true negative by definitive histology).

95% CIs calculated using spreadsheet: acknowledgement to R Newcombe,  
Cardiff University:  
[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls).

Podkrajsek, Music, Kadivec, Zgajnar, Besic, Pogacnik & Hocevar . Role of ultrasound in the preoperative staging of patients with breast cancer. Eur Radiol. 15[5]. 2005.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Slovenia, setting: Secondary care

**Inclusion criteria** 165 patients with biopsy-proven breast cancer and clinically uninvolved axillary nodes, who were scheduled for SLNB.

**Exclusion criteria** None stated.

**Population** number of patients = 165, age range 26 to 80 years, mean age = 56 years.

**Interventions** Aim: to evaluate the utility of grey scale and colour doppler US with US guided FNAC in the diagnosis of axillary metastases.

All patients underwent preoperative US axilla. Nodes seen on grey scale US underwent colour doppler evaluation. Nodes that were suspicious for malignancy underwent US guided FNAC.

Patients with any axillary malignancy detected by FNAC underwent axillary clearance to level I and II. Patients with no axillary malignancy detected by FNAC underwent SLNB.

**Outcomes** Staging performance of US alone (including colour doppler) and of US guided FNAC.

**Follow up** Not reported.

**Results** Rate of detection of lymph nodes by US =  $90/165 = 55\%$  [95% CI 47%-62%].

Staging performance of combined grey scale/colour doppler US and FNAC:

1. As reported in paper:

Sensitivity =  $32/38 = 84\%$  [95% CI 70%-93%]

Specificity =  $10/11 = 91\%$  [95% CI 62%-98%]

PPV =  $32/33 = 97\%$  [95% CI 85%-99%]

NPV =  $10/16 = 63\%$  [95% CI 39%-82%]

Note: these values are based only on 49 patients who underwent FNAC. The values considering all 165 patients in the series are as follows:

2. For all patients:

Sensitivity =  $32/65 = 49\%$  [95% CI 37%-61%]

Specificity =  $99/100 = 99\%$  [95% CI 95%-100%]

PPV =  $32/33 = 97\%$  [95% CI 85%-99%]

NPV =  $99/132 = 75\%$  [95% CI 67%-82%]

Staging performance of grey scale/colour doppler US alone:

Sensitivity =  $38/65 = 58\%$  [95% CI 46%-70%]

Specificity =  $89/100 = 89\%$  [95% CI 81%-94%]

PPV =  $38/49 = 78\%$  [95% CI 64%-87%]

NPV = 89/116 = 77% [95% CI 68%-83%]

In patients with no detectable lymph nodes on US, the prevalence of axillary metastases by SLNB was 18/75 = 24% [95% CI 16%-35%].

In the whole series 32/165 = 19% [95% CI 14%-26%] of patients were spared a second surgical procedure.

**General comments** Colour doppler US was performed on all nodes seen on grey scale US. Study does not report outcomes for grey scale US and colour doppler US separately, but combined.

Criteria for suspicious nodes on US:

Longitudinal:transverse axes ratio <1.5;

Hilus not visible;

Cortex thickness >3mm;

non-hilar-peripheral or mixed vascularity (on colour doppler).

Gold standard for staging outcomes is either SLNB or axillary clearance. Histological technique for FNAB and for SLNB was immunohistochemistry. Technique for axillary clearance was reported as 'standard method'. No reporting of blinding.

Staging outcomes for the whole series of patients denote patients with no nodes seen on US or in whom FNAC was not performed as 'negative on US' and patients with equivocal results on FNAC as 'negative on FNAC'.

95% CIs calculated using spreadsheet: acknowledgement to R Newcombe, Cardiff University:  
[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls).

Stewart, Meacock, Ljutikov, Evans, Wasan, Milnes, Akbar, Dutt, Li & Michell .  
Ultrasound and fine needle aspiration assessment of the axilla in patients with  
operable invasive breast cancer. Breast Cancer Research 8[Suppl 1]. 2006.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** 71 patients with invasive breast cancer.

**Exclusion criteria** Not reported.

**Population** number of patients = 71.

**Interventions** Aim: to evaluate US with FNAC in staging the axilla in patients  
with invasive breast cancer.

All patients underwent US axilla with FNAC, and axillary staging surgery.

**Outcomes** Staging performance of US with FNAC.

**Follow up** Not reported.

**Results** Staging performance of US with FNAC:

Sensitivity = 50%

Specificity = 100%

PPV = 100%

NPV = 71%.

**General comments** Study available in abstract only.

US criteria to indicate FNAC were:

Cortex >2mm;

Eccentrically thickened cortex;

Loss of normal morphology.

Gold standard was axillary surgery; no details of histology technique provided,  
nor of blinding.

Walsh, Dixon, Chetty & Paterson . Colour Doppler studies of axillary node metastases in breast carcinoma. Clin Radiol. 49[3]. 1994.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** 80 patients with breast cancer were randomly selected over a period of 8 months. One patient had bilateral cancer. T stage was T1 (n=15), T2 (n=53), T3 (n=8), or T4a (n=5, where n refers to number of tumours).

**Exclusion criteria** Not reported.

**Population** number of patients = 75, age range 22 to 71 years, mean age = 54 years.

**Interventions** Aim: to determine whether colour doppler US can reliably demonstrate axillary node metastases in patients with breast cancer.

All patients underwent grey scale US and any nodes visualised underwent colour doppler US.

**Outcomes** Staging performance of colour doppler US.

**Follow up** Not reported.

**Results** Staging performance of colour doppler US:

Sensitivity =  $23/33 = 70\%$  [95% CI 53%-83%]

Specificity =  $41/42 = 98\%$  [95% CI 88%-100%]

PPV =  $23/24 = 96\%$  [95% CI 80%-99%]

NPV =  $41/51 = 80\%$  [95% CI 68%-89%]

**General comments** Criterion for suspicious nodes on colour doppler US: signals within 5mm of the periphery of the lymph node or within the lymph node.

75 patients underwent 'gold standard' definitive staging procedure: sampling of a minimum of 6 nodes. Pathological technique not described, but the single pathologist was blind to the colour doppler findings.

Retrospective case series

Hergan, Haid, Zimmermann & Oser . [Preoperative axillary ultrasound in breast carcinoma: value of the method in routine clinical practice]. [German]. *Ultraschall Med* 17[1]. 1996.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Austria, setting: Secondary care

**Inclusion criteria** 74 patients with breast cancer who underwent US, identified from a larger series of 191 patients.

**Exclusion criteria** Not known.

**Population** number of patients = 74, age range 34 to 82 years, mean age = 61 years.

**Interventions** Aim: to compare the staging performance of axillary ultrasound with clinical palpation and definitive histology.

Patients underwent clinical palpation of the axilla, preoperative US of the axilla and axillary clearance to levels I and II.

**Outcomes** Staging performance of axillary ultrasound with clinical palpation.

**Follow up** Not known.

**Results** Staging performance of axillary US (all T stages):

Sensitivity = 68%

Specificity = 100%

PPV = 100%

NPV = 88%

Staging performance of axillary US (T1 tumours only):

Sensitivity = 50%

Specificity = 100%

PPV = 100%

NPV = 95%

Staging performance of clinical palpation (all T stages):

Sensitivity = 41%

Specificity = 96%

PPV = 82%

NPV = 79%

Staging performance of clinical palpation (T1 tumours only):

Sensitivity = 25%

Specificity = 100%

PPV = 100%

NPV = 92%

**General comments** Article in German: information extracted from abstract plus tables/minimal text.

Patients appear to be a consecutive series.

Criteria for suspicious nodes on US:

Round to oval shape;

Long:short ratio  $<2$ ;

Assymmetric hypoechogenic component.

For staging performance results, rate of failure to identify any axillary nodes is not known; data is tabulated for all 74 patients who underwent US. Gold standard was axillary clearance; histological methods not known. Extent of blinding not known.

Sato, Tamaki, Tsuda, Kosuda, Kusano, Hiraide & Mochizuki . Utility of axillary ultrasound examination to select breast cancer patients suited for optimal sentinel node biopsy. Am J Surg 187[6]. 2004.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Japan, setting: Secondary care

**Inclusion criteria** 262 consecutively treated patients patients with biopsy-proven breast cancer of stage T1-3.

**Exclusion criteria** Pregnancy, multiple primary breast tumours, history of neoadjuvant chemotherapy.

**Population** number of patients = 262, age range 21 to 83 years, mean age = 55 years.

**Interventions** Aim: to examine the usefulness of axillary US in selecting patients for SLNB.

All patients underwent US axilla followed by SLNB and axillary clearance.

SLNB technique: radiocolloid.

Histology technique: standard (haematoxylin and eosin)

**Outcomes** Staging performance of SLNB overall, and considering only patients with no evidence of axillary metastases on US.

Provides data on staging performance of US.

**Follow up** Not reported.

**Results** Staging performance of US:

Sensitivity =  $50/112 = 45\%$  [95% CI 36%-54%]

Specificity =  $146/150 = 97\%$  [95% CI 93%-99%]

PPV =  $50/54 = 93\%$  [95% CI 82%-97%]

NPV =  $146/208 = 70\%$  [95% CI 64%-76%]

Of the whole series, US detected axillary metastases in  $50/262 = 19\%$  of patients [95% CI 15%-24%].

The SN localisation rate was  $205/208 = 98.6\%$  in patients with negative result on US, compared to  $26/54 = 48.1\%$  in patients with positive result on US: difference 50.4%, [95% CI for difference 37%-63%],  $p < 0.005$ , (Chi square).

The FNR of SLNB was  $9/83 = 10.8\%$  [95% CI 5.8%-19.3%] in all patients, and  $1/60 = 1.7\%$  [95% CI 0.3%-8.9%]

in patients with negative US axilla result. These values for accuracy of SLNB were  $222/231 = 96\%$  [95% CI 93%-98%] and  $204/205 = 99.5\%$  [95% CI 97.3%-99.9%] respectively.

**General comments** Criteria for suspicious nodes on US: homogeneously hypoechoic node without an echo rich centre.

Gold standard: axillary clearance. Histology technique: standard methods. No

different histology technique was reported for sentinel nodes.

Study does not report a rate of detecting nodes on US, but all 262 patients are classified as either positive or negative on US. This implies a detection rate of 100% but may reflect classification of cases of failure to detect any nodes as 'negative'. Study does not report blinding.

Staging performance of US derived from constructing a 2x2 contingency table, based on data provided in the paper. 95% CIs calculated using spreadsheet: acknowledgement to R Newcombe, Cardiff University: [http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls).

van Rijk, Deurloo, Nieweg, Gilhuijs, Peterse, Rutgers, Kroger & Kroon . Ultrasonography and fine-needle aspiration cytology can spare breast cancer patients unnecessary sentinel lymph node biopsy. Ann Surg Oncol 13[1]. 2006.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Netherlands, the, setting: Secondary care

**Inclusion criteria** 726 patients with clinically T1-T3 (or T4 due to involvement of skin) unifocal breast cancer, who were scheduled for SLNB.

**Exclusion criteria** Implied by inclusion criteria.

**Population** number of patients = 726, age range 18 to 94 years, mean age = 58 years.

**Interventions** Aim: to evaluate the sensitivity of preoperative US with FNAC to detect axillary metastases and hence avoid a SLNB procedure.

All patients underwent axillary US. Patients with suspicious nodes on US underwent FNAC.

If US was not suspicious or if FNAC revealed no metastases, patients underwent SLNB. Patients with axillary metastases by US guided FNAC underwent axillary clearance or axillary RT.

**Outcomes** Staging performance of US plus FNAC.

Proportion of patients in whom SLNB could be omitted due to detection of axillary metastasis by US and FNAC.

**Follow up** Not reported.

**Results** 176/732 axillae were suspicious by US, prompting FNAC.

Of these:

59/176 = 34% were positive for axillary metastasis by FNAC;

117/176 = 66% were negative for axillary metastasis by FNAC.

Of the whole series of patients, 59/726 = 8% were spared SLNB and proceeded to axillary RT or clearance [authors report that these patients may be candidates for neoadjuvant chemotherapy].

271/732 = 37% of all axillae were tumour positive by definitive histology.

Staging performance:

US alone had sensitivity 35% [95% CI 29%-41%] and specificity 82% [95% CI 78%-86%].

FNAC had sensitivity 62% [95% CI 51%-72%] and specificity 99% [95% CI 93%-100%].

Combined technique (US + FNAC) had sensitivity 21% [95% CI 17%-27%] and specificity 99.8% [95% CI 99%-100%], PPV 98% [95% CI 91%-99.7%] and NPV 68% [95% CI 65%-72%].

**General comments** 726 patients were included; representing 732 treated axillae (i.e. 6 cases of bilateral cancer).

Criteria for suspicious nodes on US were cortex thickness of >2mm, irregular cortex, round or ovoid shape, hypoechoic core, smaller diameter >5mm; later changed to solely a cortex thickness >2.3mm.

NB By US, nodes are reported as 'suspicious' or 'not suspicious' for all patients, implying a 100% node detection rate. It may be the case that nodes that could not be detected on US were classed as 'non suspicious', indicating SLNB.

24 patients received neoadjuvant chemotherapy after US and in cases of negative US result, after SLNB.

FNAC staging performance reported is for all patients with suspicious US results.

Combined technique staging performance is for 732 axillae, and PPV and NPV values are calculated from constructing the 2:2 table from the data [95% CI provided by Cardiff University: R Newcombe, [http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls)].

## UPDATE EVIDENCE

Ciatto, Brancato, Rizzo, Ambrogetti, Bulgaresi, Maddau, Turco, Houssami. Accuracy of fine needle aspiration cytology (FNAC) of axillary lymph nodes as a triage test in breast cancer staging (2007) *Breast cancer Research & Treatment* 103:85-91

**Design:** Retrospective Data Analysis **Evidence Level:** 3

**Country:**

**Aim:** To examine the accuracy of US-guided FNAC of clinically or sonographically indeterminate or suspicious axillary nodes

### Inclusion criteria

All consecutive cases with axillary node FNAC from 1990-March 2005.

### Exclusion criteria

### Population

N=476; mean age 52 years, average pT size = 21.1mm.

### Interventions

Clinical examinations, ultrasound and fine needle aspiration cytology. Ultrasound was performed with knowledge of clinical findings and FNAC was on sonographically abnormal nodes.

### Outcomes

Sensitivity and specificity for axillary FNAC

### Results

	Excluding C1 (inadequate) results	Including C1 results
<b>FNAC Sensitivity</b>	72.6%	64.6%
<b>FNAC Specificity</b>	95.6%	95.7%
<b>Negative Predictive Value</b>	67.2%	61.3%
<b>Positive Predictive Value</b>	96.6%	96.6%

The likelihood of node FNAC being positive was strongly linked to both tumour grade and stage and was significantly associated with the number of nodes involved with metastases on histology.

	Patients with positive axillary node FNAC
<b>Tumour Grade (p&lt;0.00001)</b> (Excludes 22 positive FNAC in 30 cases where grade not reported/missing)	
Grade 1	21.5%
Grade 2	35.0%
Grade 3	53.4%
<b>Pathological State (p&lt;0.00001)</b>	
T1a	46.6%
T1b	20.0%
T1c	34.2%
T1	66.6%
T2	57.6%
<b>Number of Metastatic Nodes (p&lt;0.001)</b> (Excludes 1 positive FNAC in 3 cases where number of metastatic nodes is not reported/missing)	
1-3	55.1%
4-10	70.6%
>10	81.6%

FNAC sensitivity was highest in women with clinically suspicious nodes; 92.5% (88.2-96.7) as compared with

50.0% (41.3-58.7) in women with sonographically abnormal and clinically negative nodes. Specificity for both groups was high; 81.2% (54.5-96.0) and 97.2% (94.6-99.9) respectively.

The False- Negative rate was 15.3% and the False-Positive rate for the study was 1.4%.

**General comments**

Abnormal nodes were defined as having enlarged size, absence of hyperechoic hilum, eccentric thickening or asymmetry of the cortex or a greater vertical than horizontal diameter.

Sahoo, Sanders, Roland, Pile, Chagpar. A strategic approach to the evaluation of axillary lymph nodes in breast cancer patients: analysis of 168 patients at a single institution (2007). *The American Journal of Surgery* 194;524-526

**Design:** Retrospective Data Review **Evidence Level:** 3

**Country:** USA

**Aim:** To examine and determine the number of operative procedures that could be excluded using both fine needle aspiration biopsy (FNAB) and/or intra-operative evaluation of the sentinel lymph nodes.

**Inclusion criteria**

All patients with breast cancer that had their axillae sonographically evaluated.

**Exclusion criteria**

**Population**

N=168

**Interventions**

**Outcomes**

Sensitivity and specificity of USFNAB

Number of patients who underwent SLNB and immediate ALND based on intra-operative evaluation of SLNs

**Results**

The overall sensitivity and specificity of USFNAB was 96% and 93% respectively (overall sensitivity and specificity was calculated from those patients who had follow-up).

For the intra-operative diagnosis for SLNB the sensitivity was 98% and specificity was 100%

40 patients with positive USFNAB were spared the additional step of SLNB.

Somasunder, Gass, Steinhoff, Koeliker, Dizon, Cady, Taneja. Role of ultrasound-guided axillary fine-needle aspiration in the management of invasive breast cancer (2006) *American Journal of Surgery* 192;458-461

**Design:** Retrospective Data Review **Evidence Level:** 3

**Country:** USA

**Aim:** To report on further experience with USFNAB in staging the axilla and its subsequent affect on management decisions.

**Inclusion criteria**

Women with breast cancer who were undergoing USFNAB for the diagnosis and staging.

**Exclusion criteria**

Patients with multicentric tumours, inflammatory breast cancer or without surgical axillary evaluation.

<b>Population</b> N=168		
<b>Interventions</b>		
<b>Outcomes</b> Sensitivity and specificity of USFNAB for patients who underwent primary surgery		
<b>Results</b> 47% (N=79) patients had positive USFNAB and were spared SLNB having either ALND or NACT followed by ALND.		
T Stage	Primary Surgery (N=107)	
	<b>Sensitivity</b>	<b>Specificity</b>
T1	35%	96%
T2	67%	100%
T3/4	78%	100%

### **Health Economics Summary (for full summary please see Appendix 3 of the full guideline)**

A systematic review of the evidence regarding the cost-effectiveness of using pre-treatment ultrasound combined with needle biopsy (US+NB, either fine needle aspiration (FNA) or core biopsy (CB)) to stage the axilla of EBC patients identified three relevant studies: one full economic evaluation (Brancato et al 2004) and two partial economic evaluations (Genta et al 2007; Davies et al 2006). Two of these studies were conducted in Italy (Brancato et al 2004; Genta et al 2007) and the third one in USA (Davies et al 2006). All these studies were cost-consequences analysis, since they reported several health benefit outcomes measured as natural units, mainly the accuracy of the staging procedures and the number of patients avoiding secondary staging with US+NB (among other outcomes). None of the studies estimated the number of QALYs gained with each of the staging strategies. The costs associated with the different staging procedures were estimated and reported, either from the perspective of the hospital (Davies et al 2006), of the health care provider (Brancato et al 2004), or both (Genta et al 2007). However, no price year was reported in any of the studies. In all the studies some sort of extrapolation and/or assumptions were used to obtain the clinical effectiveness of one or more of the staging procedures compared. As the study by Brancato et al (2007) highlighted, considerable variations exist regarding the costs of the different staging procedures across countries; therefore, it is difficult to generalise the results from country to country. This was confirmed by the differences in the unit costs observed across studies: in the study by Davies et al (2006) the cost of SLNB was much higher than that of ANC, i.e. \$6,300 (£3,895) and \$3,700 (£2,287), respectively; on the other hand, the study by Brancato et al (2007) reported a unit cost of €216 (£156) for SLNB and €1,550 (£1,119) for ANC. All studies concluded that US+NB seemed to be a cost-effective staging strategy when compared to SLNB, although none of them stated on what basis they considered cost-effectiveness. All three studies identified the potential of US+NB to lead to cost-savings under specific scenarios.

#### Summary of individual studies

The study by Brancato et al (2004) was based in a diagnostic study that assessed the accuracy of palpation, US and FNA. The study design seemed appropriate since the three staging procedures were undertaken and compared across all included patients. The results of the diagnostic study were used to simulate five staging strategies by extrapolating the results. The cost analysis was conducted from the Italian NHS perspective and the cost costs included were those of the procedures. The price year was not reported, which would hinder reflation exercises to other settings. The authors reported that considerable variations exist regarding the unit costs of the staging procedures across countries; consequently, results do not seem to be generalisable to settings different to the Italian context. No ICER was provided to identify the additional cost per patient avoiding an inappropriate procedure (although enough information was reported in the paper as to make the corresponding estimation). No sensitivity analyses were conducted to assess the uncertainty surrounding the study results. The authors concluded that the most cost-effective staging procedure appeared to be US for all patients followed by FNA if lymph nodes suspicious at US and immediate ANC in those patients with suspicious nodes at FNA only. This strategy would avoid SLNB in 13 patients over 159 patients examined, at a cost of €133 per patient staged (compared to €104 per patient staged following current practice in the Italian setting). Palpation and US, either alone or in combination, were reported to be inadequate procedures to stage the axilla of BC patients.

The partial economic evaluation by Davies et al (2007) was based on a diagnostic study that assessed the accuracy of US+FNA/CB to stage the axilla in EBC patients. The authors reported the number of patients avoiding SLNB by undergoing US+FNA/CB. In total, 15 patients (out of 37) would avoid SLNB with US+FNA/CB. Since the study included patients at high risk of axillary metastasis, the prevalence of metastasis among the included group of patients was 59% (much higher than that observed from the clinical review of topic 6). No relevant effectiveness outcomes were reported for SLNB. The cost of the SLNB group was estimated by implicitly assuming that all patients with axillary metastasis would be appropriately identified with SLNB (i.e. there would not be false negative patients, which does not correspond with the review of the clinical evidence for this topic). Therefore, the costs related to SLNB may have been overestimated (by assuming that all patients with nodal metastasis would undergo complete clearance, rather than only those actually identified by SLNB). The authors concluded that the use of US+FNA/CB in EBC patients at high risk of axillary metastasis is cost-effective since it can reduce the number of patients undergoing SLNB and decrease the associated costs by approximately 20% (according to their data).

The partial economic by Genta et al (2006) used a somewhat confusing study design, since the effectiveness of three of the staging strategies evaluated seemed to have been obtained through extrapolation of the results of a cohort study assessing the accuracy of US+FNA. On the other hand, the cost analysis compared three alternative staging strategies comprising a combination of staging procedures. There seems to be a contradiction in the study: the authors reported that US+FNA was conducted in patients with clinically positive nodes, while SLNB was conducted in patients with clinically negative nodes (which

would limit any potential comparison between the two staging strategies); however, when results were reported, it seemed that all the patients included in the study had undergone US. The cost analysis did not include only the costs of the staging procedures but also the costs of breast surgery. Additionally, the costs were not compared across the different staging strategies, but the study was limited to compare, for each staging strategy, the costs that the Italian NHS would pay with the costs that the hospital would bill. The price year was not reported. The authors concluded that US+FNA can identify reliably the presence of axillary metastasis and can be used to refer these patients directly to ANC without further SLNB. In total, 33% of patients would avoid SLNB with US+FNA. According to the authors, the cost saving from the lower number of SLNBs conducted seemed to be compensated by the costs of US+FNA.

**Economic Evaluations**

Brancato, B., et al., Role of ultrasound-guided fine needle cytology of axillary lymph nodes in breast carcinoma staging. *Radiologia Medica*, 2004. 108(4): p. 345-355.

**Design:**Type of economic evaluation:

Full economic evaluation.

Clinical effectiveness:

A diagnostic study was conducted to assess the accuracy of several staging procedures for axillary metastasis in EBC. Three staging procedures were undertaken for all patients and the reference standard used was reported.

Cost estimation:

The authors estimated the additional costs of alternative staging strategies when compared to clinical practice from the Italian NHS perspective. The costs included were those of the staging procedures undertaken. The Italian's National Health Service price-list was used as the source of unit costs (ultrasonography = €36.15; cytologic examination = €33.78; SLNB (as outpatient procedure) = € 216.29; ANC (i.e. price of mastectomy + ANC – mastectomy) = €1,550). The price year not identified.

**Country:** Italy, **setting:** Hospital

**Inclusion criteria** Not stated

**Exclusion criteria** Not stated

**Population**

Patients with breast carcinoma (159 patients, 163 axillae examined), with 155 patients (159 axillae) with known lymph node histology available after the study.

**Interventions**

The accuracy of three staging procedures was assessed in the clinical study: palpation, US and FNAB. Histological findings at SLNB or at ANC were used as the reference standard used to assess accuracy. In study, all patients with visible nodes underwent FNA.

For the economic evaluation, the authors simulated five alternative staging strategies (including Italian current practice) based on the previous staging procedures:

- US in all cases, followed by cytology for visible nodes and immediate ANC for positive nodes and SLNB for negative nodes
- US in all cases, followed by cytology for suspicious nodes and ANC for those resulting positive, SLNB for the remaining cases.
- US for clinically negative axilla, followed by cytology on all visible nodes, and ANC for those with suspicious findings at palpation or cytology, and SLNB in the remaining cases.
- US only for those with clinically negative axilla, followed by cytology if suspicious visualised nodes, ANC on suspicious findings at palpation or after cytology, and SL in remaining cases.
- Current practice: Palpation with suspicious cases followed by ANC and all other by SLNB (followed by ANC only if positive node involvement is found)

**Results –**

OUTCOME OF INTEREST	Palpation	US
Sensitivity for palpable lymph nodes	62.9	91.4
Sensitivity for suspicious lymph nodes	51.9	64.3
Specificity for palpable lymph nodes	74.2	22.5
Specificity for suspicious lymph nodes	93.0	86.5
Positive predictive value for palpable lymph nodes	65.7	48.1
Positive predictive value for suspicious lymph nodes	85.7	78.9
Negative predictive value for palpable lymph nodes	71.7	76.9
Negative predictive value for suspicious lymph nodes	70.9	75.5
Visualisation of axillary lymph nodes (%)	-	83

OUTCOME OF INTEREST	US+FNA		
	Excluding inadequate cases	Inadequate cases assumed negative	Inadequate cases assumed positive
Sensitivity	68.3	64.1	58.6
Specificity	100	100	100
Positive predictive value	100	100	100
Negative predictive value	76.5	75.0	75.4

OUTCOME OF INTEREST	A	B	C	D	Current practice
Number of inappropriate ANCs	0	0	6	6	6
Δ Number of inappropriate ANCs compared to current practice	6	6	0	0	-
Number of inappropriate SLNBs	29	31	21	23	34
Δ Number of inappropriate SLNBs compared to current practice	5	3	13	11	-
Total cost (€)	16,511	14,377	21,178	19,213	16,654
Δ average cost to avoid inappropriate surgical procedures (compared to current practice)	-143	-2,277	348	232	-
Cost per staged case (€)	103	90	133	120	104

Other outcomes reported were: true positive and negative patients, false positive and negative patients.

**Authors' conclusions –**

The authors concluded that the most cost-effective staging procedure appeared to be US for all patients followed by FNA if lymph nodes suspicious at US and immediate ANC in those patients with suspicious nodes at FNA only. Palpation and US, either alone or in combination, are inadequate procedures to stage the axilla of BC patients.

**General comments –**

The economic evaluation was based in a diagnostic study, which seem appropriate since three staging procedures were undertaken in all possible patients. The results of the diagnostic study were used to simulate five staging strategies by extrapolating the results. The cost analysis appeared to be appropriate given the study question and included the costs of the procedures. The price year was not reported, which would hinder reflation exercises to other settings. The authors reported that considerable variations exist regarding the unit costs of the staging procedures across countries; consequently, results do not seem to be generalisable to settings different to the Italian context. No ICER was provided to identify the additional cost per patient avoiding an inappropriate procedure (although enough information was reported in the paper as to make the corresponding estimation). No sensitivity analyses were conducted to assess the uncertainty surrounding the study results.

**Partial Economic Evaluations**

Davies JT, Brill YM, Simmons S, et al. Ultrasound-guided fine-needle aspiration of clinically negative lymph nodes versus sentinel node mapping in patients at high risk for axillary metastasis. *Annals of Surgical Oncology* 2006; 13(12):1545-1552.

**Design:**

Type of economic evaluation:

Partial economic evaluation (effectiveness for SLNB was not reported, only costs). The study was a cost-consequences analysis.

Clinical effectiveness:

Cohort study

**Cost estimation:**

Costs included were those of the hospital, according to the number of procedures undertaken, and included: ultrasonography (unit cost: \$200), FNA/CB (unit cost: \$1250), SLNB (unit cost: \$6300) and complete axillary node dissection (unit cost: \$3700). The source of the costs was the hospital administration. The cost estimation does not include physician charges and does not represent actual insurance reimbursement. No price year reported.

**Country:** USA, **setting:** Hospital

**Inclusion criteria** Patients with clinically negative axilla at high risk of axillary nodal metastasis (i.e. grade III, size > 1cm or grade II, size > 1.5cm at the time of initial diagnosis, with or without lymphovascular invasion).

**Exclusion criteria** Not stated

**Population** number of patients = 37 (selected from a total of 144 patients)

**Interventions**

Ultrasound-guided fine-needle aspiration biopsy (US+FNA/CB) followed by complete axillary node dissection in patients with detected positive nodes, and by SLNB in patients with negative nodes (whom, at the same time, would follow complete axillary node dissection if positive nodes detected).

**Follow up** After sonographic evaluation of the axilla

**Results**

<b>OUTCOME OF INTEREST</b>	<b>US+FNA/CB</b>	<b>SLNB</b>
Patients with axillary metastasis at the time of definitive surgery: number (%)	22 (59%)	-
Patients with accurate prediction of axillary status with FNA: number (%)	16 of 21 (71%)	-
Patients with accurate prediction of axillary status with CB: number (%)	13 of 16 (81%)	-
False negative patients with FNA/CB: number	3	-
False negative patients for US only: number	4 of 15	-
Patients avoiding SLNB by US+FNA/CB	15	-
Total cost per group of 37 patients (\$)	254,900	314,500
Cost per patient (\$)	6,890	8,500

Other outcomes reported were: the number of patients with normal versus abnormal US; the number of patients with positive/negative US/FNA after abnormal US; the number of patients with SLNB positive/negative after normal US; the number of patients with SLNB positive/negative after negative US/FNA results.

**Authors' conclusions –**

The authors concluded that the use of US+FNA/CB in EBC patients at high risk of axillary metastasis is cost-effective since it can reduce the number of patients undergoing SLNB and decrease the associated costs by approximately 20% (according to their data).

**General comments –**

It seems that the gold standard used to assess accuracy of US+FNA/CB was SLNB or ANC, depending on the last procedure the patients undertook; while ANC is an accepted gold standard to identify nodal status, SLNB is not 100% sensitive, which introduces potential biases into the accuracy results. Note that this seems to be a potential bias present in most of the studies of the same type, since patients identified as node negative also by SLNB do not usually undergo any further staging procedure. In terms of the relevance of this study for the PICO question posed, the most relevant outcome to consider here would be the number of patients avoiding SLNB by undergoing US+FNA/CB. In total, 15 patients (out of 37) would avoid SLNB with US+FNA/CB. Since the study included patients at high risk of axillary metastasis, the prevalence of metastasis among the included group of patients was 59% (much higher than that observed from the clinical review of topic 6).

No relevant effectiveness outcomes were reported for SLNB. The cost of the SLNB group was estimated by implicitly assuming that all patients with axillary metastasis would be

appropriately identified with SLNB (i.e. there would not be false negative patients, which does not correspond with the review of the clinical evidence for this topic). Therefore, the costs related to SLNB may have been overestimated (by assuming that all patients with nodal metastasis would undergo complete clearance, rather than only those actually identified by SLNB).

No quality assessment checklist was completed for this study since it was a partial economic evaluation.

Genta F, Zanon E, Camanni M, et al. Cost/accuracy ratio analysis in breast cancer patients undergoing ultrasound-guided fine-needle aspiration cytology, sentinel node biopsy, and frozen section of node. *World J Surg* 2007; 31:1155-1163.

**Design:**

Type of economic evaluation:

Partial economic evaluation since effectiveness for three of the four staging strategies considered at analysis was hypothetical. The study was a cost-consequences analysis.

Clinical effectiveness:

Cohort study

Cost estimation:

Two alternative perspectives were considered when estimating the costs: that of the Italian NHS and that of the hospital (i.e. amount billed by the hospital for the procedures). The costs included not only the staging procedures undertaken but the costs of breast surgery as well. For the hypothetical interventions, costs were extrapolated using data from interventions assessed in the cohort study. The cost analysis took into account a combination of the staging strategies considered at analysis: 1) Palpation + postoperative SLNB if suspicious nodes; 2) US+FNA, followed by postoperative SLNB if negative nodes; 3) US+FNA followed by SLNB (both intra and postoperatively) if patients identified with negative nodes. The price year was not reported.

**Country:** Italy, **setting:** Hospital

**Inclusion criteria** Consecutive patients eligible for SLNB and with: <3cm, unifocal, invasive or microinvasive, previously untreated cancer; or high grade or > 4cm DCIS. Only patients with clinically positive axilla underwent US.

**Exclusion criteria** Not stated

**Population** 417 patients: 381 with invasive or microinvasive BC, 36 with DCIS

**Interventions**

- US, followed by FNA if suspicious nodes were found with US. If FNA positive, ANC was conducted; if FNA negative, intraoperative SLNB (i.e. frozen section) was conducted.

The authors extrapolated the results of the observational study to obtain three hypothetical scenarios, representing three additional interventions assessed in the partial economic evaluation:

- Palpation followed by ANC if patients had clinically suspected nodes
- Postoperative SLNB for all the patients, followed by ANC if nodes positive.
- Intraoperative SLNB followed by ANC if nodes positive and postoperative SLNB if nodes negative. If postoperative SLNB positive, then delayed ANC would be conducted.

**Results**

<b>EFFECTIVENESS RESULTS: OUTCOME OF INTEREST</b>	<b>US+FNA</b>	<b>Preoperati ve SLNB</b>	<b>Postoperat ive SLNB</b>	<b>Palpation</b>
Patients for whom SLN could not be identified (%)	-	22 (5.28%)	-	-
Sensitivity	For US alone: 0.51 For			0.29

	US+FNA: 0.33			
Specificity	For US alone: 0.87 For US+FNA: 1.00			0.93
Patients with positive nodes (%)	131 (32.43%)			
Positive node rate among patients with invasive BC	26.3%			
Patients with positive nodes correctly identified	43 (33.33%)	40 (31.01%)	46 (35.66%)	38 (29.46%)
Patients avoiding SLNB	43 (33.33%)	0	0	0
Patients undergoing unnecessary ANC	-	-	-	15
<b>COST RESULTS (€)</b>	<b>US+FNA + SLNB (preop and postop)</b>	<b>US+FNA + SLNB (postop)</b>	<b>Palpation + SLNB (postop)</b>	
Total cost per group (Italian NHS perspective)	1,218,256	1,226,881	1,125,841	
Total cost per group (hospital billing)	1,063,689	1,079,308	1,034,668	
Δ cost per group (Italian NHS - Hospital billing)	154,567	147,573	91,173	

**Authors' conclusions –**

The authors concluded that US+FNA can identify reliably the presence of axillary metastasis and can be used to refer these patients directly to ANC without further SLNB. The cost saving from the lower number of SLNBs conducted seemed to be balanced by the costs of US+FNA.

**General comments –**

The study design was somewhat confusing since the effectiveness of three of the staging strategies evaluated seemed to have been obtained through extrapolation of the results of the cohort study for US+FNA. On the other hand, the cost analysis was done for a combination of strategies. There seems to be a contradiction in the study: the authors reported that US+FNA was conducted in patients with clinically positive nodes, while SLNB was conducted in patients with clinically negative nodes (which would limit any potential comparison between the two staging strategies); however, when results were reported, it seemed that all the patients included in the study had undergone US. The cost analysis did not include only the costs of the staging procedures but also the costs of breast surgery. Additionally, the costs were not compared across the different staging strategies, but the study was limited to compare, for each staging strategy, the costs that the Italian NHS would pay with the costs that the hospital would bill. The price year was not reported.

No quality assessment checklist was completed for this study since it was a partial economic evaluation.

### **2.3 What are the effective strategies to manage psychological distress in patients with early stage breast cancer?**

#### **Short summary**

The evidence base for this topic comprises 24 papers: 3 systematic review (Tatrow & Montgomery, 2006, Bantum *et al.*, 2007 and Zimmermann *et al.* 2007) 20 RCTs (Allard, 2007, Allen *et al.* 2002, Andersen *et al.* 2004, Antoni *et al.* 2006, Badger *et al.* 2007, Burton *et al.* 1995, Cohen & Fried, 2007, Dey *et al.* 2002, Gotay *et al.* 2007, McArdle *et al.* 1996, Mutrie *et al.* 2007, Ritz *et al.* 2000, Samarel *et al.* 2002, Sandgren and McCaul, 2003, Sandgren and McCaul, 2007, Stanton *et al.* 2005, Manne *et al.*, 2007, Classen *et al.*, 2008, Vos *et al.*, 2007 and Meneses *et al.*, 2007) and two prospective comparative studies (Mock *et al.* 1997 and Ambler *et al.* 1999). The quality of papers was generally good and most study designs compared the effects of one or more interventions with one or more controls measured at two or more time points, the maximum follow-up being one year.

#### **Cognitive behavioural therapy (CBT)**

A high quality systematic review of RCTs found that CBT interventions had a low effect size compared with controls. There was RCT evidence of no significant difference between CBT and guided imagery in reducing psychological stress or the perception of stress, although both interventions were significantly better than non-interventional controls.

Good quality evidence from two RCTs suggested that group therapy with non-CBT counselling or a group therapy intervention comprising CBT and several other psychosocial elements significantly reduced subjective levels of emotional distress whilst objective assessments of anxiety were not significantly different from controls.

#### **Group therapy**

A moderate quality systematic review found that group interventions provided significant improvements in emotional well-being when compared with individual interventions. The provision of multiple treatment elements was more useful than targeted clinical services. Only self help and information/education as single interventions had significant effects on emotional well-being.

RCT data showed that those who derived benefit from a couple-focused group intervention were women who naturally selected an emotional coping strategy to having breast cancer and women with unsupportive partners who attempted to understand and express their emotional reactions.

A multi-centre RCT showed that, compared with education, there was no evidence that psychological distress was alleviated by brief supportive-expressive group therapy. Neither was therapist training and experience associated with any treatment effect. It was thought that perhaps women with early breast cancer may be more likely to have pragmatic, rather than existentialist, concerns.

A small RCT compared group psychotherapy with group social support, neither of which was effective in improving psychosocial adjustment to breast cancer. Generally, body image improved significantly over time, particularly in women who had received breast-conserving surgery, and the limitations of breast cancer on recreation were also reduced.

#### **Other interventions**

Several, generally good quality, RCTs demonstrated that a variety of interventions including preoperative interview, attention focus and symptom management, telephone interpersonal counselling and structured exercise programs alleviated anxiety for variable lengths of time whilst not significantly improving depression, negative affect or general quality of life.

**Intervention providers**

A systematic review and meta-analysis found that psychologists were better qualified to deliver CBT to a woman with breast cancer either after the diagnosis, surgery or much later but not during other medical treatment. Nursing staff were better in delivering education to women with early stage disease, either individuals or in groups, preferably after diagnosis or surgery.

Moderate quality evidence suggested that adding the services of an advanced practice care nurse to standard care significantly reduced uncertainty, complexity, inconsistency and unpredictability without influencing quality of life or mood. Other studies found that support from a breast care nurse specialist following cancer surgery alleviated depression over time but made no significant difference to anxiety. However, receiving support from the breast care nurse specialist before and after receiving a pre-surgical diagnosis significantly lowered clinical relevant anxiety when measured two weeks after surgery, regardless of eventual diagnosis.

RCT evidence also showed that a psychoeducational intervention, delivered by a specialist nurse, demonstrated effectiveness amongst women with breast cancer after primary treatment thus providing a ‘safe passage’ from treatment to survivorship.

**PICO**

POPULATION	INTERVENTION	COMPARISON	OUTCOME
Patients with early stage breast cancer ( <b>with</b> clinically manifest psychological distress)	Any strategy to treat psychological distress: <ul style="list-style-type: none"> <li>• Educational/provision of information</li> <li>• Counselling/cognitive behavioural therapy (CBT)</li> <li>• Psychotherapeutic</li> <li>• Group support</li> <li>• Drugs (e.g. antidepressants)</li> <li>• Exercise</li> <li>• ‘Buddy’ system/use of volunteers</li> <li>• Practical support e.g. financial, child care</li> </ul> 1] The engagement / involvement of family and/or friends	Versus each other or versus no intervention	Alleviation of psychological distress  Note who provides the intervention (i.e. type of professional)

POPULATION	INTERVENTION	COMPARISON	OUTCOME
	2] Alternative therapies - relaxation therapies e.g. yoga – reflexology.  3] Linking to specialist nurses e.g. Macmillan to advise and assist

### Full evidence summary

The evidence base for this topic comprises eighteen papers (n=5,630 study participants): 1 systematic review, 15 RCTs and 2 prospective comparative studies from the USA (n=10), UK (n=5), Israel (n=1) and Canada (n=1). The quality of papers is generally good and most study designs compare the effects of one or more interventions with one or more controls measured at two or more time points, the maximum follow-up being one year.

The statistical methodology employed is usually single and repeated-measures analyses of variance (ANOVA). A few reviewers also compared study arms at specific time points using unpaired t-tests, the validity of which is open to question. When an intervention is assessed with multiple instruments, and hence reported in different ways, (as dichotomous or continuous data, for example) the overall effect size was sometimes reported as Cohen's d statistic. It is generally held that a value for Cohen's d of 0.2 is indicative of a small effect, 0.5 a medium and 0.8 a large effect size.

The studies examined issues broadly addressing quality of life, depression and psychological distress but at different times in the patient pathway: at diagnosis (n=2), before surgery (n=2), after surgery and/or before or during adjuvant therapy (n=10), after all treatment (n=1) or on first recurrence (n=1). The systematic review did not make these distinctions but included all women with breast cancer and all treatment points, as did one RCT (Ritz *et al.*, 2000).

The majority of studies did not specifically enrol women with 'clinically manifest psychological distress' but, given the circumstances attendant at any particular point in the patient pathway, made general assumptions on the likely emotional state of the women that they were recruiting and since, in many studies, outcomes such as anxiety declined over the course of time this may have been appropriate.

The interventions examined in these studies included: cognitive behavioural therapy (CBT), psychoeducation, group support, individual counselling, specific nursing roles, exercise, relaxation and problem-solving. The diversity of interventions and treatment stages means that there is only limited evidence for any one circumstance. The strongest evidence base, including as it does a systematic review and two RCTs is for CBT.

One possible problem with consistency across studies is the large variety of measures and assessment instruments used throughout since the transferability between these is not

known and hence studies cannot easily be combined and must be seen only as individual pieces of work. The study populations, however, are broadly consistent and, despite all efforts from some quarters to enrol women from ethnic minorities, participants are generally white, middle income, educated and married.

The evidence has been summarised by treatment phase since this parameter is easier to categorise clearly than the numerous therapies. Abbreviations used are explained at the end of the text:

### **[i] All stages of breast cancer**

A high quality systematic review (Tatrow and Montgomery, 2006) included 19 RCTs of CBT techniques (including activity pacing, assertiveness & communication training, autogenic training, behavioural activation, biofeedback, cognitive and attentional distraction, cognitive restructuring, contingency management, goal setting, imagery, hypnosis, meditation, modelling, pleasant activity scheduling, problem-solving, relaxation training, role playing, systematic desensitisation or visualisation) used to treat women with breast cancer for the relief of distress. Of 19 included studies, 63% were of women with early breast cancer (total n=1,649).

The adjusted overall effect size (Cohen's d) of the CBT technique for the treatment of distress, taking into account the variability of sample sizes in each RCT, was 0.13 (95%CI: -0.2-0.29; nsd). This result is between zero and the 'low' threshold in terms of effect size and could be interpreted as: 55% of participants in the intervention arms had a better outcome when compared with the average control participant.

The authors concluded that CBT appeared to have some benefits for breast cancer patients and the results suggested that individual therapies might be better than group therapies ( $P < 0.05$ ), if only for the outcome of addressing distress. The stage of cancer did not appear to make a significant difference to this outcome.

Ritz *et al.* (2000) conducted an RCT of moderate size (n=211) assessing the impact made by adding the services of an advanced practice care nurse to standard medical care for women with breast cancer of all stages (96% of which were 0-III) and at all points in the patient pathway i.e. before and after surgery, during adjuvant therapy and after all treatment. Follow-up extended over two years but was only presented up to 1 year because of high attrition thereafter. The outcome 'uncertainty' was significantly lower in the intervention group at 1 month ( $P=0.001$ ) 3 months ( $P=0.026$ ) and 6 months ( $P=0.011$ ) compared with baseline assessment and control values. The intervention group also had significantly lower scores compared with the control group on the 'complexity' ( $P=0.005$ ), 'inconsistency' ( $P=0.005$ ) and 'unpredictability' ( $P=0.038$ ) subscales (instrument=MUIS). Mood or sub-scale elements were not significantly affected by the intervention (instrument=POMS) unless a sub-group analysis controlling for marital status, treatment history and family history were included. Similarly, QOL was not significantly improved when assessed by the FACT-B instrument unless marital status was controlled for in the analysis.

### **[ii] At the time of breast cancer diagnosis**

Ambler *et al.* (1999) presented a good quality prospective comparative study of UK women (n=110) with either a benign or malignant breast condition (n=67) who were awaiting surgery and about to receive a diagnosis of their condition. This RCT compared standard

practice, in which the breast care nurse (BCN) met patients only after the diagnosis with a change of protocol such that the BCN took the role of patient advocate before the diagnosis, helped the woman to prepare for the interview, accompanied her to see the surgeon and played a shortened counselling and support role afterwards. The total nursing time was not changed, just the way in which that time was used. The intervention group showed a significantly lower incidence of clinically relevant anxiety ( $P < 0.05$ ) at 2 weeks post-surgery compared with pre-surgery, regardless of diagnosis, but this was not true for the women with breast cancer sub-group when separately analysed (instrument=HADS). However, women with breast cancer reported a significant reduction in distress at 2 weeks post-surgery compared with pre-surgery ( $P < 0.05$ ) (instrument=RSCL).

Dey *et al.* (2002) compared attendance at a one-stop NHS clinic ( $n=267$ ) for the diagnosis of suspected breast cancer with attendance at a dedicated breast clinic ( $n=211$ ). At the one-stop clinic, attendees received a mammogram, cytology and ultrasonography, if indicated. When imaging reports were available, a consultant assessed patients and discussed future management. Women in the control group received similar care but the women generally had to wait a week for their results. The purposes of the RCT were to examine cost-effectiveness and reduce the added psychological distress of waiting for test results. Anxiety was found to be significantly lower at 24 hours for women who had attended the one-stop clinic ( $P < 0.0001$ ) but after 3 weeks was not significantly different from control group participants (instrument=STAI). Similar outcomes were non-significant when measured by a different instrument (HADS). The cost of providing rapid laboratory results outweighed the transient advantage to patients.

### **[iii] Participants recruited before surgery**

Two papers recruited women with breast cancer scheduled to receive surgery. McArdle *et al.* (1996) designed a four-arm RCT to evaluate the effects of receiving support from a BCN, a voluntary support organisation, a combination of both or routine support on the prevalence of psychological morbidity after surgery for breast cancer. Participants were recruited before surgery ( $n=272$ ). The BCN was highly qualified and experienced with this patient group and her role included information, support, counselling, reassurance and provision of future contact. The Glasgow-based support group, Tak Tent, offered three types of support: information, counselling, and regular group meetings with fellow cancer sufferers. Assessments were made at 1, 3, 6 and 12 months post surgery. General health ( $P=0.015$ ), anxiety & insomnia ( $P=0.027$ ) and social dysfunction ( $P=0.031$ ) were all significantly improved in those patients receiving care from the BCN alone (instrument-GHQ). Depression was also significantly lower in her patients over time than in any other group ( $P=0.003$ ) but anxiety was no different between study arms (instrument=HADS).

Burton *et al.* (1995) designed a four-arm RCT for UK women about to undergo mastectomy for breast cancer ( $n=244$ ) and which compared a preoperative interview (conducted with a clinical psychologist) with or without an unstructured chat or psychotherapeutic intervention (both with by a Rogerian trained consultant surgeon) to standard care. The preoperative interview dealt with the patient's history, emotions, responses, information requirement, regrets, concerns and worries. Expression of feelings by the patient was encouraged. The post-interview intervention placed the crisis of illness within the patient's life situation whereas the chat was purposely not related to illness or surgery. Anxiety and depression both decreased over time (4 days, 3 months and 1 year post-surgery) for all participants but only anxiety was significantly reduced in the intervention groups compared with controls ( $P=0.043$ ) (instrument=HADS). Coping ability also improved with time for all women, especially intervention participants, but, of all sub-

scales, only 'fighting spirit' was significantly higher for the intervention groups compared with controls ( $P=0.031$ ). The interview, with or without intervention/chat, had a highly significant positive effect on body image distress ( $P=0.009$ ). However, only women who had experienced a highly stressful life gained a particular advantage to the intervention, compared with the chat, following interview ( $P=0.04$ ).

#### **[iv] Participants recruited after surgery and/or before or during adjuvant therapy**

Allard (2007) described a Canadian RCT ( $n=117$ ) comparing usual care with an Attention Focus and Symptom Management Intervention (AFSMI) delivered by telephone to women who had undergone breast cancer surgery 9-10 days previously. A follow-up call was made a week later on days 17-18 after surgery. During these calls patients were encouraged to discuss symptoms and self-care strategies with the researcher, who also collected outcome data. Emotions expressed by the woman were acknowledged. Control participants received a telephone call from the ward nurse in which their well-being was briefly discussed. On the whole, the intervention made no significant impact on functional status, with the exception of the 'home management' sub-scale score, which was significantly affected by the intervention ( $P=0.03$ ) (instrument=SIP). Emotional distress was also significantly reduced by the intervention between baseline (2-3 days post-surgery) and the first post-operative follow-up call ( $P=0.03$ ), but distress and confusion were not significantly affected (instrument=POMS).

Allen *et al.* (2002) conducted a study amongst young women in the US ( $n=164$ ) who were about to start their first course of adjuvant chemotherapy for stage 0-III breast cancer. The study assessed the efficacy of a program of 6 training sessions on problem-solving skills including problem orientation, problem definition, generation of alternatives, decision making and solution implementation and verification when compared with a single session for controls. None of the outcomes (mental health or psychological reaction, measured using MHI and IES instruments) showed significant differences between arms, a result which the authors felt was possibly due to the 'soft' nature of the intervention, the purpose of which had been to see if it could be adapted to help women cope with problems and emotional difficulties as result of receiving this diagnosis in mid-life.

Antoni *et al.* (2006) presented a study of women with early breast cancer who had received surgery in the previous 8 weeks. The authors compared a 1-day educational seminar given to a group but with no group interactions, with a program of ten weekly group interventions practising elements of CBT, stress management, relaxation exercises, home assignments (e.g. relaxation practice), role modelling, skills in anxiety reduction, conflict resolution, encouragement of emotional expression and confidence building. Baseline outcomes assessments were followed up at 6 and 12 months. Thought intrusion was significantly different between intervention and control groups ( $P<0.005$ ) but thought avoidance was not significantly different (instrument=IES). A significant effect of the intervention was also seen for the outcome of emotional distress where Cohen's  $d=0.43$ , a medium effect, (instrument=ABS) but there was no significant difference between arms for interviewer-rated anxiety (instrument =HRSA).

Mock *et al.* (1997) presented a small US RCT ( $n=50$ ) comparing a 6-week program of unsupervised walking exercise with usual care. The participants were women with early breast cancer who had undergone breast conserving surgery and were starting radiotherapy. The exercise was self-paced and progressive in intensity. Researchers kept in communication with participants by telephone throughout to assess progress and offer encouragement. Significant differences were found between study arms in pre- and post-

test measures of exercise level ( $P < 0.001$ ), anxiety ( $P = 0.029$ ), sleeping difficulty ( $P = 0.027$ ) but not depression (instrument=SAS).

Andersen *et al.* (2004) described a moderate RCT ( $n = 227$ ) which, having recruited US women with stage II or III breast cancer awaiting adjuvant therapy, compared a group therapy intervention designed to improve mood disturbance with a non-interventional control group. The therapy group met weekly for 18 weeks and were led by clinical psychologists who taught methods for reducing stress and emotional distress including progressive muscle relaxation, positive coping, problem solving, relaxation training and understanding stress responses. Baseline assessments of total mood disturbance were repeated after 4 months in both groups and, when levels of initial cancer stress were included as a variable, showed a significant reduction of mood disturbance overall between study arms ( $P < 0.05$ ). For the anxiety sub-scales, there was a significant reduction in anxiety in the intervention group compared with controls ( $P < 0.05$ ) (instrument=POMS) regardless of initial levels of stress.

Badger *et al.* (2007) presented the results of a three-arm US RCT ( $n = 96$ ) of telephone interpersonal counselling (TIPC) compared with a self-managed exercise program and a control group. The TIPC group received weekly calls for 6 weeks which were given by a psychiatric nurse counsellor and dealt with cancer education, social support, awareness and management of the symptoms of anxiety & depression and role transition. The exercise group focused on regular, low impact exercise with weekly telephone calls to check progress and give encouragement. The control group received just one brief, non-interventional call a week. All follow-up assessments were made by telephone. Depression was not significantly reduced by the interventions compared with the control or for all participants over time. Anxiety decreased for all participants over time ( $P < 0.001$ ) and this decline was significantly stronger for the intervention groups ( $P = 0.01$ ). Post hoc tests suggested that this improvement in anxiety was sustained, but not increased, up to 10 weeks after the final telephone call (instrument=various, including CES-D, SF-12, ICS, PNAS and others).

Cohen and Fried (2007) presented the results from an Israeli RCT of cognitive behavioural therapy (CBT) versus relaxation & guided imagery (RGI) compared with each other and with a control. These interventions were tested in women with early breast cancer ( $n = 144$ ) undergoing adjuvant therapy to determine the effects on psychological distress. The CBT techniques included eliciting negative thinking patterns, monitoring automatic thoughts, restructuring automatic thoughts into more adaptive patterns, mental distraction, reframing, problem solving, decision making, activity scheduling, grading of task assignments, distraction and behavioural experiment techniques. RGI included deep relaxation, deep breathing and autogenic relaxation. Participants were also taught techniques to reduce pain, anxiety and nausea and to improve sleep. The control group received standard care. There was no significant difference between CBT and RGI interventions in the reduction of psychological or perceived stress at any time point or overall but both groups showed a significant reduction in psychological stress over time compared with the control arm with an effect size,  $\eta_p^2 = 0.07$  (where medium=0.6). Similarly, the reduction in perceived stress was significant for both interventions compared with control and  $\eta_p^2 = 0.08$  (instruments=BSI, PSS).

Mutrie *et al.* (2007) presented the findings from a high quality UK RCT ( $n = 201$ ) comparing a 12-week exercise program, including attendance at two classes and one home regime every week, with a standard care control group. All the participants were receiving

adjuvant therapy. The exercise schedule comprised a warm-up period, structured exercise such as walking or cycling and a cool-down period and then participants met for a group discussion which dealt with themes concerning behavioural changes in relation to exercise. Although there was no significant difference in the general quality of life (instrument=FACT-G) between study arms, breast cancer-specific outcomes (instrument=FACT-B) showed an overall significant improvement both from baseline to 3 months ( $P=0.0007$ ) and from 3 months to 6 months ( $P=0.039$ ). Positive affect was also significantly higher in the intervention group at both time periods ( $P=0.0005$  and  $P=0.0008$  respectively) (instrument=PANAS) although negative affect was not changed.

Samarel *et al.* (2002) presented a high quality paper reporting the results of a three arm US RCT which compared two telephone interventions given by oncology nurses or social workers, compared with a non-intervention control group. The study had three timed phases during which each group had a different exposure: the intervention group had weekly telephone support/ weekly in-person support + resource kit/twice monthly telephone support, the 1<sup>st</sup> control group had weekly telephone support/ weekly telephone support + resource kit/twice monthly telephone support and the 2<sup>nd</sup> control group had just the resource kit. The kit contained a variety of formats all centred on reflections of self-concept and interdependence, special exercises to enhance learning and other reading. The purpose of the study was to address the frequency and intensity of cancer-related worry (instrument=VAS-W) and mood disturbance (instrument=POMS) and to improve well-being (instrument=EWBS) of women with early breast cancer following surgery and before or during adjuvant therapy. There were no significant differences between the groups for any outcome except for mood disturbance which was significantly lower in the intervention group and 1<sup>st</sup> control compared with 2<sup>nd</sup> control at all assessment phases ( $P<0.01$  to  $P=0.03$ ) but not between intervention and 1<sup>st</sup> control at any point.

Sandgren and McCaul (2003) described a high quality US RCT ( $n=222$ ) which assessed the value of two nurse-led interventions both using the telephone compared with standard care. Participants had either stage I or II breast cancer and were undergoing adjuvant therapy. One telephone intervention centred on health education (understanding breast cancer, managing post-surgical changes, understanding treatment, managing side effects & fatigue and maintaining a healthy life style) and the other on emotional expression in which women were encouraged to express their feelings and were provided with support and encouragement. Both interventions were ineffective with respect to knowledge, self-efficacy (instrument=CBI), QOL (instrument=FACT-B), mood (instrument=POMS) and perceived control (with the exception of the sub-scale of health education ( $P<0.01$ )) (instrument=PSS), although some parameters declined over time for all women. An update paper (Sandgren and McCaul, 2007) showed no significant changes after long-term follow-up.

#### **[v] After active therapy**

Stanton *et al.* (2005) presented results on an US RCT of women ( $n=558$ ) who were finishing active treatment for breast cancer and were allocated to one of three groups in the 'Moving Beyond Cancer' study. A psychoeducational counselling intervention comprised an individual in-person session and one telephone session which centred on the patient's concerns about physical health, emotional well-being, interpersonal relationships and life perspectives. As well as reviewing goals and making an action plan for the future, women were also given information in the form of a booklet 'Facing Forward' and a manual 'Moving Beyond Cancer' which deal with issues relating to cancer survival.

Participants of the videotape intervention received the same manual and a videotape version of the 'Facing Forward' booklet. Women in the control group were sent a letter and a copy of the booklet 'Facing Forward'. Data were analysed at three time points – baseline, after 6 months and after 1 year. Of the many outcomes assessed, including vitality, cancer-specific stress, depression and post-traumatic growth, only that of vitality was significantly different between the videotape intervention and control arms at the 6 month assessment point (instrument=SF-36). All other comparisons at all time points were of no statistical significance. The authors hypothesised that these disappointing results may have been due to baseline inequalities or the 'soft' nature of the interventions.

#### **[vi] At first disease recurrence**

Gotay presented a good quality US RCT (n=305) comparing a telephone intervention with standard care for women who had been treated with stage I-III breast cancer and who were experiencing a first disease recurrence which was defined as any distant metastatic site, chest wall or nodal site. A telephone intervention was given by trained counsellors who were also breast cancer survivors and at least one year post recurrence. Participants received 4-8 counselling/information sessions by weekly telephone calls, one to two calls per week. The content reflected the most common domains in multi-dimensional models of QOL and patient need. A standardised packet of information (NCI pamphlets) was also sent to each woman. The control group received standard care. Assessments were made at baseline, 3 months and 6 months. Examining only those women whose scores showed them as being at risk for either psychosocial stress (instrument=CARES-SF) or depression (instrument=CES-D) were reported. There were no significant differences in either outcome between intervention and control arms at any time point or across the follow-up period as a whole.

#### Updated evidence - Summary

Updated evidence on the management of psychological distress comprised two moderate quality systematic reviews on psychosocial interventions (Bantum *et al.*, 2007 and Zimmermann *et al.* (2007) a RCT on a couple-focused group intervention (Manne *et al.*, 2007) a RCT on supportive-expressive group therapy (Classen *et al.*, 2008) a poor quality RCT comparing a group psycho-therapy intervention with group social support (Vos *et al.*, 2007) and a RCT comparing a psychoeducational intervention with a wait control (Meneses *et al.*, 2007).

One systematic review found that with respect to significant improvement of emotional well-being, group interventions provided some advantage over individual interventions. The provision of multiple treatment elements was seen as being more useful than targeted clinical services. Only self help and information/education as single interventions had significant effects on emotional well-being. A second review included a meta-analysis the results of which suggested that psychologists were the most appropriate persons to deliver CBT in an individual context to women at any disease stage, preferably after diagnosis/surgery or much later but not during treatment. Medical staff appeared to be better suited for delivering education to individuals or groups, preferably after diagnosis or surgery, but only for women with early stage disease.

RCT data suggested that women with early stage breast cancer who naturally selected an emotional coping strategy may benefit from a couple-focused group intervention. In particular, women who had unsupportive partners and who attempted to understand and

express their emotional reactions to having cancer may derive the most benefit from such an intervention.

A multi-centre RCT showed that, compared with education, there was no evidence that distress was alleviated by brief supportive-expressive group therapy. Neither was therapist training and experience associated with any treatment effect. It was thought that perhaps women with early breast cancer may be more likely to have pragmatic, rather than existentialist, concerns.

A small RCT compared a group psychotherapy intervention with group social support, neither of which was effective in improving the participants' psychosocial adjustment to breast cancer. The authors observed few significant changes in psychosocial parameters over the period of follow-up which may have been because women's' baseline levels were comparable to the general population and therefore little improvement may have been expected. Body image improved significantly over time, particularly in women who had received breast-conserving surgery and the limitations of breast cancer on recreation were also improved.

RCT evidence also showed that a psychoeducational intervention, delivered by a specialist nurse, demonstrated effectiveness amongst women with breast cancer after primary treatment thus providing a 'safe passage' from treatment to survivorship.

<b>Design:</b> Systematic review of RCTs (therapy), evidence level: 1+ <b>Country:</b> United States
<b>Inclusion criteria:</b> Included studies: RCTs of CBT techniques Studies were published in English Use of a 'no treatment' or 'standard care' control group Sufficient data to allow for calculation of effect size Randomisation Prospective design Measures of distress (and pain)  Included patients: Women with breast cancer
<b>Exclusion criteria:</b> Excluded studies: Studies not using any CBT technique
<b>Population:</b> Number of patients = 1,649
<b>Interventions:</b> Studies using any CBT technique (including activity pacing, assertiveness & communication training, autogenic training, behavioural activation, biofeedback, cognitive and attentional distraction, cognitive restructuring, contingency management, goal setting, imagery, hypnosis, meditation, modelling, pleasant activity scheduling, problem-solving, relaxation training, role playing, systematic desensitisation or visualisation)
<b>Outcomes:</b> [1] Estimates of overall effect size of CBT techniques on distress  [2] Comparison of effect sizes of CBT on individual versus group treatment formats for distress  [3] Comparison of effect sizes by cancer stage  Across all studies, outcomes were measured using one or more of the following tools: BDI (Beck Depression Inventory) CES-D (Centre for Epidemiological Studies-Depression Scale) DES-IV (Differential Emotions Scale-IV) EORTC QLQ-C30 (European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire C30) HADS (Hospital Anxiety and Depression Scale) IES (Impact of Event Scale) MOS (Medical Outcomes Scale) POMS (Profile of Moods Scale) STAI (State Trait Anxiety Inventory) VAS (Visual Analogue Scale)

Affects scales  
Faces mood scale  
Mood rating scale

**Follow up:**  
NA

**Results:**

[1] Estimates of overall effect size of CBT techniques on distress

The overall effect size (Cohen's d) of the CBT technique for the treatment of distress was 0.31 (95%CI: 0.07-0.55;  $P < 0.05$  when compared with 0). This result is between 'low' and 'medium' in terms of effect size and could be interpreted as: 62% of participants in the intervention arms had a better outcome when compared with the average control participant (note that the absolute minimum percentage in this respect would be 50% and so this result is not impressive by comparison).

These data were adjusted to take into account the variation in sample sizes between individual studies. The adjusted (d) value (D) was 0.13 (95%CI: -0.2-0.29; nsd) reducing the 62% to 55% and rendering the effect size as not significantly different from 0.

[2] Comparison of effect sizes of CBT on individual versus group treatment formats for distress

When examining the data from 16 individual therapy studies versus 7 group therapy studies, the authors calculated a (d) value for individual therapies of 0.48 (95%CI: 0.17-0.78) and for group therapies of -0.06 (95%CI: -0.22-0.09). The difference between these two being significant ( $P < 0.05$ ) in favour of individual therapy.

[3] Comparison of effect sizes by cancer stage

When examining the data from 13 studies from women with, versus without, metastases, the authors calculated a (d) value for patients with non-metastatic cancer of 0.43 and for women with metastatic cancer of 0.18. The confidence intervals and P values were not given but the data were stated to be not significantly different between the comparators.

**General comments:**

This paper presented a systematic review and meta-analysis of cognitive behavioural therapy given to breast cancer patients. The outcomes of interest were relief of depression (and pain).

Twenty RCTs were included in the analysis but one of these dealt with pain only and hence 19 studies included measures of depression.

Of 19 studies, 3 were of breast cancer patients with metastases, 5 were of patients with mixed breast cancer stages but the majority, 12 studies, were of women with early breast cancer only.

The following databases were searched for relevant literature: PsychInfo,

Medline, CancerLit and CINAHL. Searches were conducted from 1974 to June 2004. The search terms were given. The authors did not state by how many reviewers papers were screened for inclusion/exclusion or how conflicts were resolved.

The statistical methodology used to calculate individual effect sizes (where not stated by authors) and the overall effect size appears to be sound and generated a value for Cohen's d. This statistic gives the overall effect size across multiple tests in which the outcomes may have been reported in different ways (as dichotomous or continuous data, for example). It is generally held that a value for Cohen's d of 0.2 is indicative of a small effect, 0.5 a medium and 0.8 a large effect size.

Only the outcome [1] reflects the aims of the included studies i.e. determining the effect of CBT when compared with a standard treatment or no therapy. The comparisons of group versus individual therapy and by cancer stage are observations made on the data which could have been made *post hoc*, although the authors stated otherwise. None of the included studies made these comparisons and hence they have not been formally tested and the results and authors' conclusion should be viewed with caution.

The authors concluded that CBT appeared to have some significant benefits for breast cancer patients and that the results suggested that individual therapies might be better than group therapies, if only for the outcome of addressing distress. The stage of cancer did not appear to make a significant difference to this outcome.

Allen *et al.* 2002

**Design:** Randomized controlled trial (therapy), evidence level: 1-

**Country:** United States

**Inclusion criteria:**

Women <50 years of age

No history of breast cancer

Histologically/cytologically confirmed breast cancer stage 0-III

Starting first course of chemotherapy

Written informed consent

**Exclusion criteria:**

None stated

**Population:**

Number of patients = 164, mean age = 42 years.

**Interventions:**

Intervention (n=87):

A program of 6 training sessions on problem-solving skills and a instructional manual, 'Home Care Guide for Women with Breast Cancer'.

Problem-solving skills training included: problem orientation, problem definition, generation of alternatives, decision making and solution implementation and

verification.

The book was adapted from an earlier manual 'Home Care Guide for Cancer' and based on prior research from focus groups populated by the target population, identifying their needs, both physical and psychosocial.

The training sessions were led by an oncology research nurse. Following identification of specific problems, study participants were coached in the use of problem-solving techniques and given feedback on their progress in the application of the intervention.

Control (n=77):

Women in the control arm met the research nurse for a single problem-solving skills training session which focused on breast cancer survivorship issues.

**Outcomes:**

[1] Mental health (emotional distress) - measured by the Mental Health Inventory (MHI) which is a 5 item subscale of the Medical outcomes Study 36-Item Short-Form General health Survey (SF-36) that scores from 0-100. Higher scores indicate better mental health.

[2] Psychological reaction to distressing events e.g. cancer diagnosis - measured on the Impact of Events Scale (IES) which has two sub-scales, intrusion (7 items, scored from 0-35) and avoidance (8 items, scored from 0-40)

[3] Assessing the level of rehabilitation needs, describing the unmet need for assistance and social problem-solving ability (data not presented here). These measures were undertaken to determine whether or not certain groups of women would be more likely to benefit than others at baseline from the intervention.

**Follow up:**

Progress was monitored by telephone. Four calls were made, each two weeks apart. Participants were asked to complete worksheets and were also encouraged to contact the interventionist at any time to discuss pertinent issues.

Follow-up assessments were made 4 and 8 months post baseline, a time when the majority of participants would have finished their oncology therapy. Most participants completed the first (baseline) questionnaire just over three weeks from their first chemotherapy session.

By the final assessment, 76/87 (87%) women in the intervention arm and 73/77 (95%) in the control arm provided outcome data.

**Results:**

The sample of women who completed the study were predominantly: with a PSP (78%), married (66%), with children (75%), educated to bachelor's degree or above (40%) and with good incomes (40%). The women who failed to complete the study were significantly less likely to have been white, non-Hispanic, employed or have good incomes. However, participants who dropped out were also more likely to have had higher baseline levels of physical and

psychosocial problems.

#### Results

[1] Mental health (control vs intervention) mean +/- SD:

Baseline 64.6 (16.0) vs 65.2 (17.0)

4 months 68.7 (15.6) vs 73.1 (15.4)

8 months 69.7 (16.8) vs 72.1 (16.6)

[2] Psychological reaction (control vs intervention) mean +/- SD:

#### Intrusion

Baseline 14.6 (9.5) vs 14.3 (8.4)

4 months 10.6 (8.8) vs 10.6 (8.8)

8 months 11.0 (7.5) vs 11.6 (9.1)

#### Avoidance

Baseline 12.0 (9.0) vs 12.2 (8.7)

4 months 12.6 (8.4) vs 10.8 (7.4)

8 months 9.5 (7.9) vs 9.8 (9.4)

None of the results from this comparison between arms and across time showed statistical significance (MHI or IES scales)

Regression analyses were undertaken to identify possible factors that might impact on outcomes. These showed that women in the intervention arm were significantly less likely to report unmet need for practical assistance at 4 months ( $P < 0.05$ ) and also had an improved mood state ( $P < 0.05$ ) but neither was statistically significant at 8 months.

#### **General comments:**

This paper describes a study of problem solving therapy (based on CBT principles) given to young women with non-metastatic breast cancer who were recruited between April 1996 and November 1999 from 31 oncology practices throughout the USA. The purpose of this study was to see if this intervention could be adapted to help women cope with problems and emotional difficulties as result of receiving this diagnosis in mid-life.

Participants were first approached by letter from the principal investigator, followed by a telephone call and assessment of eligibility. Candidates completed the baseline interview and returned a mailed questionnaire before being randomised into control and intervention arms. Data were randomised on treatment centre and involvement, or otherwise, of a primary support person (PSP) nominated by the subject e.g. partner, significant other.

Data were analysed by single ANOVA to assess the difference in mean outcome scores over time (within-group) and between groups. The effects of controlling factors, such as the influence of a PSP, on outcomes were tested using regression analyses.

The authors observed that whilst this intervention was effective for helping the majority of participants to deal with a range of problems relating to cancer and its treatment, those with lower baseline problem-solving skills would be less

likely to derive such a benefit. They expressed the opinion that such women may even have found the intervention an additional burden, perhaps because of its 'light' nature. There was some, inconclusive evidence that women with excellent baseline problem-solving skills may similarly have been adversely affected by the intervention and that therefore appropriate targeting of the intervention was important.

Cohen & Fried (2007)

**Design:** Randomized controlled trial (therapy), evidence level: 1-

**Country:** Israel

**Inclusion criteria:**

Women with breast cancer of stage I or II  
Surgery between 2-12 months previously  
Receiving chemotherapy or radiotherapy  
Fluent spoken Hebrew  
No known psychiatric illness

**Exclusion criteria:**

none stated

**Population:**

Number of patients = 144.

**Interventions:**

Interventions were conducted by the first author and other qualified personnel. Groups of 6-8 participants met weekly for 90-minute sessions over the course of 9 weeks. A new group started every 12 weeks.

Intervention 1 (n=39):

Cognitive behavioural therapy (CBT) included learning and practising: eliciting negative thinking patterns, monitoring automatic thoughts, restructuring automatic thoughts into more adaptive patterns, mental distraction, reframing, problem solving, decision making, activity scheduling, grading of task assignments, distraction and behavioural experiment techniques. Participants were given written material and exercises to perform at home. The experience of the intervention was discussed.

Intervention 2 (n=42):

Relaxation & guided imagery (RGI) included learning and practising: deep relaxation, deep breathing and autogenic relaxation. Participants were also taught techniques to reduce pain, anxiety and nausea and to improve sleep. Participants were given audio cassettes or CDs to continue therapy at home. The results and experiences of these exercises were discussed and help was given if problems were identified.

Control (n=43):

Standard care in the oncology unit, including support from the social work and nursing teams (no further details)

**Outcomes:**

[1] Overall psychological distress – Brief Symptom Inventory (BSI) was used to measure 9 symptoms (somatisation, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation and psychoticism) each scored on a 5-point scale from 0 (not at all) to 4 (extremely). A Global Severity Index (GSI) was calculated from the mean of these scores. The GSI comprised 8 symptom dimensions. One dimension, somatisation, had been excluded since results could have been ascribed to the concurrent use of chemotherapy or radiotherapy

[2] Subjective feelings of stress – measured by the Perceived Stress Scale (PSS), a single item scale from 1 (no stress) to 6 (extreme feelings of stress)

[3] Adherence to practice at home – measured on a scale of 1 (not at all) to 5 (five times a week or more)

**Follow up:**

Assessments of outcomes were made at baseline (pre-intervention), post-intervention and 4 months after conclusion of the therapy cycles.

Out of the 170 patients invited to participate in the study, 144 were enrolled. Data were not analysed for 30 participants (CBT = 16 and RGI = 14) because they had missed more than 2 of the 9 scheduled meetings for reasons not given.

10 women did not provide all three assessment measurements (CBT = 1, RGI = 3, control = 6) for reasons not given.

**Results:**

Data were analysed for 79% of the enrolled participants (CBT = 38, RGI = 39 and control = 37). Approximately 60% of participants were undergoing chemotherapy during the study and the remainder were having radiotherapy.

There was no significant difference between CBT and RGI in the reduction of psychological or perceived stress at any time point or overall.

[1] Overall psychological distress and [2] Perceived stress

Within-group levels of stress (from GSI and perceived stress measures) dropped significantly in both intervention groups between pre-treatment and post-treatment assessments ( $P < 0.001$  for both). The control groups scores, whilst declining, did not change significantly over the same time period.

Within-group levels of stress (from GSI and perceived stress measures) also dropped significantly in both intervention groups between pre-treatment and follow-up assessments ( $P < 0.01$  for both). The control group scores, whilst declining, did not change significantly over the same time period.

MANOVA showed that the intervention arms both had a significant reduction in GSI over time compared with the control arm with an effect size,  $\eta_p^2 = 0.07$ . Similarly the reduction in perceived stress was significant for both interventions compared with control and  $\eta_p^2 = 0.08$

Regression analysis showed that participants who received chemotherapy achieved less reduction in perceived stress.

[3] Adherence to practice at home

Participants in the RGI intervention group reported significantly higher adherence to home practice than those in the CBT group (Cohen's  $d = 0.53$ ;  $P < 0.05$  a medium effect).

Regression analysis showed that adherence to home practice was significantly associated with enhanced decreases of GSI scores over time.

**General comments:**

This paper describes a RCT of cognitive behavioural therapy (CBT) versus relaxation & guided imagery (RGI) compared with each other and with a control. These interventions were tested in women with early breast cancer to determine the effects on psychological distress (also fatigue and perceptions of health locus of control which are not reported here). Participants were recruited from the out-patient department of a single oncology centre by social workers and nurses.

The data were analysed using multivariate repeated measured analysis of variance (MANOVA) to determine the change in outcome over the three time points for each group and univariate analysis with *post hoc* analysis measured the differences between pairs of groups (e.g. intervention 1 *cf* intervention 2, intervention 1 *cf* control etc.) for each outcome. An effect size was expressed as  $\eta_p^2$ , a measure that can be translated as values of 0.1 being a small effect, 0.6 a medium and 0.14 a large effect size. The *t* test was used to analyse compliance with home practice and an effect size was computed and expressed as Cohen's *d* statistic. The independent variables (time since diagnosis, type of treatment, intervention group and adherence to practice at home) were tested for their significance in affecting outcomes in multiple regression analysis.

The authors stated that the findings support their hypothesis, and that of other studies, that show a significant improvement in overall psychological distress as a result of participation in an intervention group for cancer patients with a primary disease. They concluded that it was evident that both CBT and RGI were equally efficient in reduction psychological distress I primary breast cancer patients.

Although a good study, the reason for the high attrition rate was not examined thoroughly. It is plausible that bias may have been introduced since the remaining study population may have differed e.g. degree of motivation, level of psychological distress, from those who failed to complete the study or provide follow-up data. A longer follow-up period may have been of value. The statistical data analysis was not intention-to-treat, which can reduce type I error and, using MANOVA as opposed to, for example, latent growth curve modelling, meant that a lot of data were lost that might have been used. However, for the purpose of not rejecting the null hypothesis for the outcomes of interest, these arguments may not be of great importance.

Antoni <i>et al.</i> (2006)
<b>Design:</b> Randomized controlled trial (therapy), evidence level: 1- <b>Country:</b> United States
<b>Inclusion criteria:</b> Women with breast cancer stage 0-III Surgery in the previous 8 weeks
<b>Exclusion criteria:</b> Prior cancer Prior psychiatric treatment for a serious disorder (detailed) Lack of fluency in English
<b>Population:</b> Number of patients = 199, mean age = 50 years.
<b>Interventions:</b> Both intervention and control conditions comprised groups of 8 people meeting in rooms equipped with couches and a comfortable seating area. Sessions were led by trained personnel who rotated between study arms but who did not carry out the patient assessments.  Intervention (n=107):  A 10 week intervention was started between 10-12 weeks after surgery for breast cancer. Participants met together every week for a 2 hour session within which were practised elements of CBT stress management, relaxation exercises, home assignments (e.g. relaxation practice), role modelling, skills in anxiety reduction, conflict resolution and emotional expression, encouragement of emotional expression and confidence building.  Control (n=92):  Women were invited to attend a 1 day seminar which lasted 5-6 hours. Participants received a condensed educational version of the same information as received by the intervention group. However, there was no opportunity for the same group interactions, role playing, support, learning physical exercises, relaxation techniques or coping strategies.
<b>Outcomes:</b> [1] Thought intrusion and avoidance - measured by the Impact of Events Scale (IES) measured on two subscales, with responses coded 0,1, 3 and 5. The thought in question was 'the diagnosis and treatment of breast cancer'  [2] Interviewer-rated anxiety - measured by the Hamilton Rating Scale for Anxiety (HRSA) and assessed by personnel specifically trained by clinical psychologists  [3] Emotional distress - measured by the Affects Balance Scale (ABS) assessing negative affect, depression, hostility, guilt and anxiety experienced in the past week and scoring on a range from 0 (never) to 5 (always).
<b>Follow up:</b>

Baseline assessment was made at three time points: upon recruitment (4-8 weeks post surgery) and then repeated 6 and 12 months later.

**Results:**

Number of participants per stage:

Intervention (n=107):

0 = 17

I = 44

II = 39

III = 7

Control (n=92):

0 = 10

I = 32

II = 43

III = 7

[1] Thought intrusion and avoidance

The predictive nature of the latent growth-curve model for thought intrusion showed that the third time point at 1 year did not fit the data. To give the best linear relationship this point was freely modelled and was found to be 7.02 months, only a slight progression from time point 2 at 6 months. Hence the improvement in scores over time would not have continued to increase at the same rate beyond this point.

The group effect of the intervention on thought intrusion scores overall was (Cohen's  $d$ ) = 1.22 with  $P < 0.001$  (a large effect). The differences between intervention and control scores were significant at 6 months ( $P < 0.03$ ) and at 12 months ( $P < 0.005$ )

This means that the within-group scores changed significantly over time for the intervention and the between-group scores were significantly different between the intervention and the control.

The effect of the intervention on thought avoidance was not significant compared with the control but scores decreased significantly in both arms over time. This means that this parameter naturally improved with time but that the intervention did not speed the process significantly.

[2] Interviewer-rated anxiety

The data modelled well to the three time points. Although there was a significant decrease in anxiety over time for the intervention arm, the initial scores between experimental and control arms were very different which led to a crossover effect. There were, for this reason, no significant between-groups differences at any time point.

This means that although the intervention arm experienced a significant within-group improvement in this parameter over time, there was no valid comparator to inform the researchers whether or not the therapy was responsible for this improvement.

[3] Emotional distress

The data modelled well to the three time points. The group effect changed the slope of the three data points where  $(d) = 0.33$ , a medium effect. At the third time point (1 year) the groups were also significantly different and the effect size of the intervention was expressed by  $(d) = 0.43$

This means that the within-group scores changed significantly over time for the intervention and the between-group scores were significantly different between the intervention and the control.

**General comments:**

The study design did not control for the attention time i.e. 6 hours for controls versus 20 hours for intervention but did alleviate the likelihood of attrition from a non-treatment control.

Data were analysed at three time points using latent growth-curve modelling. This method measures the trajectory of change over time and can, more successfully than repeated measures ANOVA, cope with missing data instead of deleting all data from participants who don't provide a complete data set. In addition, this model can adequately address non-linear change in the outcome e.g. if the benefits of an intervention plateau at a particular time point rather than continue to increase. Effect size was reported as Cohen's  $(d)$ .

This was a good paper with a well conducted study and report. The methodology of the statistics was complex but thorough but there was less detail about randomisation, allocation and blinding which means that bias cannot be excluded with certainty.

Ritz *et al.* (2000)

**Design:** Randomized controlled trial (therapy), evidence level: 1-  
**Country:** United States

**Inclusion criteria:**

Women  $\geq 21$  years  
Diagnosed with breast cancer between 1995 and 1997  
Able to read and write English  
Able to give informed consent

**Exclusion criteria:**

History of cancer  
Comorbidities that limited functional ability  
Severe psychiatric illness

**Population:**

Number of patients = 211.

**Interventions:**

Intervention group (n=106):

Standard medical care plus the care of an advanced practice nurse (APN). The interventions with the nurse were presented in a lengthy and fully detailed

summary but briefly included:

- a] Pre-operative: assessment, education and care co-ordination,
- b] Post-operative: assessment, education and care co-ordination
- c] Therapy: assessment, education, symptom management, care co-ordination, consultation and referral
- d] Post-treatment follow-up: assessment, education and care co-ordination

Initial APN contact was within 2 weeks of diagnosis and included written and verbal information about breast cancer, what to expect in a consultation, answering questions and giving support. Subsequent contacts were made at scheduled clinic visits, by telephone and at home, sometimes at the initiation of the patient.

Control group (n=105):

Standard medical care (not detailed)

**Outcomes:**

Quality of life (QOL) - measured on three scales:

[1] Mishel Uncertainty in Illness Scale (MUIS) which assesses the inability to determine the meaning of illness-related events (a higher score means greater uncertainty)

[2] Profile of Moods State (POMS) which includes 6 measures of mood and has been previously validated in studies of adjustment to breast cancer (a higher score means greater mood disturbance)

[3] Functional Assessment of Cancer Therapy (breast) (FACT-B) which measures QOL on 6 dimensions (a higher score relates to greater well-being).

**Follow up:**

Participants completed baseline questionnaires at enrolment and by mail 1, 3, 6, 12, 18 and 24 months thereafter. Participants received several reminders when questionnaires were due to be returned.

One patient in the control group was re-staged after enrolment and removed from this study.

**Results:**

Cancer grades of participants (%):

Intervention group (n=106) vs Control group (n=104):

I = 14 vs 15

II = 52 vs 39

III = 27 vs 43

IV = 7 vs 2

These data are significantly different (P=0.04) at baseline. In addition a higher percentage (59%) of women in the intervention were receiving endocrine therapy than controls (43%) which was significant (P=0.03) at baseline.

Results:

QOL - [1] MUIS:

Uncertainty was significantly lower in the intervention group compared with the control group at 1 month (P=0.001), 3 months (P=0.026) and 6 months (P=0.011) but not at 12 months (P=0.589).

The intervention group had significantly lower scores compared with the control group on the complexity (P=0.005), inconsistency (P=0.005) and unpredictability (P=0.038) subscales.

#### QOL - [2] POMS:

The intervention and control groups did not differ significantly in scores across six subscales and across all time periods when all women were included in the analysis.

There was a significant difference in mood between study arms when the participant data were analysed according to marital status: unmarried women in the intervention group had a significantly greater decrease in mood disturbance than control at 1 month (P=0.01) and 3 months (P=0.043) and women with no family history of breast cancer also had a greater decrease in mood disturbance at 1 month (P=0.002), 3 months (P=0.01) and 6 months (P=0.004) when compared with controls.

#### QOL – [3] FACT-B:

Intervention and control groups did not differ significantly at any time point either as a global score or in individual sub-scales. Unmarried women in the intervention group had a greater well being than control at 1 month (P=0.036) only.

#### **General comments:**

This paper describes a RCT which aimed to assess the value of the advanced practice nurse, in terms of QOL (and health economics). The intervention covered most aspects of this nursing role with regard to breast cancer patients when compared with standard medical care.

Univariate and multi-variate tests were used to analyse QOL data, with regression analyses for repeated measures. There were two significant baseline differences between the intervention and control arms: women in the intervention group were significantly more likely to have lower histology (P=0.04) and to receive adjuvant hormone therapy (P=0.03), factors which may have influenced outcomes.

QOL analyses were conducted for up to 12 months because the response rate was considerably reduced by 24 months (76% for intervention and 52% for controls) and the need for support was also reduced and QOL scores were not, by then, significantly different between arms.

That authors concluded that women with newly diagnosed breast cancer and who are given APN interventions show decreased uncertainty for up to 6 months. Unmarried women and those with no family history of breast cancer also gain significant improvements in QOL with respect to mood or well being.

Overall this was a reasonable paper but it would have been helpful to know the exact number of participants who provided data at each time point in order to

appreciate the power of the statistical significance. This information was only given for baseline and 1 year.

Ambler *et al.* (1999)

**Design:** Prospective comparative study (therapy), evidence level: 2++  
**Country:** United Kingdom

**Inclusion criteria:**

Women attending at a breast care clinic  
Benign or malignant breast condition  
Scheduled to undergo surgery

**Exclusion criteria:**

None stated

**Population:**

Number of patients = 110, age range 22 to 80 years, mean age = 50 years.

**Interventions:**

Both intervention and control participants were seen by the same specialist breast care nurse before and/or after the consultation in which the patient would be informed of her test results i.e. formal diagnosis.

Control (n=66):

Standard care nursing: The breast care nurse met with each patient following the diagnostic consultation. This meeting would last approximately 25 minutes.

Intervention (n=37):

Advocacy nursing: The breast care nurse, after training by a clinical psychologist, met with the patient immediately before the diagnostic consultation, identified the patient's main concerns and helped her to prepare for the consultation by developing a list of questions that could be asked. This meeting lasted approximately 9 minutes. The nurse (unaware of the patient's diagnosis) attended the consultation with the patient and helped her by ensuring all questions were dealt with by the surgeon and intervening, if necessary, on the patient's behalf. After the consultation the nurse continued counselling the patient for a short while (mean 16 min) and contacts thereafter were conducted on an 'as needed' basis.

**Outcomes:**

[1] Anxiety, depression and psychological distress - measured on the Hospital Anxiety and Depression Scale (HADS) which has 14 items. A higher score suggests increased anxiety or depression. Scores of >11 are deemed to be clinically relevant.

[2] Extent to which patients were bothered by symptoms - measured by the Rotterdam Symptom Checklist (RSCL) which includes a sub-scale relating to psychological well being.

**Follow up:**

1 person died before study completion prior to her last assessment; 6 pts failed to attend this last assessment and, therefore, n=103 (data incomplete so

ppts withdrawn). Three were lost from controls and 4 from the intervention group.

Data collection was started before surgery and follow-up assessments were made by an independent researcher 2 weeks and 6 months thereafter.

**Results:**

Of all the women who provided data for this study (n=103), 67 had a diagnosis of breast cancer and the remainder had a benign breast lump. 21/67 (31%) women with breast cancer were in the intervention arm.

Post-surgical treatment of women with BC by allocation (% intervention vs control):

Adjuvant therapy:

Chemotherapy: 4 vs 14

Radiotherapy (RT): 52 vs 33

Chemotherapy & RT: 13 vs 5

No treatment: 30 vs 48

Outcome results:

[1] Anxiety, depression and psychological distress – HADS:

Women with breast cancer had significantly higher levels of pre-surgical anxiety than women with benign breast lumps (P=0.03). There was no significant differences in levels of depression between the intervention and control groups. Participants in the intervention arm had significantly lower levels of anxiety at 2 weeks post-surgery (P=0.034). However, when subsequent diagnosis was taken into consideration, there was no significant difference in anxiety between intervention and control groups for women with breast cancer at any assessment time point. However, the incidence of clinically relevant anxiety was higher for women in the control group, regardless of diagnostic outcome:

Incidence of clinically relevant anxiety (intervention vs control) n (%) :

Pre-surgery: 9 (43) vs 25 (54)

2 weeks post-surgery: 1 (4.8) vs 6 (13)\*\*\*

6 months post-surgery: 2 (9.5) vs 6 (13)

\*\*\* P<0.05

[2] Psychological well being - RSCL:

There were no statistically significant differences in scores or in the levels of clinical relevance between the intervention and control arms. However, women with breast cancer who were in the intervention arm reported a bigger drop in distress between pre-surgery and the 2-week assessment point when compared with women with breast cancer in the control group:

Psychological distress (intervention vs control) mean (SD) :

Pre-surgery: 10.80 (5.48) vs 9.35 (5.63)

2 weeks post-surgery: 5.00 (4.18) vs 6.85 (4.36)\*\*\*

6 months post-surgery: 5.00 (3.70) vs 5.69 ( 4.84)

\*\*\* P<0.05

**General comments:**

This paper describes a study on the optimal role of specialist nurse counsellor

to determine the effects of advocacy nursing compared with a more conventional style (in which the nurse meets the patient for the first time after the patient's initial consultation and following her diagnosis). Participants of this comparative study (not a RCT) were recruited after receiving the intervention or control treatment in order to ask for follow-up assessments to be made at two later dates.

The study ran consecutively i.e. firstly, all participants in what would become the control group were treated, using the standard protocol, by the nurse after which all participants in what would become the intervention arm were treated, using the revised protocol. This design was felt to remove possible confounders of having two nurses taking part in the study whilst avoiding the impracticality of the same nurse using alternating methodology. Whilst not a RCT, this comparative study seems practical and is observing the effects of a change in practice.

Whilst there may be some useful data in this study, the emphasis for the researchers was to test a new mode of therapy on all breast patients, regardless of diagnosis. The results highlighted the obvious distress and anxiety felt by all women awaiting a potentially life-changing diagnosis and tried to address this problem by changing what was the current protocol into a regime calculated to alleviate this distress. Because women with breast cancer were not specifically targeted the numbers of such patients within the larger study arms are low which makes the results statistically underpowered and the conclusions open to question.

Dey <i>et al.</i> (2002)
<b>Design:</b> Randomized controlled trial (therapy), evidence level: 1- <b>Country:</b> United Kingdom
<b>Inclusion criteria:</b> None stated
<b>Exclusion criteria:</b> None stated
<b>Population:</b> Number of patients = 478, age range 35 to 95 years, mean age = 50 years.
<b>Interventions:</b> Intervention: Attendance at an one-stop clinic (n=267): Attendees received a mammogram, cytology and ultrasonography, if indicated. When imaging reports were available, a consultant assessed patients and discussed future management.  Control: Attendance at a dedicated breast clinic (n=211): Attendees were assessed by a surgeon and, if further investigations were made, women were asked to return a week later to discuss the results and further management.
<b>Outcomes:</b> Psychological distress - measured by:

[1] State Trait Anxiety Inventory (STAI) and  
[2] the anxiety element of the Hospital Anxiety and Depression Scale (HADS)

**Follow up:**

Data was obtained at baseline for both questionnaires and then after 24hrs (STAI), 3 weeks and 3 months (HADS)

**Results:**

Mean anxiety scores in both groups were lower at all assessment times compared with baseline. The reduction in mean anxiety was greater for one-stop clinic patients at 24 hours but not thereafter.

**STAI:**

One stop (n=220) vs dedicated (n=172) clinic, mean (SD):

Baseline: 48.1 (14.9) vs 47.2 (14.9)

24 hours: 34.5 (14.6) vs 39.8 (15.8) P<0.0001

**HADS:**

One stop (n=208) vs dedicated (n=153) clinic, mean (SD):

Baseline: 8.9 (4.4) vs 8.8 (5.0)

3 weeks: 7.3 (4.7) vs 7.4 (4.3) (P=0.55)

**HADS:**

One stop (n=220) vs dedicated (n=158) clinic, mean (SD):

Baseline: 8.9 (4.4) vs 9.0 (5.0)

3 months: 7.0 (4.6) vs 7.5 (4.7) (P=0.22)

**General comments:**

This paper describes the findings from a NHS study of a one-stop clinic for the assessment of women with suspected breast cancer. Patients were recruited at one hospital between April 1995 and November 1996.

Participants were allocated by clerks and randomised by a balanced block design which had been generated by an independent statistician. Women were randomised prior to giving their consent to take part in the trial.

Unexpected sources of attrition caused the study to be extended but, even then, insufficient women were recruited to achieve more than a 79% power to exclude a 15% difference between arms.

This paper was predominantly examining the use of a one-stop clinic compared to a dedicated breast clinic, both on the grounds of health economics and for the alleviation of patient anxiety and depression, as a result of not having to wait so long for test results. Unfortunately, the relief was only very transient (24 hours) and did not offset the increased cost of same-day reporting of the diagnostic tests.

McArdle *et al.* (1996)

**Design:** Randomized controlled trial (therapy), evidence level: 1+

**Country:** United Kingdom

**Inclusion criteria:**

Women <70 years  
Undergoing breast cancer surgery

**Exclusion criteria:**

None stated

**Population:**

Number of patients = 272.

**Interventions:**

Before surgery, patients were randomised by telephone to one of four groups:

- (a) Routine support from ward staff and an information booklet (Understanding Cancer of the Breast - BACUP) (n=67)
- (b) Routine ward care and support from a specialist breast care nurse (n=66)
- (c) Routine ward care and support from a voluntary organisation (n=69)
- (d) Routine ward care and support from both the breast care nurse and the voluntary organisation (n=70).

The breast care nurse in this trial was appropriately qualified and highly experienced with this group of patients. Her role included informing patients of pre- and post-operative routines, possible after effects of surgery, provision of prosthesis if required, advising on appropriate exercise to regain physical function, explanation of post-surgical adjuvant therapies, counselling, listening, reassurance and provision of future contact. Her initial consultation lasted for about 30 minutes and subsequent appointments were tailored to need and time constraints.

The voluntary organisation was called Tak Tent (Glasgow based) and offered three types of support: information, counselling, and regular group meetings with fellow cancer sufferers. Patients allocated to receive support from them were given an introductory leaflet and subsequently contacted by one of the counsellors after discharge from hospital. It was up to individual counsellors to decide the level of support required and there were no restrictions on the methods the organisation might use which might include maintaining contact by telephone or post, arranging one to one meetings for counselling and encouraging attendance at group meetings.

**Outcomes:**

To evaluate the effect of support from a nurse specialising in breast care and a voluntary support organisation on prevalence of psychological morbidity after surgery for breast cancer.

Psychological morbidity was measured with self rating scales:

[1] A 28 item general health questionnaire - scores ranged from 0 to 28 and measured non-specific psychological morbidity. The questionnaire also contained subscales: somatic symptoms, anxiety & insomnia, social dysfunction and severe depression. Lower scores indicate better outcomes.

[2] Hospital Anxiety and Depression Scale (HADS) - scores range from 0 to 21 for both anxiety and depression. Lower scores indicate better outcomes.

**Follow up:**

Assessments were made at the first post-operative clinic visit and at 3, 6 and 12 months after surgery.

Within the first year after surgery 14 patients developed local recurrence, 12 developed disseminated disease and 9 died.

48/272 women missed 1 or more of their 4 planned assessments: 10 patients were terminally ill or had died, 6 developed other serious illnesses, 8 were chronic non-attenders 8 refused to fill in questionnaires and data were not available for 16 patients.

**Results:**

122 patients underwent a mastectomy, 144 underwent a lumpectomy, 124 patients received no adjuvant treatment or tamoxifen alone, 103 received radiotherapy and 41 patients received chemotherapy.

Most assessment scores tended to fall over the 12 month period. For each scale, scores were consistently lower in the group of patients offered support from the breast care nurse alone compared with the other groups, which were similar to each other.

[1] 28 item General Health questionnaire.

General Health. Mean (SD) at 1, 3, 6 and 12 months:

Routine: 5.2 (5.7); 5.2 (5.7); 4.2 (6.0); 3.7 (6.2)

Breast care nurse: 3.4 (4.6); 2.7 (3.7); 2.7 (3.6); 1.9 (3.5)

Tak Tent: 5.4 (5.4); 5.3 (5.5); 3.8 (4.5); 5.0 (6.5)

Nurse and Tak Tent: 5.1 (5.6); 4.6 (5.0); 4.4 (5.7); 3.9 (4.9)

General health. P=0.015 overall

Subscale results:

Anxiety and insomnia. Mean (SD) at 1, 3, 6 and 12 months:

Routine: 5.8 (4.2); 5.4 (4.2); 4.4 (4.7); 4.7 (4.6)

Breast care nurse: 4.9 (4.1); 4.3 (3.5); 4.0 (4.1); 3.5 (3.4)

Tak Tent: 3.4 (3.5); 3.2 (3.2); 3.0 (2.6); 3.2 (3.2)  
Nurse and Tak Tent: 3.0 (3.5); 2.7 (2.8); 3.0 (2.9); 3.0 (3.4)  
Depression P=0.003

### **General comments:**

This paper describes a RCT in which participants were randomly allocated to receive routine care from ward staff, routine care plus support from breast care nurse, routine care plus support from a voluntary organisation, or routine care plus support from the breast care nurse and from the organisation. The aim was to assess the impact of the breast care nurse and a support organisation on the prevalence of psychological morbidity in patients undergoing surgery for breast cancer.

Within the first year after surgery, members of the Tak Tent organisation contacted patients by telephone on 456 occasions and by letter on 72 occasions. Counsellors received 14 telephone calls from patients and visited patients on 64 occasions. Patients attended 25 group meetings. 26 counsellors participated in the study.

During the course of the study the breast care nurse received 101 telephone calls either directly from patients or their immediate relatives. Queries included patients seeking information, concerns about recurrence, prostheses, side effects of treatment to requiring reassurance and calming of anxiety states or suicidal thoughts.

The timing of interventions differed in that the nurse saw the patients in the perioperative period whereas the voluntary organisation saw them after

discharge. These differences reflect the reality of how breast care nurses and many self help organisations operate.

Authors concluded that support from breast care nurse could significantly reduce psychological morbidity, as measured by self rating scales, in women undergoing breast cancer surgery.

This is a good paper of apparently sound design. However, there were few details of inclusion, exclusion criteria, allocation or randomisation methodology which means that the possibility of bias in selection cannot be excluded.

Mock *et al.* (1997)

**Design:** Prospective comparative study (therapy), evidence level: 2  
**Country:** United States

**Inclusion criteria:**

Women undergoing treatment for stage I or II breast cancer  
Aged 35-65 years  
Had breast-conserving surgery  
Scheduled to receive radiotherapy  
Written informed consent

**Exclusion criteria:**

Concurrent major health problems including cardiovascular disease, acute or chronic respiratory disease or cognitive dysfunction  
Being <35 years or >65 years  
Already participating in a structured exercise program

**Population:**

Number of patients = 50, age range 35 to 64 years, mean age = 49 years.

**Interventions:**

Intervention group:

Self-paced and progressive program of brisk, incremental walking for 20-30 minutes followed by 5 minutes of slow walking. Subjects walked in their local neighbourhood or in a gym and self-prescribed the frequency (4 or 5 times per week) and exercise intensity.

Participants kept a diary with dates, exercise regimes and subjective data. Adherence was measured after the study but women were encouraged to stick to the schedule and were recommended to walk with a partner for support. Researchers made regular contact by telephone or during clinic visits in order to assess progress and provide encouragement.

Control group:

Usual care (not defined). These women were also contacted by researchers in order to minimise differential treatment effects.

**Outcomes:**

Symptom experience - measured by the Symptom Assessment Scales (SAS). Difficulty sleeping, depression and anxiety are three of the elements included in this assessment tool.

The main outcomes of this study (not reported here) were fatigue and physical function.

**Follow up:**

Baseline measurements of physical status were made using the 12-minute walk test and assessed using the Symptom Assessment Scales (SAS) and Piper Fatigue Scale (PFS). These tests were repeated at mid-therapy (about 3 weeks) and at the end of RT (about 6 weeks).

Four participants left the study: 1 because of treatment complications, 2 withdrew from RT and 1 woman left because of time constraints.

**Results:**

72% of women had stage I breast cancer (17 in the intervention group and 16 in the control group). Subjects in both study groups received RT for 5 days per week and there were no significant differences overall in dose and intensity.

SAS (analysis of covariance - mean scores):

Exercise level for intervention group: 4.51

Exercise level for control group: 0.92

P<0.001

Depression for intervention group: 9.51

Depression for control group: 21.05

P=0.104 (nsd)

Anxiety for intervention group: 10.44

Anxiety for control group: 26.93

P=0.029

Difficulty sleeping for intervention group: 12.38

Difficulty sleeping for control group: 32.58

P=0.027

**General comments:**

This paper describes a prospective comparative study conducted by two teaching hospitals which hypothesised an association between exercise and improvement of physical or psychosocial well-being in women with early breast cancer scheduled to receive RT after surgery.

Outcomes over the three time periods were tested by using multi-variate ANOVA controlling for possible confounders such as age, marital status, employment status, ethnicity etc.

Significant differences were found between study arms in pre- and post-test measures of exercise level, anxiety, sleeping difficulty but not depression. Fatigue was also significantly lower in the intervention group.

Measures of dissatisfaction with body correlated positively with fatigue, anxiety, depression and difficulty sleeping and negatively with walking (P=0.004).

The authors commented that subjects of the intervention increased their level of exercise as radiotherapy progressed whilst control subjects tended to do more less physical activity. They observe that patients in the intervention group appeared to be less fatigued, sleep better and experience lower levels of anxiety but not, for some reason, depression.

One weakness of the study was that participants in the intervention arm performed their exercises in their chosen environment and therefore the adherence was self-reported. Secondly, this was not a RCT and therefore the results may conceal a selection bias which may have affected internal validity i.e. was the observed effect due to the intervention alone?

Mutrie *et al.* (2007)

**Design:** Randomized controlled trial (therapy), evidence level: 1+  
**Country:** United Kingdom

**Inclusion criteria:**  
Women with stage 0-III breast cancer  
Receiving chemotherapy or radiotherapy  
Written informed consent

**Exclusion criteria:**  
Concurrent unstable cardiac, hypertensive or respiratory disease, cognitive dysfunction  
Already taking regular exercise

**Population:**  
Number of patients = 201, age range 29 to 76 years, mean age = 52 years.

**Interventions:**  
Intervention group (n=99):

Standard care from the healthcare team plus participation in a 12-week exercise program. This involved attendance at 2 classes and one home exercise regime per week. The 45-minute exercise program involved a 10 minutes warm-up, 20 minutes of activity (such as walking, cycling low level aerobics, muscle strengthening) followed by a cool-down and relaxation period. Participants were monitored to ensure that they did not exceed 50-75% of age-adjusted maximum heart rate.

Exercise was followed each week for 6 weeks, by a group discussion which dealt with a new theme each time. Conversations centred on relevant topics in order to promote behaviour change in relation to exercise and encourage women to continue with individually constructed exercise programs at the end of the study. Women were also invited to join a local general practice referral scheme after the 3 months assessment.

Control group (n=102):

Standard care and receipt of a leaflet about safe exercise regimes. After 6 months women were given an individually constructed exercise programs and invited to join a local general practice referral scheme.

**Outcomes:**

[1] Quality of life (QOL) - measured by the Functional Assessment of Cancer Therapy, general (FACT-G) which includes a core domain of emotional function (FACT-GE) and can be complemented by the addition of the breast cancer-specific scale (FACT-B)

[2] Depression - measured using the Beck Depression Inventory (BDI)

[3] Positive and negative affect scale (PANAS)

[4] Physical activity outcomes (not described here)

**Follow up:**

Baseline assessments were repeated at 3 and 6 months.

15 women (12 from the intervention group) were lost to follow-up at 3 months because they: were not contactable (n=4), were excluded from the analysis (wrong treatment) (n=2), did not return questionnaires (n=7) or had died (n=2). Some of these women were assessed after 6 months.

At 6 months, 11 women (7 from the intervention group) were lost to follow-up because they: did not return their questionnaire (n=6), withdrew (n=1), were not contactable (n=2), were too ill (n=1) or had died (n=1).

**Results:**

Intervention group (n=82)

Control group (n=95)

Effect size estimates (95%CI):

FACT-GE from baseline to 3 months = 0.7 (-0.3-1.7) P=0.19

FACT-GE from 3 months to 6 months = 0.6 (-0.4-1.7) P=0.23

FACT-B from baseline to 3 months = 2.5 (1.0-3.9) P=0.0007\*

FACT-B from 3 months to 6 months = 1.5 (0.1-2.9) P=0.039\*

BDI from baseline to 3 months = -1.7 (-0.3-0.2) P=0.083

BDI from 3 months to 6 months = -1.8 (-3.8-0.1) P=0.064

PANAS+ from baseline to 3 months = 4.0 (1.8-6.3) P=0.0005\*

PANAS+ from 3 months to 6 months = 3.9 (1.6-6.1) P=0.0008\*

PANAS- from baseline to 3 months = -0.7 (-2.5-1.0) P=0.41

PANAS- from 3 months to 6 months = -0.7 (-2.5-1.0) P=0.39

\* of statistical significance.

**General comments:**

This good quality paper describes a pragmatic randomised controlled open trial assessing a 12-week exercise program intended to improve quality of life for early breast cancer patients who were receiving chemotherapy or radiotherapy at (three) oncology clinics in Scotland.

Participants were recruited between January 2004 and January 2005 and randomised into two groups, stratified on the basis of treatment schedule and centre, by means of a permuted block design. Allocation was done by telephone using an interactive voice system. Blinding was not possible but assessments responses were concealed from researchers and measured independently.

The number of participants was sufficient to give a 90% power to detect a change of 7.5 in the FACT-G scores between study arms. Data were analysed on an intention-to treat basis.

There was no significant intervention effect on FACT-G (general scale) at 3 months and this was still non-significant ( $P=0.053$ ) at 6 months. Breast cancer-specific QOL and mood were significantly positively affected by the intervention both at the 3 and 6 months follow-ups.

The authors admit that it would not be easy to determine which part of the intervention may have been responsible for the successful psychological outcomes e.g. whether exercise or the group setting itself but since some of the physical outcomes were significantly improved e.g. shoulder mobility, these at least can be directly attributed to exercise.

The authors concluded that supervised group exercise in addition to usual care could provide functional and psychological benefits at the end of a 12 week program and at least up to the 6 months follow-up.

Stanton *et al.* (2005)

**Design:** Randomized controlled trial (therapy), evidence level: 1-

**Country:** United States

**Inclusion criteria:**

Women with stage I or II breast cancer

Any surgery for primary breast cancer must have been within previous 6 weeks

Invasive epithelial cancer of any nodal status

**Exclusion criteria:**

Prior history of breast cancer

Non-invasive breast cancer or inflammatory breast cancer

Planned use of neoadjuvant chemotherapy or high dose chemotherapy with stem cell rescue

Protracted reconstructive surgery

Surgical complications

Severe physical, cognitive or psychiatric illness

Inability to read and write in English

Participation in another RCT with a QOL intervention

**Population:**

Number of patients = 558, age range 26 to 86 years, mean age = 58 years.

**Interventions:**

After randomisation, participants were allocated to one of three groups:

[a] Psychoeducational counselling (EDU) (n=184) - participation in one individual counselling session (of duration 80 minutes) and one telephone session with trained educators. Participants were invited to voice their concerns in each of the domains of physical health, emotional well-being, interpersonal relationships and life perspectives. By identifying a particular concern the woman could review their goals and develop an action plan. participants were also given a copy of the NCI booklet 'Facing Forward' and a 60-page manual entitled 'Moving beyond Cancer: Your Guide to a Successful Recovery'. The follow-up telephone call dealt with reactions to the material and revisions of strategies and action plans.

[b] Videotape intervention (VID) (n=187) - a personalised letter thanking the recipient for completing the baseline questionnaire and enclosing a copy of the NCI booklet 'Facing Forward'. Also enclosed was a NCI videotape entitled 'Moving beyond Cancer' which lasts for 24 minutes and addresses challenges for re-entry including physical health, emotional well-being, interpersonal relationships and life perspectives. This film was designed to promote adaptive modelling by portraying four breast cancer survivors outlining the problems and advice on coping skills.

[c] Standard print control group (CTL) (n=187) - a personalised letter thanking the recipient for completing the baseline questionnaire and enclosing a copy of the NCI booklet 'Facing Forward' which contains information for cancer survivors.

**Outcomes:**

[1] Vitality - a subscale from the Short Form-36 (SF-36)

[2] Cancer-specific distress - measured with the Revised Impact of Events Scale (IES) which graded how distressing 22 experiences had been on a 5-point scale from 0 (not at all) to 5 (extremely). Such experiences included, for example, intrusive thoughts, avoidance, hyperarousal etc.

[3] Depressive symptoms - measured using the Center of Epidemiologic Studies-Depression Scale (CES-D) which has 20 items to rate depressive symptoms in the previous week on a 4-point scale where total scores range from 0-60.

[4] Positive changes after stressful experience - measured on the Post-Traumatic Growth Inventory (PTGI). Women rated items with regard to cancer as the life stressor from 0 (change not experienced) to 5 (experiencing the change to a very great degree)

Other outcomes included intervention fidelity, medical outcomes and perceived preparedness for re-entry (data not presented here).

**Follow up:**

Follow-up was conducted for 12 months.

Overall, 67% of participants completed three assessments, the first at baseline and then at 6 and 12 months. 66 patients completed baseline one follow-up point and 117 completed only at the baseline. Participants who did not complete the 6 month assessment tended to be older ( $P<0.001$ ), employed ( $P=0.009$ ), to be taking tamoxifen ( $P=0.009$ ) and less likely to report cancer-specific distress ( $P=0.002$ ) or depressive symptoms ( $P=0.005$ ) at baseline. The findings were similar at 12 months.

7/151 women in the EDU arm failed to participate in the intervention because they: were unable to be contacted ( $n=2$ ), had a schedule conflict ( $n=3$ ) or for other reasons ( $n=2$ )

**Results:**

At 6 months data were available for CTL ( $n=136$ ), VID ( $n=139$ ) an EDU ( $n=143$ ) and at 12 months for CTL ( $n=134$ ), VID ( $n=135$ ) and EDU ( $n=130$ ).

There were significant baseline differences in the scales of depressive symptoms, vitality and other variables (the control groups scored highly for vitality and low for depressive symptoms compared with either intervention group) and so the analysis used these baseline scores as a covariate.

Results - 6 months and 12 months:

SF-36 vitality - 6 months/12 months. Mean (SD):

SPC: 3.84 (1.58) / 6.06 (1.53)

VID: 9.06 (1.54) / 9.38 (1.51)

EDU: 5.00 (1.54) / 7.36 (1.56)

VID vs CTL at 6 months ( $P=0.018$ )

Log (IES) - 6 months/12 months. Mean (SD):

SPC: -0.09 (0.02) / -0.13 (0.02)

VID: -0.08 (0.02) / -0.10 (0.02)

EDU: -0.06 (0.02) / -0.11 (0.02)

No significant differences at either time point

CES-D - 6 months/12 months. Mean (SD):

SPC: -0.94 (0.62) / -1.79 (0.57)

VID: -1.25 (0.61) / -1.32 (0.56)

EDU: 0.02 (0.61) / -0.68 (0.58)

No significant differences at either time point

PTGI - 6 months/12 months. Mean (SD):

SPC: 0.75 (1.46) / 2.43 (1.58)

VID: 2.65 (1.43) / 3.00 (1.56)

EDU: 3.32 (1.41) / 5.44 (1.60)

No significant differences at either time point

**General comments:**

This paper describes a RCT which compared a peer-modelling videotape with

two educational sessions or a control. Participants were initially recruited from the offices of collaborating oncologists. Volunteers were then contacted at the end of active treatment, completed baseline questionnaires and randomly assigned via a random number generated list. Assignment was stratified by treatment, clinic and marital status. Participants were recruited between July 1999 and June 2002.

Recruitment was close to providing a 90% power sufficient to detect a standardised effect size of 0.46. Data were analysed on an intention-to-treat basis using appropriate statistical methods (ANOVA).

The results were not as anticipated by the reviewers. No significant differences were found for the majority of outcomes, possibly because of the inequality at baseline forcing adjustment to the statistical analyses. Additionally, the interventions were relatively 'light' and hence non-compliance and failing to submit questionnaires might be understandable.

Burton <i>et al.</i> (1995)
<b>Design:</b> Randomized controlled trial (therapy), evidence level: 1- <b>Country:</b> UK
<b>Inclusion criteria:</b> Women with breast cancer awaiting total or partial mastectomy Written informed consent (intervention groups only)
<b>Exclusion criteria:</b> None stated
<b>Population:</b> Number of patients = 244, mean age = ~61 years.
<b>Interventions:</b> The preoperative interview covered subjects such as: discovery of breast lump, patient's thoughts about possible cause of illness, response to the need for surgery, desire for information, worries about body image, past and future regrets, concerns etc. Expression of feelings by the patient was encouraged.  The psychotherapeutic intervention placed the crisis of illness and surgery within the patient's life situation. Patient's feelings were explored.  [a] Pre-operative interview between the patient and a clinical psychologist followed by a 30 minutes brief psychotherapeutic intervention which was given by the consultant surgeon who was trained in Rogerian counselling techniques.  [b] Pre-operative interview as above, plus a 30 minute chat with the consultant surgeon described as 'a friendly discussion of matters unrelated to illness and surgery'.  [c] Pre-operative interview, as above.  [d] Standard care from surgical and nursing staff.

**Outcomes:**

[1] Hospital Anxiety and Depression Scales (HADS). This was administered at the four time points for interview groups and at 3 months and 1 year for controls.

[2] Coping – a manual was devised to measure this outcome and classified: denial, fighting spirit, stoic acceptance, helpless/hopelessness and anxious preoccupation.

[3] Body image distress.

**Follow up:**

After preoperative interviews, patients (other than controls) completed baseline outcomes measures. These patients were followed up in hospital at 4 days after surgery and (all patients) at 3 months and 1 year.

**Results:****Reduction in anxiety and depression over time in the three interview groups (no control):**

Mean HADS score – Anxiety (n=86):

Pre-operatively: 7.2

4 days post-surgery: 4.3

3 months post-surgery: 4.5

1 year post-surgery: 4.4

P<0.00001

Mean HADS score – Depression (n=86):

Pre-operatively: 3.2

4 days post-surgery: 2.4

3 months post-surgery: 3.1

1 year post-surgery: 3.3

P=0.01

NB. This is a within-group analysis i.e. changes across time for all intervention groups, not a comparison

**Comparison of HADS scores at 3 months and 1 year (all interview groups vs controls):**

Mean HADS score – anxiety at 3 months:

Interview + intervention: 4.3

Interview + chat: 4.2

Interview only: 5.1

Control: 6.1

P=0.043

Mean HADS score – depression at 3 months:

Interview + intervention: 2.8

Interview + chat: 3.0

Interview only: 3.4

Control: 3.7

nsd

Mean HADS score – anxiety at 1 year:

Interview + intervention: 4.6

Interview + chat: 3.4

Interview only: 5.3

Control: 5.6

nsd

Mean HADS score – depression at 1 year:

Interview + intervention: 3.7

Interview + chat: 2.3

Interview only: 3.9

Control: 3.7

nsd

NB. This is a between-groups analysis i.e. comparison between interventions and controls.

**Significant changes in coping ability over time in the three interview groups (no control):**

% Coping Scores (n=130):

Denial preoperatively: 29

Denial 1 year post-surgery: 13

P<0.00001

Fighting spirit preoperatively: 31

Fighting spirit 1 year post-surgery: 43

P<0.00001

Stoic acceptance preoperatively: 19

Stoic acceptance 1 year post-surgery: 17

Helpless/hopelessness preoperatively: 9

Helpless/hopelessness 1 year post-surgery: 10

Anxious preoccupation preoperatively: 12

Anxious preoccupation 1 year post-surgery: 17

P=0.0002

NB This is a within-group analysis i.e. changes across time for all intervention groups, not a comparison

**Comparison of coping ability at 1 year (all interview groups vs controls) % total coping:**

Denial:

Interview + intervention: 13

Interview + chat: 16

Interview only: 11

Control: 15

nsd

Fighting spirit:

Interview + intervention: 45

Interview + chat: 40  
Interview only: 44  
Control: 36  
P=0.031

Stoic acceptance:  
Interview + intervention: 15  
Interview + chat: 21  
Interview only: 14  
Control: 18  
nsd

Helpless/hopelessness:  
Interview + intervention: 8  
Interview + chat: 11  
Interview only: 12  
Control: 11  
nsd

Anxious preoccupation:  
Interview + intervention: 19  
Interview + chat: 13  
Interview only: 19  
Control: 21  
nsd

**Comparison of body image distress between preoperative interview and controls:**

The interview, with or without intervention/chat had a significant effect on body image distress. All experimental groups vs controls:  
Mean body image distress at 3 months = 1.34 vs 3.22  
Mean body image distress at 1 year = 1.03 vs 2.96  
When these data were analysed with non-parametric methods, because of skewed distributions, the results were lower than original findings but still highly significant (P=0.009)

**Comparison between the psychological intervention and the chat:**

An analysis of this comparison showed that only patients who had experienced severe stressful life events found the intervention superior to the chat with respect to distress (P=0.04).

**General comments:**

This paper presents the results of a UK four-arm RCT which examined the impact of a preoperative interview with or without a chat and/or psychotherapeutic intervention compared with routine care. The anticipated benefits for the patient were measured by several psychological variables a few days after mastectomy and in the months following.

Patients were randomised to their study arms by the use of random number tables. Unusually, women randomised to the control arm were not formally told that they were participating in a RCT until the one year follow-up because the 3 month interview was conducted by a member of the Mastectomy Association

rather than by a reviewer. The reasons given for this methodology was that if informed and given baseline questionnaires this group would cease to be considered as receiving 'standard care' by definition. This has methodological merit, but means that, as there were no baseline data for controls, the interview can be compared against one another but individual interventions cannot be compared with a non-intervention (control) group.

The authors noted the high drop-out pre-randomisation (80 patients) and their reasons for refusal to join a CT which, commonly, were either a denial of having feelings about the surgery or a desire not to express their feelings on this subject. Coping strategies changed over time with significant changes in denial, fighting spirit and anxious preoccupation shown by interview groups but a comparison with control at 1 year showed that only fighting spirit was significantly different (lower) in controls.

The authors concluded that the comparisons between outcomes in interview groups suggested that the pre-surgical interview was more likely to have contributed to the most positive outcomes than either the intervention or the chat. This would have been a useful comparison to have made with a control group. It might also be feasible for such an intervention to have been given by a clinical nurse specialist as opposed to a clinical psychologist.

Andersen <i>et al.</i> (2004)
<b>Design:</b> Randomized controlled trial (therapy), evidence level: 1- <b>Country:</b> USA
<b>Inclusion criteria:</b> Women with stage II or III breast cancer and awaiting adjuvant therapy
<b>Exclusion criteria:</b> Stage I disease (mentioned in the results section) Prior cancer diagnosis Refusal of cancer treatment Age <20 >85 Living more than 90 miles from the research centre Mental retardation, severe or untreated psychopathology, neurological disorders, dementia Any immunologic disease or condition
<b>Population:</b> Number of patients = 227, mean age = 51 years.
<b>Interventions:</b> Control group (n=113): Baseline assessment of psychological, behavioural, medical and treatment data was made. Blood samples were taken for immunological outcomes that are not reported here.  Intervention group (n=114): Identical baseline assessments were made as for controls. Participants were grouped in 13 cohorts (n=8-12 participants). Each group met weekly for one and a half hours over 18 weeks. Sessions were conducted by two clinical

psychologists and were described as including strategies to 'reduce stress, improve mood, alter health behaviours and maintain adherence to cancer treatment':

Stress: Understanding stress responses, progressive muscle relaxation training  
Emotional distress: Relaxation training, positive coping, problem solving

Statistical analysis showed that there was no difference in the way that successive intervention sessions were conducted or in the way in which individual components were rated for helpfulness or the intervention for its importance as a whole. If a patient was absent from a session a therapist would call, give support if required and discuss the current topic in the group intervention.

**Outcomes:**

[1] Stress – measured by the Impact of Events Scale (IES) which examines stress-related intrusive thoughts, denial of thoughts and avoidance behaviours relating to cancer and treatment.

[2] Emotional distress – measured by Profile of Moods States (POMS) which measures negative mood and consists of five scales: anxiety, depression, anger, fatigue and confusion. Total Mood Disturbance is the sum of these scales minus the score for vigour.

There were many other outcomes including health behaviours, adherence to treatment and immunological response which are not detailed here.

**Follow up:**

Baseline assessment of psychological, behavioural, medical and treatment data was made. Blood samples were taken for immunological outcomes. Tests were repeated after 4 months.

Before the 4 month assessment, 29 patients (intervention = 22) dropped out (from the intervention but remained in the trial), missed their assessments, experienced disease recurrence (n=2) or had died (n=1). Only 12/224 patients missed their final assessment. Absences were often due to work commitments or treatment toxicities.

**Results:**

Participants had stage II or III breast cancer. Between 89-90% of these women in total were of stage II.

[1] Stress. Baseline scores were not significantly different between intervention and control groups: 26.26 ( $\pm$  14.42) vs 26.28 ( $\pm$  14.46) respectively. This outcome may only have been used to assess baseline stress since no 4 month data were given.

[2] Emotional distress. Baseline values were significantly different between intervention and control groups and a single ANOVA showed nsd between groups. The data were then re-analysed with initial levels of cancer-related stress as a co-factor:

Total Mood Disturbance - POMS (intervention vs control):

31.38 (± 32.11) vs 41.42 (± 35.67) P<0.05

Subscales (intervention vs control):

Anxiety: 12.02 (± 6.91) vs 14.17 (± 7.72) P<0.05

Depression: 10.83 (± 9.32) vs 12.68 (± 11.28)

Anger: 7.49 (± 6.7) vs 8.22 (± 6.19)

Confusion: 8.19 (± 5.37) vs 9.75 (± 5.53)

Fatigue: 8.65 (± 5.97) vs 10.49 (± 6.49)

Vigour: 16.0 (± 6.43) vs 13.89 (± 6.13)

No 4 month data were given in the text but analyses were performed as indicated. Straightforward two-way analysis of data for Total Mood Disturbance showed no significant difference between intervention and control groups. A three-way analysis, introducing the variable of subjects with high initial cancer stress, however, rendered the data of significance in favour of the intervention (P=0.04). When the authors focused on the anxiety sub-scale they found that there was a significant two-way interaction such that there was a greater reduction of anxiety in the intervention arm than in the control arm (P=0.04) but which was not affected statistically by initial cancer stress.

**General comments:**

This paper describes a RCT which compared a psychological intervention with a non-intervention control group in assessing the effects of this therapy on various outcomes, either relating to treatment, physical health and biochemical status but also to distress. The study appears to have been well conducted but there were no details about recruitment, allocation or randomisation. Since bias is a strong possibility, findings from this trial must be viewed with some caution.

Data were analysed with appropriate statistics (repeated measures and multivariate ANOVA) and intention-to treat, including 15% of the intervention group who did not participate but remained in the trial.

The authors focus on the positive outcome for the anxiety sub-scale of the POMS which conferred an advantage to the intervention but showed no data for the remaining sub-scales which were not significant (except for fatigue which was significant if initial cancer stress was factored in). More positive results were forthcoming for other outcomes such as dietary habits, smoking cessation and biochemical and immunological measures.

Samarel *et al.* (2002)

**Design:** Randomized controlled trial (therapy), evidence level: 1+

**Country:** USA

**Inclusion criteria:**

Women with non-metastatic (0-III) breast cancer

Previous surgery within 4 weeks

No previous cancer diagnosis (except non-melanoma skin cancer)

No major medical problems e.g. chronic renal or cardiac disease

Written informed consent

**Exclusion criteria:**

None stated

**Population:**

Number of patients = 183, age range 30 to 83 years, mean age = 54 years.

**Interventions:**

For all three groups, treatment was phased: (i) 8-10 weeks beginning 4 weeks after surgery (ii) 8 weeks and (iii) 8 months:

[a] Intervention group:

- (i) Weekly telephone social support and education
- (ii) Weekly in-person social support and education (including resource kit handed out in 1<sup>st</sup> meeting)
- (iii) Twice monthly telephone social support and education for 3 months followed by monthly telephone social support and education for 5 months

[b] Control 1 group:

- (i) Weekly telephone social support and education
- (ii) Weekly telephone social support and education (including resource kit handed out in 1<sup>st</sup> meeting)
- (iii) Twice monthly telephone social support and education for 3 months followed by monthly telephone social support and education for 5 months

[c] Control 2 group:

- (i) No intervention
- (ii) Mailed resource kit (women could telephone oncology nurse or social worker re. contents)
- (iii) No intervention

The content of the telephone and group components comprised elements of managing symptoms and stress, dealing with fear of recurrence and issues of self-image and sexuality. The resource kit consisted of an information manual, audiotapes, videos and pamphlets which together encompassed reflections of self-concept and interdependence, special exercises to enhance learning and other reading. Telephone interventions were provided by oncology nurses or social workers.

**Outcomes:**

[1] Frequency and measure of cancer-related worry – measured on the Visual Analogue Scale – Worry (VAS-W) which has possible scores ranging from 0-200 from low to high frequency and intensity.

[2] Well-being, satisfaction with life was measured on the Existential Well-Being Scale (EWBS) which is a sub-scale of the Spiritual Well-Being Questionnaire and asks questions the response to which range from 0-6 on a Likert scale.

[3] Mood disturbance – measured on the Profile of Mood States (POMS) which has six polarised sub-scales: tension-anxiety, depression-dejection, anger-hostility, vigour-activity, fatigue-inertia and confusion-bewilderment each rated on a 5-point Likert Scale.

**Follow up:**

58 patients were dropped from the data analyses: lack of continued interest

(n=35), missing more than 2 group sessions (n=2), data not returned or beyond deadline (n=18), death (n=2) and not receiving education materials (n=1). Of these 58 women, 21 were in the intervention group, 20 in the control 1 group and the remaining 17 in the control 2 group with no significant differences in attrition rate.

Baseline data were collected and follow-up assessments were made at the completion of each treatment phase.

**Results:**

Post-surgical treatment: chemotherapy (n=55) or radiotherapy (n=33). Data at the baseline were not significantly different between the three arms and hence these data were not used as a covariate in statistical analysis. Experimental group (n=34), control group 1 (n=48) and control group 2 (n=43).

[1] Frequency and measure of cancer-related worry. Range: 0-200. Mean (SD):

[a] Intervention:

Baseline: 78.24 (46.63)

Phase i: 54.12 (42.77)

Phase ii: 58.18 (46.13)

Phase iii: 54.97 (45.13)

[b] Control 1:

Baseline: 80.44 (57.82)

Phase i: 61.69 (47.20)

Phase ii: 71.60 (55.49)

Phase iii: 55.77 (53.79)

[c] Control 2:

Baseline: 89.74 (58.28)

Phase i: 81.95 (56.53)

Phase ii: 82.74 (52.28)

Phase iii: 70.49 (50.10)

[2] Well-being, satisfaction with life. Range: 0-60. Mean (SD):

[a] Intervention:

Baseline: 23.21 (9.20)

Phase i: 21.29 (6.82)

Phase ii: 20.65 (7.77)

Phase iii: 19.15 (8.29)

[b] Control 1:

Baseline: 23.79 (9.59)

Phase i: 22.85 (10.25)

Phase ii: 24.60 (11.06)

Phase iii: 23.04 (9.59)

[c] Control 2:

Baseline: 24.12 (9.27)

Phase i: 24.47 (10.21)

Phase ii: 25.77 (10.70)

Phase iii: 23.37 (10.18)

[1] Mood disturbance. Range: -32-+232. Mean (SD):

[a] Intervention:

Baseline: 25.68 (37.53)

Phase i: 14.06 (27.69)

Phase ii: 14.06 (35.92)

Phase iii: -2.40 (23.19)

[b] Control 1:

Baseline: 21.21 (33.52)

Phase i: 13.00 (29.71)

Phase ii: 11.17 (24.97)

Phase iii: -5.00 (15.71)

[c] Control 2:

Baseline: 23.14 (34.62)

Phase i: 35.16 (38.77)\*\*P=0.02 (cf Experimental group) or P<0.01 (cf Control 1)

Phase ii: 39.65 (37.84)\*\*P<0.01 (cf Experimental group or cf Control 1)

Phase iii: 27.68 (27.99)\*\*P<0.01 (cf Experimental group) or P=0.03 (cf Control 1)

There were no significant differences between groups for any other outcome, apart from mood disturbance and no significant difference between the intervention and control 1 groups for any outcome, including mood disturbance.

**General comments:**

This good quality paper describes a three-arm RCT which tests interventions with a view to improving the self concept and interdependence modes of the Roy (1999) model of nursing. Participants were recruited in response to mailed invitations sent to areas in New Jersey, USA.

Patients were randomised using a permuted block design. When successive cohorts of 4-8 women had been recruited each cohort was randomly assigned to a treatment arm using a sealed envelope technique. Enough women were recruited to achieve 80% power to detect for effect size of 0.25. Appropriate statistics (MANOVA or non-parametric tests) were used to analyse the data but it was not stated whether or not these analyses were performed independently.

The authors observed that the results were surprising and had not supported hypotheses about the efficacy of this model of support and education. It was also unexpected that, whilst mood was changed significantly between the education-only group and the other two groups, none of the protocols had a significant effect on either well-being or cancer-related worry. The authors concluded that perhaps social support and education may not be as influential in overcoming such emotions at a time when a woman is receiving treatment for a potentially life-threatening illness.

Allard (2007)

**Design:** Randomized controlled trial (therapy), evidence level: 1-

**Country:** Canada

**Inclusion criteria:**

Women with newly diagnosed breast cancer or a suspected lesion  
Scheduled to undergo first breast surgery on an out-patient basis  
Able to speak and write French  
Age >18 years  
No hearing impairment  
Possession of a home telephone  
Written informed consent

**Exclusion criteria:**

Previous cancer or major psychiatric diagnosis

**Population:**

Number of patients = 117, age range 26 to 86 years, mean age = 54 years.

**Interventions:**

Intervention group:

Attention Focus and Symptom Management Intervention (AFSMI). The researcher collected baseline data from participants 2-3 days after surgery. The first interventional telephone call was made 9-10 days after surgery during which the researcher assessed outcome responses by inviting a detailed, objective description of symptoms giving encouragement and suggesting new or additional self-care strategies in response to such requests from the woman. Emotions expressed by women were acknowledged by the researcher who also completed outcome questionnaires with each participant. Duration of the call was not limited. This intervention was repeated one week later and outcome data collected.

Control group:

Usual care comprised peri-operative teaching given by nurses both before surgery and after leaving hospital. Participants also received a telephone call from the staff nurse of the surgical ward enquiring after their well-being. The researcher also called and collected outcome data at the same time intervals as intervention participants.

**Outcomes:**

[1] Functional status – measured by the Symptom Impact Profile (SIP) which examines the extent to which surgery impacts on daily life. The higher the score the higher the level of disruption.

[2] Emotional distress – measured with the short form of the Profile of Moods States (POMS) which has 37 items each rated on a 5 point Likert scale. Sub-scales include anger, depression, confusion and anxiety and a higher score indicates a higher level of anxiety.

**Follow up:**

Assessments were made at baseline (T1: 2-3 days after surgery), one week after the 1<sup>st</sup> intervention session (T2: 9-10 days after surgery) and one week following the 2<sup>nd</sup> intervention session (T3: 17-18 days after surgery).

**Results:**

The majority of women with a final diagnosis of breast cancer were at stage I (40%) or stage II (25%). Nine women had benign disease. The authors only presented statistically significant outcomes.

[1] Functional status:

Only the home management element (score range: 0-100) of this outcomes measure was significantly affected by the intervention:

Scores across time. Mean (SD):

Intervention group (n=?):

T1: 45.26 (25.30)

T2: 18.91 (18.49)

T3: 12.12 (15.00)

Control group (n=?):

T1: 45.54 (30.50)

T2: 25.87 (25.62)

T3: 17.10 (17.51)

Both groups showed declines in mean score over time which reached significance between T2 and T3, meaning that this element was naturally less disruptive as time passed. The intervention and control groups were statistically significantly different from one another across time ( $P=0.03$ ) but not at any specific time point, meaning that being in the intervention group was associated with a better rate of decline in disruption to home management.

[2] Emotional distress (sub-scale of POMS where range: 27-135):

Scores across time. Mean (SD):

Intervention group (n=?):

T1: 47.23 (15.51)

T2: 41.20 (14.69)\*

T3: 41.03 (15.87)

Control group (n=?):

T1: 49.96 (19.76)

T2: 47.91 (18.12)\*

T3: 45.61 (16.41)

Neither group showed significant changes in mean score over time nor was there an overall group effect but intervention and control groups were significantly different from one another at time T2 ( $P=0.03$ ). This means that at the second time point, being in the intervention group was associated with a lower level of emotional distress but that, on the whole, group assignment made no significant difference to outcome.

Confusion (sub-scale of POMS where range: 5-25):

Scores across time. Mean (SD):

Intervention group (n=?):

T1: 9.79 (3.73)

T2: 7.98 (3.58)\*

T3: 8.03 (3.54)

Control group (n=?):

T1: 9.57 (4.13)

T2: 9.49 (3.98)\*

T3: 8.82 (3.74)

Both groups showed significant declines in mean score over time ( $P=0.01$ ) and

the rate of decline was significantly different between groups across time ( $P=0.02$ ) and between groups at time T2 ( $P=0.05$ ). This means that the element of confusion naturally improved over time but that being in the intervention group was associated both with a better rate of decline and a lower mean score for confusion at time T2.

The scores in the Depression sub-scale also naturally declined over time ( $P=0.05$ ) but there was no group differences either over time or between specific time points.

**General comments:**

This paper describes a Canadian RCT which examined the effects of a psycho-educational nursing intervention which was given in the immediate post-operative period following day surgery for breast cancer. The purpose of the intervention was to help women to focus on symptom experiences and the decisions made to manage those symptoms. Since recruitment and use of the intervention occurred prior to a final diagnosis, some of the participants did not have breast cancer. However, for the purposes of assessment, these women were included since it may be that their levels of emotional distress were equal to women who were later diagnosed positively.

Women were recruited over a 2 years period from rural and urban areas. The study numbers were sufficient to detect a moderate effect size (no number given) with 80% power. Randomisation was achieved by means of a table of random number and women were allocated by a research assistant. Data were stratified by whether or not they had axillary node biopsy as part of their surgery.

Significant differences in baseline data between groups necessitated the use of the pre-test scores to be used as covariates in the statistical ANOVA. Importantly, it was not clear how many of the 117 recruited participants actually completed all the assessments or how many were in each study arm. This information would have useful in confirming the validity of the published results and so conclusions should, perhaps, be viewed with some degree of caution since less than 117 women would render the trial underpowered.

Authors concluded that AFSMI significantly affected the home management element of functioning and had an overall positive effect on emotional distress, particularly in the early post-surgical period, and improved the symptoms of confusion both across time and in the early post-surgical period. Other outcomes were not significant. The authors felt that a nursing intervention applied immediately after surgery could reduced emotional distress and enhance coping.

Sandgren & McCaul (2003)

**Design:** Randomized controlled trial (therapy), evidence level: 1+

**Country:** United States

**Inclusion criteria:**

Diagnosis of stage I-III breast cancer

Ability to speak English  
Ability to talk by phone  
Undergoing adjuvant treatment

**Exclusion criteria:**  
Serious comorbid conditions

**Population:**  
Number of patients = 222, age range 30 to 84 years, mean age = 55 years.

**Interventions:**  
Intervention group:  
Nurse phone intervention which comprised five weekly telephone calls, each lasting for 30 minutes. A follow-up call was made after a further 6 months, usually when chemotherapy had finished. The intervention centred on 2 approaches:

(a) Health education (n=78): participants received a curriculum detailing study subjects which included understanding breast cancer, managing post-surgical changes, understanding treatment, managing side effects & fatigue and maintaining a healthy life style.

(b) Emotional expression (n=89): participants received the same number of calls as the other intervention arm. Women were encouraged to express their deepest feelings about the cancer and any attendant issues. The nurse listened and provided support and encouragement.

Nurses were trained, and initially supervised, to give these interventions. 7 nurses completed the entire project and were all involved with both sub-groups.

Control group (n=55): Standard care which included access to the usual nursing care line, if required.  
Standard care

**Outcomes:**  
[1] Knowledge - measured by means of testing knowledge on a specific topic (lymphoedema) and asking an open ended question: 'list the way to prevent lymphoedema'.

[2] Perceived control - measured from 4 items on the Perceived Stress Scale (PSS) and scored from 0-4.

[3] Self-efficacy - measured using 2 sub-scales from the Cancer Behaviour Inventory (CBI) comprising 8 items to assess the degree to which the user sought and understood medical information and 7 items to assess affect regulation.

[4] QOL - measured by the Functional Assessment of Cancer Therapy-Breast (FACT-B). which assesses physical, functional, social and emotional well-being and is also directed to issues relating specifically to breast cancer.

[5] Mood - measured by the Profile of Mood States (POMS) sub-scales for depression-dejection, tension-anxiety, fatigue-inertia, vigour-activity, anger-

hostility and confusion-bewilderment.

**Follow up:**

Baseline measures were made before the start of the intervention (T1), usually post-surgery and during adjuvant therapy. The follow-up assessment was after 5 months (T2).

All randomised participants completed the study.

**Results:**

Of 222 patients that completed the study, 49% had stage I and 13% had stage II breast cancer.

[1] Knowledge

No baseline measures were tested and so this outcome is presented as the result at time T2. Results scale = 0-10. Mean (SD):

(a) Health education arm: 2.86 (2.30)

(b) Emotional expression arm: 1.92 (1.70)

(c) Standard care arm: 1.74 (1.30)

$P < 0.01$  when (a) compared with (b)

[2] Perceived control. Results scale = 0-16. Mean (SD):

(a) Health education arm:

T1: 5.12 (2.90)

T2: 3.53 (2.80)

(b) Emotional expression arm:

T1: 4.75 (3.00)

T2: 3.81 (2.60)

(c) Standard care arm:

T1: 5.27 (3.60)

T2: 4.56 (3.10)

$P = 0.03$  when (a) compared with (b)

Across all groups, women reported greater control ( $P < 0.01$ ) with time but also more social constraint ( $P = 0.03$ ). Other comparisons of mediators related to therapy (including CBI outcomes) did not produce results of significance over time or between study arms.

[4] QOL:

As a whole group, women reported significant improvements over time for physical, functional and emotional well-being and for QOL as a whole ( $P < 0.01$ ) but not for social outcomes including the relationship with the physician.

[5] Mood:

As a whole group, women reported significant improvements over time for overall mood and individual mood states ( $P < 0.01$ ), except for fatigue. None of the outcomes were significantly different between control and intervention groups.

**General comments:**

This paper presents results from a three arm RCT which compared two telephone interventions given by trained nursing staff. One intervention focused on elements of patient education and the other on emotional expression. Both were compared with a control condition of standard care.

Participants were recruited by a psychologist and two oncology nurses during clinic appointments and were randomly assigned to study group by means of block and stratified by stage. The statistics (ANOVA) were appropriate.

Only the health education participants showed positive outcomes when compared with control subjects, having greater knowledge and perceived control. Control was a parameter which improved as a whole for all subjects across time.

The sample size had 83% power to detect a moderate (Cohen's  $d = 0.4$ ) difference between arms, had there been one. The authors offered hypotheses as to why the interventions were largely ineffective which summarised to (1) verbal emotional expression being possibly weaker than written emotional expression, (2) the telephone being a less effective medium than in-person therapy, (3) possible inadequacy in nurse qualification, (4) participant background, (5) incorrect follow-up time and (6) the lack of need for any intervention as women tended to improve in these outcomes over time anyway with good standard care alone.

These findings and conclusions were not changed by additional data presented in a follow-up paper (Sandgren *et al.*, 2007).

Badger *et al.* (2007)

**Design:** Randomized controlled trial (therapy), evidence level: 1-

**Country:** United States

**Inclusion criteria:**

Women with stage I-III breast cancer

Currently receiving adjuvant therapy for breast cancer

Ability to speak English

Ability to speak on the telephone

No physical or psychological disabilities (sufficient to prevent participation in any interventional activities)

Available partner (who were also involved in the trial but this element is not reported here).

**Exclusion criteria:**

None stated

**Population:**

Number of patients = 96.

**Interventions:**

All arms were conducted over the telephone and by counsellors suitable trained in the particular intervention.

Intervention 1 (n=38)

Telephone Interpersonal Counselling Intervention (TIP-C)

For 6 weeks, the participant received weekly telephone calls (mean duration of 34 minutes) from a psychiatric nurse counsellor who had oncology expertise. The conversation centred on cancer education, social support, awareness and management of depressive & anxiety symptoms and role transition.

Intervention 2 (n=23)

A 6-week self managed exercise protocol which focused on regular, low impact exercise with weekly telephone calls (mean duration of 11 minutes) to check progress and give encouragement. Scale of involvement was measured during the course of these calls - participants were asked rate the nature of the exercise, duration and intensity (on a scale of 0-10).

Control (n=37)

Participants received printed information about breast cancer and weekly (brief) telephone calls over the 6 week period. No counselling, advice or tips for exercise were offered and if any problems were highlighted during these calls the patient was referred to her doctor.

**Outcomes:**

[1] Depression - measured by a 20-item Centre for Epidemiological Studies - Depression Scale (CES-D) where scores >16 are considered positive for clinical depression.

[2] Anxiety - measured on several scales and combined into a 8-point composite index of anxiety:

(i) Positive and Negative Affect Scale - four sub-units: nervous, jittery, scared, afraid.

(ii) SF-12 - one sub-unit: calm & peaceful

(iii) Index of Clinical Stress - 3 items: feel so anxious want to cry, hard to relax, feel very panicked.

**Follow up:**

Baseline assessments (T1) were made before the trial started using various instruments including those reported in the paper. Follow-up assessments were made in the week after the sixth call (T2) and a month later, 10 weeks after the final call (T3). All assessments were conducted by telephone.

Three women dropped out before T2 and five before T3. Reasons included lack of interest or a failure to collect data. These women did not start the study with significantly higher levels of anxiety or depression than those women who remained in the study.

**Results:**

Of 96 participants, 53% had stage II breast cancer and 14% stage III, the rest

were stage I. 75% of women were undergoing chemotherapy, 36% were on endocrine therapy and 54% radiation therapy.

There were no baseline differences between groups, either in assessment for pre-study depression or anxiety, demographics, current treatment, type of breast cancer surgery or psychiatric history.

[1] Depression. Mean (SD):

TIP-C arm:

T1: 16.44 (1.74)

T2: 14.08 (1.52)

T3: 14.25 (1.76)

Exercise arm:

T1: 13.26 (2.39)

T2: 11.32 (2.10)

T3: 10.53 (2.42)

Control:

T1: 9.88 (1.79)

T2: 9.35 (1.57)

T3: 8.82 (1.81)

Over the duration of the study, levels of depression did not change significantly for the study population as a whole nor was there a significant difference between groups over time. This means that the interventions did not alter already non-significant changes in levels of depression. Unfortunately, there was a significant difference in overall levels of depression between the intervention arms and the control group with both intervention arms having a much higher level of depression from baseline and at all time points. However, the authors pointed out that one mean depression score which was >16 (in the TIP-C arm) did fall below this level by time T2.

[2] Anxiety. Mean (SD):

TIP-C arm:

T1: 4.39 (0.33)

T2: 3.21 (0.27)

T3: 3.19 (0.28)

Exercise arm:

T1: 4.14 (0.46)

T2: 2.64 (0.38)

T3: 2.85 (0.38)

Control:

T1: 3.05 (0.34)

T2: 2.85 (0.28)

T3: 2.81 (0.29)

Over the duration of the study, levels of anxiety did change significantly ( $P < 0.001$ ) for the study population as a whole and there was a significant

difference between groups over time ( $P=0.01$ ). There were no main group effects, unlike the analyses for depression, meaning that as a whole, the within group variance was not different between study arms, including at baseline.

*Post-hoc* t-tests were performed to attempt identification of time interval at which the effect of the interventions were significant. This occurred for the TIP-C ( $P<0.001$ ) and exercise ( $P=0.002$ ) groups between baseline and time 1 but changes between T1 and T2 were not significant. This means that improvements seen after six weeks were sustained but not enhanced a month later.

**General comments:**

This paper describes a small RCT of women and their partners who were recruited at a single oncology centre to participate in a trial which made comparisons between two interventions, one psychological, one physical and a control. All study arms involved an element of telephone use between researcher and participant. Partners of participants were also recruited and received the same interventions, albeit at a different rate and time but these outcomes are not included here.

Data were analysed with appropriate statistics (RM-ANOVA) but the significant difference in baseline scores between intervention and control arms for depression, but not anxiety, is unexplained. Such baseline variance may occur as a result of inadequate randomisation or biased allocation. Another important factor is that randomisation (the methodology for which no details were given other than it was undertaken by the project leader) occurred before baseline assessments were made. Perhaps knowledge of allocation may have affected levels of depression, if not anxiety. In any event, results should be treated with great caution as the possibility of bias is strong.

Gotay *et al.* (2007)

**Design:** Randomized controlled trial (therapy), evidence level: 1+  
**Country:** United States

**Inclusion criteria:**

Women with first recurrence after surgery for stage I, II or III breast cancer  
 Informed of recurrence within previous 56 days  
 No current psychiatric condition affecting participation  
 Ability to read and understand English  
 Completion of baseline assessment  
 Written informed consent  
 First recurrence was defined as any distant metastatic site and/or chest wall or nodal site

**Exclusion criteria:**

Women with ipsilateral breast tumour recurrence after lumpectomy or isolated contralateral, primary breast cancers.

**Population:**

Number of patients = 305, age range 25 to 93 years, median age = 54 years.

**Interventions:**

Telephone intervention (TG) (n=152):

The majority of trained counsellors were breast cancer survivors and were at least 1 year post-recurrence. Participants received 4-8 counselling/information sessions by weekly telephone calls, one to two calls per week. The content reflected the most common domains in multi-dimensional models of QOL and patient need. A standardised packet of information (NCI pamphlets) was also sent to each woman.

Intervention content included:

Physical concerns, social support, stress management and existential concerns.

Control group (CG) (n=153):

Usual supportive care.

Participants were mailed the same information received by the intervention group members at the 6 month point.

**Outcomes:**

[1] Psychosocial stress (emotional well-being) - measured by the Cancer Rehabilitation Evaluation System - Short Form (CARES-SF) Psychosocial scale which has 5 sub-scales. A score of 0.615 or more reflects a risk status for emotional problems.

[2] Depressive symptoms - measured with the Centre for Epidemiological Studies-Depression (CES-D). A score of 16 or more indicates a risk for depression.

**Follow up:**

After baseline assessment, follow-up data were collected by post at 3 months and 6 months. Participants were also asked to rate the intervention in terms of their satisfaction from 1 or (low) to 3 or 4 (high).

42% of control group patients and 26% of TG patients experienced disease progression whilst on study. At 3 months, 1% of TG patients and 5% CG patients had died and at 6 months this had increased to 7% and 10% respectively.

30/152 women on the TG did not complete the intervention because: patient refused (n=15), patient could not be reached (n=8), progression (n=5) or death (n=2).

**Results:**

Median total no. of telephone calls = 6 (range: 1-24)

Median no. of sessions = 5 (range: 0-9)

Median no. of mins delivering intervention = 120 (range: 0-390)

Topics discussed over study:

Physical concerns = 82%

Social support = 77%

Stress management = 76%

Existential concerns = 74%

**Results:**

Psychosocial stress. % of participants with a CARERS-SF score above 0.615:

TG (n=124):

Baseline: 77

3 months: 66

CG (n=122):

Baseline: 78

3 months: 70

There was no evidence to suggest that the intervention significantly impacted on the outcome (P=0.50).

Depression. % of participants with a CES-D score above 16:

TG (n=124):

Baseline: 48

3 months: 47

CG (n=128):

Baseline: 48

3 months: 40

There was no evidence to suggest that the intervention significantly impacted on the outcome (P=0.24).

No subsequent analyses, stratifying the data on psychosocial status, depressive symptoms or other factors, affected the statistical significance of these outcomes.

Despite the lack of significance of impact, the great majority of patients who had received the intervention expressed satisfaction with it.

**General comments:**

This paper describes a good quality RCT of women with newly recurrent breast cancer who received a telephone counselling and information intervention over a period of about 4 weeks.

Participants were recruited, between July 1998 and November 2002, by oncology nurses, research associates or physicians. After initial assessment, women were randomised via a central networked allocation system and data were stratified by age, recurrence site and time since diagnosis.

Despite the fact that three data sets were obtained for this study, only the results of the comparison between baseline and three months is presented in this paper. The participant number at this time point was sufficient for a 90% power to detect up to 21% difference between study arms in psychosocial stress or depression symptoms. The results were expressed only for patients in each study arm whose baseline assessment scores had exceeded cut-off points indicative for risk of stress and/or depression rather than the groups as a whole.

At baseline, more women in the TG arm had received chemotherapy for recurrence (P=0.01) whilst more women in the CG group had received endocrine therapy (P=0.03) and had experienced disease progression (P=0.004). These differences could have impacted on outcomes but the authors tested for this feature and found this not to be the case.

The authors tried, by several post-hoc analyses, to determine the factors which may have influenced the lack of impact of this intervention. They concluded that there being no relationship between intensity of intervention, no particular patient sub-group and no overall temporal decline in outcomes were responsible. Rather they intuited that at this moment in the patients' pathway such an intervention would not be effective.

Bantum (2007)
Design: Systematic review of randomised trials (therapy). Evidence level: 1 Country: United States of America
Inclusion criteria: Included studies: Randomised controlled trials
Included study participants: Women with breast cancer
Exclusion criteria: Studies which addressed specific health behaviours e.g. smoking.
Population: Number of patients = 4931 (mean number per study = 89). Mean age = ~52 years.
Interventions: Psychological, social or psychoeducational interventions (for example, the use of social support, targeted education, cognitive behavioural strategies or emotional expression).
Outcomes: Studies evaluated outcomes which included emotional well-being (87%), physical well-being or symptoms (53%) but were less likely to report social well-being (41%), global QOL (33%) functional well-being (25%) survival (8%) or coping strategies (33%). Across studies 34% reported significant improvements as a result of the intervention under consideration.
Follow up: -
Results: Type of intervention (n=61) / %: Individual treatment = 48.3 Group therapy = 41.4 Couple or family = 1.7 Other or not reported = 6.9  Intervention (n=61) / %: Emotional expression / venting of feelings = 52.5

Relaxation training = 52.5  
Social support = 47.5  
Information / education = 47.5  
Rehearsal of new skills = 29.5  
Problem-solving training = 27.9

Intervention provider (n=61) / %:

Nurse = 45.9  
Psychologist = 37.7  
Social worker = 29.5  
Clinical trainee = 9.8  
Psychiatrist = 9.8  
Research assistant = 4.9  
Cancer survivor = 1.6  
No provider = 3.3

Studies with significant findings (n=61) / % of n (number of studies):

Coping = 45 of 20  
Emotional well-being = 43.4 of 53  
Functional well-being = 13.3 of 15  
Physical well-being = 34.4 of 32  
Social well-being = 32 of 25  
Quality of life = 25 of 20  
Growth/ benefit finding = 100 of 1  
Survival = 20 of 5  
Other = 52.9 of 34

Interventions that improved emotional well-being:

23 studies found significant improvements in this outcome and these studies had a mean of 5.35 treatment elements per intervention. 30 studies did not find a significant improvement in emotional well-being and had a mean number of 3.6 treatment elements per study ( $P < 0.05$ ).

Professional providing the intervention (significant findings vs non-significant findings) / %:

Nurse = 39.1 vs 60.9  
Psychologist = 43.5 vs 26.7  
Social worker = 34.8 vs 26.7  
Clinical trainee = 13 vs 10  
Psychiatrist = 26.1 vs 0 ( $P < 0.01$ )  
Research assistant = 4.3 vs 6.7  
Cancer survivor = 4.3 vs 0  
No provider = 0 vs 6.7

Type of intervention (significant findings vs non-significant findings) / %:

Individual treatment = 30.4 vs 66.7 ( $P < 0.05$ )  
Group therapy = 60.9 vs 30 ( $P < 0.05$ )  
Couple of family = 1.6 vs 0  
Other or not reported = 4.3 vs 3.3

Mean quality of study score (significant findings vs non-significant findings) / %:

3.7 vs 3.5 (out of a maximum of 5 points).

General comments:

This paper presents the findings of a systematic review of 61 RCTs on psychological therapies for women with breast cancer where the outcomes were all or some measurable constituents of quality of life. These psychosocial interventions were to be aimed at helping patients manage the symptoms of their disease or develop adequate coping strategies in order to address their cancer experience. 65.6% of included studies were conducted with women having early stage breast cancer.

Papers were identified by searching PsychInfo, PubMed, Social Abstracts and ERIC databases up to 2004 (search terms were listed). An unknown number of reviewers rated each study for content, methodology and quality. Such factors included whether or not studies were likely to have had sampling bias, equivalence of study groups, follow-up and attrition. Of all the studies, 28% received the maximum of 5 marks for all possible parameters and 16% received only 1 mark.

Because emotional well-being was the most commonly used outcome across studies, this was reported in detail. The results of this analysis showed that studies reporting significant outcomes were those in which the interventions had used multiple treatment elements ( $P = 0.012$ ) were more likely to have been provided by a psychiatrist ( $P = 0.004$ ) utilised a group-based format ( $P = 0.016$ ) and were less likely to treat participants individually ( $P = 0.035$ ). Only two single interventions were rated with significant findings for emotional well-being: self help ( $P = 0.05$ ) and information and/or education ( $P = 0.022$ ). Fewer than half of the studies that reported this outcome demonstrated an improvement and of 245 separate measures, only 22% showed statistically significant improvements over time.

The authors concluded that group interventions would provide some advantage over individual interventions, for example the understanding and support which could be given by women facing similar experiences. The provision of multiple treatment elements was seen as being more useful than targeted clinical services.

This review offered no tests of heterogeneity between studies which would be expected to be considerable given the broad range of interventions and outcomes. The authors pointed out that many of the included studies had failed to give sufficient details of the sample population, intervention or outcome. This would make evaluation of efficacy difficult. There is also a possibility of publication bias (only positive outcomes reported) and also perhaps selection bias (very little ethnic mix). The findings of this review must therefore be interpreted with caution.

Zimmerman *et al.* (2007)

Design: Systematic review of RCTs (therapy). Evidence level: 1-  
Country: Germany

Inclusion criteria:  
Included studies:  
Randomised controlled trials

Included study participants:  
Women with breast cancer (a separate study was conducted with heterogeneous cancer types but the results are not reproduced here).

Exclusion criteria:  
Studies in which details of the intervention provider were not given

Population:

Number of patients = 6419. Age range: 40 to 65 years. Mean age =  $52.4 \pm 4.7$  years

**Interventions:**

Psychological, social or psychoeducational interventions (for example, the use of social support, targeted education, cognitive behavioural strategies or emotional expression). Interventions were categorised as psychoeducational (EDU) cognitive-behavioural (CBT) supportive (SUP) and relaxation (REL). Multi-modal treatments including a behavioural component were included in the CBT group.

Treatment providers were classified as either being or not being a psychologist.

The effect size of each factor was expressed as Cohen's d where values of 0.2, 0.5 and 0.8 corresponded with 'small', 'moderate' and 'large' respectively.

**Outcomes:**

To determine the modifying factors which determines the success of psychosocial interventions to treat emotional distress and focusing on the cancer type, intervention type and intervention giver primarily.

**Follow up:**

-

**Results:**

**Effect size:**

The average effect size across studies = -0.47 to 2.66 with a mean of 0.26 (SE 0.07) being different from zero ( $P < 0.001$ ). The assumption of homogeneity between studies was rejected and moderators (including type of intervention and intervention giver) were tested.

**Effect size of intervention type, format, timing and disease stage**

Type of interventions were EDU (n=8) CBT (n=24) SUP (n=15) REL (n=2) 'mindfulness' (n=2) and a cosmetic class (n=1).

**Effect size (d) of intervention vs control:**

EDU = 0.53 ( $P < 0.01$ )

CBT = 0.19 (NSD)

SUP = 0.13 ( $P < 0.01$ )

REL = 0.30 ( $P < 0.01$ )

Mindfulness = 0.29 (NSD)

When a comparison was made between EDU and CBT, taking into account the nature of the control groups, the effect size of CBT vs standard care was further reduced to  $d = -0.05$

96% of studies reported on the intervention format of which 28 studies were individual, 22 were group activities, 2 were couple and others were self-help (n=1) patient plus family (n=1). A comparison between group and individual interventions show a higher effect size for individual format than group ( $d = 0.30$  vs  $d = 0.19$ ) ( $P < 0.001$ ).

82% of studies reported the timing of interventions of which 33% were conducted after diagnosis or surgery, 33% during or after medical treatment (i.e. chemotherapy or radiation therapy) and the remainder months or years after initial diagnosis. Those interventions conducted directly after diagnosis or surgery achieved a higher effect size ( $d = 0.33$ ) than during treatment ( $d = 0.18$ ) ( $P < 0.01$ ) or years/months after diagnosis ( $d = 0.16$ ) ( $P < 0.001$ ).

54% of studies reported disease stage of the study participants of which 43% were stage I to III or

stage IV and 14% were of mixed stage. Patients with early stage disease had a higher effect size ( $d = 0.32$ ) than those with advanced disease ( $d = 0.13$ ) ( $P < 0.01$ ).

#### Effect size of intervention practitioner

73% of studies reported the practitioner of the intervention of which 21 studies were led by a psychologist and 11 by a nurse. Psychologist-led interventions achieved a significantly higher effect size than those led by a nurse ( $d = 0.30$ ) ( $P < 0.001$ )

For EDU interventions, delivery by medical staff had a higher effect size ( $d = 0.73$ ) than those given by a psychologist ( $d = 0.27$ ) whereas for CBT based interventions the effect size was greater if delivered by a psychologist ( $d = 0.40$ ) and of no effect if delivered by given by nurses or social workers. With SUP interventions the practitioner was not influential and this could not be ascertained for REL interventions due to lack of comparative data.

Psychologists had greater effect size when working in individual treatment settings ( $d = 0.52$ ) compared with group format interventions ( $d = 0.16$ ) ( $P < 0.05$ ) and were also more effective directly after diagnosis ( $d = 0.12$ ) than during treatment ( $d = 0.01$ ). Non-psychologist-led interventions were not influenced by either by format or timing.

#### Influence of control groups on effect size

89% of studies reported on the type of control group of which 30 studies employed standard care, 8 were waiting list groups, 8 groups received educational material and 1 had stress management, relaxation and support. Standard care and waiting list were deemed to be 'passive' whereas the remainder were 'active'. The effect size of intervention compared with passive controls was greater than those compared with an active control ( $d = 0.34$  vs  $d = 0.11$ ) ( $P < 0.001$ ).

#### General comments:

This paper presents the findings of a meta-analysis of data from 34 RCTs on psychosocial therapies to relieve emotional distress in women with breast cancer. The reviewers wished to determine the factors which affected outcomes such as cancer type, intervention type and interventionist. Between this review and that of Bantum (2007) there are 24 included RCTs in common. Papers were identified by searching PsychInfo, Psynindex and Medline databases up to October 2004 (search terms were briefly listed). For the majority of studies, two reviewers coded papers with regard to type of cancer, intervention and intervention provider. No reference was made to the scoring of studies for quality etc. Where data were incomplete, study authors were contacted by reviewers.

Tests for homogeneity were performed and a random effects model applied to the meta-analysis. As with Bantum (2007) the authors pointed out a likely publication bias (only positive outcomes reported) and calculated an estimation of its impact.

The authors reported (data not shown here) that the effect size of psychosocial interventions was lower for breast cancer patients than for cancer patients as a whole and that this difference also applied according to the therapy with the exception of SUP (supportive) interventions. They hypothesised that this may be due to one or more of several factors including gender, natural recovery rates for breast cancer compared with other cancers or that the implications of having breast cancer are not addresses by these interventions i.e. having no focus on sexuality, personal relationships, body image etc.

The conclusions reached by the reviewers were that psychologists were the most appropriate persons to deliver CBT in an individual context to women at any disease stage, preferably after diagnosis/surgery or much later but not during treatment. Medical staff appeared to be well suited

for delivering educational interventions either to individuals or groups preferably after diagnosis or surgery and only for early stage disease.

Manne <i>et al.</i> (2007)
Design: Randomised controlled trial (therapy). Evidence level: 2 Country: United States of America
Inclusion criteria: Women with early stage breast cancer Breast cancer surgery within previous 6 months ECOG status of 0-1 Married or cohabiting with a significant other Were 18 years or older English speaking
Exclusion criteria: None stated
Population: Number of patients = 238. Age range: 27 to 75 years. Mean age = 49.5 ± 10.4 years.
Interventions: Intervention group (n=120): Couple-focused group (CG) comprising 6 weekly 90 minutes sessions focusing in understanding the psychological impact of cancer on the couple and their relationship plus enhancing the relationship, communication and support.  Control group (n=118): Usual care.  Assessment time points occurred pre-intervention (time 1) 1 week post-intervention (time 2) and 6 months after the intervention (time 3). Patients were paid to complete these questionnaires.
Outcomes: The primary outcomes were psychological distress and well-being over time. Instruments used to measure these outcomes included the Mental Health Inventory-18 and the Impact of Event Scale. The potential moderators of response were assessed by the Emotional Approach Coping Scale, Emotional Processing Scale, Acceptance (from COPE), Unsupportive Behaviours Scale and Protective Buffering Scale.  The main objective of this exercise was to see if a couple-focused intervention would be more or less effective when taking into account the coping strategy already adopted by subjects before study entry.
Follow up: -
Results: There were no group differences for any of the outcomes at the first, baseline time (1). Patient age and physical functioning were significant predictors of all

outcomes. Participants in the intervention arm reported significantly lower depressive symptoms than controls. Partner unsupported behaviour moderated the treatment effects on depressive symptoms in the intervention but not control group.

#### Moderator analyses (ITT)

##### Emotional expression

Participants one standard deviation above the mean for this parameter had significantly lower mean depression than those women in the control arm ( $P = 0.0033$ ). Participants that were one standard deviation below the mean for this parameter showed no treatment condition effect.

##### Emotional processing

Participants one standard deviation above the mean for this parameter had significantly lower mean depression than those women in the control arm ( $P = 0.0088$ ). Participants that were one standard deviation below the mean for this parameter showed no treatment condition effect.

##### Acceptance

Participants one standard deviation above the mean for this parameter had significantly lower mean depression than those women in the control arm ( $P = 0.0062$ ). Participants that were one standard deviation below the mean for this parameter showed no treatment condition effect.

##### Protective buffering

This parameter was not a moderator of treatment group for the outcome of depression.

These results indicate that women who started the intervention therapy with higher emotional processing and emotional expression had fewer depressive symptoms compared to participants who did not use these coping mechanisms. There were similar, although marginal, results for acceptance. Those women previously employing a partner buffering coping strategy received no advantage to treatment compared with controls.

#### General comments:

This paper describes a RCT comparing a couple-focused group with standard care for women with breast cancer. The primary outcomes were measures of psychological distress and well-being over time. The starting hypothesis was that the adoption of certain coping strategies by cancer patients before the study began might influence their response to the couple-based intervention which used the same strategies (emotional processing, emotional expression, protective buffering or acceptance).

Across the study, 36% of women had stage I breast cancer, 53% stage II, 3% stage IIIa and 9% had DCIS. Women were recruited from three cancer centres and four hospitals between April 2000 and October 2003.

The authors concluded from this complex analysis that women with early stage breast cancer who naturally selected an emotional coping strategy may benefit from a couple-focused group intervention. It was stressed, however, that the converse may not be true i.e. that women who were not naturally employing such

coping strategies would not benefit from this intervention. The authors also suggested that women who had unsupportive partners at baseline and who attempted to understand and express their emotional reactions to their cancer may derive the most benefit from this intervention.

Meneses *et al.* (2007)

Design: Randomised controlled trial (therapy). Evidence level: 2  
Country: United States of America

Inclusion criteria:  
Women of at least 21 years of age  
Histological confirmation of stages 0-II breast cancer  
No evidence of local recurrence or metastatic disease  
Within 1 year of diagnosis  
Surgery at least one month previously  
Having had chemotherapy or radiotherapy  
Able to communicate in English  
Written informed consent

Exclusion criteria:  
None stated

Population:  
Number of patients = 261. Mean age = 54.5 ± 11.58 years

Interventions:  
Intervention (n=129):  
A psychoeducational support comprising individual face-to-face education and support sessions (months 1, 3 and 6), telephone and face-to-face follow-up education and support sessions (months 2, 4 and 5) with written and audiotape reinforcement. These educational supplements included a notebook of materials which corresponded with the education and support session and audiotapes also based on these sessions to reinforce learning.  
Wait control (n=132): Women in this group received baseline assessment and then four attention control telephone calls (months 2, 4 and 5), three face-to-face education and support sessions (month 6) and one follow-up telephone education and support session (month 7).

Both intervention and control elements were delivered over a six-month period by a Breast Care Education Intervention (BCEI) nurse, part of a larger research team. The nurse had received training specifically for this trial and a procedure manual was produced and followed throughout.

Outcomes:  
Overall quality life (QOL) including psychological well-being.

Instruments used included the Breast Care Treatment and Social Demographic Data Tool

Follow up:  
All participants received baseline assessment of outcomes which were then repeated at 3 and 6 months. In the experimental group, four women dropped out before the 3 month assessment. In the control group one subject died from

unrelated causes before the 6 month assessment. All other participants were included in the final data analyses.

**Results:**

No significant difference in patient demographics or QOL outcomes was found between study arms at baseline. Data were compared between intervention and control groups by comparing each with their own baseline.

Difference in QOL between baseline and month 3 (time 0 to time 1) / significance:

Control group (n=132): P = 0.522 (NSD)

Intervention group (n=125): P < 0.001

Comparison between arms: P < 0.001

Difference in QOL between baseline and month 6 (time 0 to time 2) / significance:

Control group: P = 0.016

Intervention group: P < 0.001

Comparison between arms: P < 0.001

Difference in QOL between month 3 and month 6 (time 1 to time 2) / significance:

Control group: P = 0.004

Intervention group: P = 0.094 (NSD)

Comparison between arms: P = 0.274 (NSD)

Control group showed a reduction in QOL from baseline to time 1 but then a slight improvement by time 2. The intervention arms showed an improvement in time 2 and time 3. Therefore, the improvement in quality of life was significantly better for the intervention group than the control group and compared with its own baseline, an effect which was maintained with time.

A sub-group analysis of specific domains of the QOL instrument show significant improvements for the intervention compared with controls were shown for psychological and social well-being (P < 0.001) but not in the domains of physical or spiritual well-being.

**General comments:**

This paper describes the findings from a small trial comparing a psychoeducational intervention with a wait control for women who were classified as cancer survivors, being in the first year after their treatment for early stage disease.

Allocation and randomisation methods were not described but this procedure was carried out by a member of the research team (statistician) which does not eliminate the possibility of bias. The study is simply designed and appropriately analysed with modest participant numbers.

Quality of life assessments were made from baseline to 6 months and showed that the intervention arm experienced better outcomes in the domains of psychological and social well-being than the wait controls. Controls also showed an improvement in QOL between 3 and 6 months time points which may reflect

natural history but was still significantly below QOL achieved by the intervention group.

The authors concluded that this psychoeducational intervention, delivered by a specialist nurse, demonstrated effectiveness amongst women with breast cancer after primary treatment thus providing a 'safe passage' from treatment to survivorship.

Vos *et al.* (2007)

Design: Randomised controlled trial (therapy). Evidence level: 2

Country: The Netherlands

Inclusion criteria:

Women between 18 and 70 years of age

Having undergone surgery for primary breast cancer not earlier than 4 months prior to study

No distant metastases

Sufficient knowledge of Dutch language

No psychiatric illness

Written informed consent

Exclusion criteria:

None stated

Population:

Number of patients = 87. Age range: 29 to 68 years. Mean age =  $49 \pm 7.9$  years

Interventions:

Intervention - Group psychotherapy (n= 33):

Based on experiential and existential theories. The intervention started with a relaxation or meditation exercise. Participants then related something of their feelings on cancer which allowed identification of topics of leading importance for the group and informed later discussions in which participants were encouraged as a group to address those feelings and thoughts. After a break participants were shown ideas and applications that they could make in daily life with reference to the earlier discussion. A second mediation or relaxation session ended the program.

Control - Social support group (n=34):

Based on letting cancer patients share their mutual experience about their disease and receiving information from experts on topics of interest. These groups also met for 2.5 hours with a 30 minutes break. Emotional and peer support was encouraged. Participants chose the discussion topics for the following week. The structure of the sessions was unchanging.

Both interventions were delivered over 12 weeks. Each session lasted 2.5 hours including a 30 minute break. After regular session there were follow-up sessions 1 and 2 months later. The groups were closed and each contained up to 10 women. All the facilitators were appropriately trained and, in each group, one was a woman. The leaders of group therapy were highly trained therapists who received one days extra training relevant to their intervention. The social support groups were led by social workers or oncology nurses who had received only

one days training for the intervention.

Outcomes:

[1] Emotional adjustment: Profile of Mood States (POMS)

[2] Psychosexual functioning: Sexual Functioning and Body Image modules of the QLQ-BR32 (part of European Organisation for Research and Treatment of Cancer QLQ-30)

[3] Social adjustment: Social Interactions and Recreation modules of the Sickness Impact Profile instrument.

Follow up:

Baseline assessments (T0) which were made before randomisation, were followed up after completion of the study (time 1) and 12 months later (time 2).

20/87 women dropped out of the study due to: death (n=1) attendance at a group became too emotional (n=2) illness (n=3) did not meet expectations (n=1) or failed to give a reason (n=13).

Results:

There were no observed differences between study arms at baseline with regard to type of surgery, age, disease stage or psychological, psychosocial and social adjustment. At the end of the study, the mean number of group psychotherapy sessions attended was 9.6 with 10 women at all sessions and 3 women attending fewer than 2 sessions. The mean number of attendances in the social support group was 8.7 with 8 women at all sessions and 3 women attending fewer than 2 or fewer sessions.

There were no significant changes over the study time periods for the parameters Distress, Vitality, Sexual Functioning or Social Interaction. Body Image and Recreation changed positively with time (both  $P < 0.001$ ). The type of surgery undergone was significantly related to Body Image outcomes with those having had breast conserving therapy reporting more positively.

The intervention resulted in no significant effects on psychosocial adjustment when compared with the control group.

General comments:

This paper describes the findings from a small RCT which compared group psychotherapy with group social support where the outcome was psychosocial adjustment. Women who participated in this trial were about 4 months post-surgery and had been recruited from several hospitals in the Netherlands during an unknown time period.

Despite the starting hypotheses of the authors no significant difference was seen between study arms and no significant changes occurred in many of the parameters over time. The authors pointed out that the women were psychologically well adjusted at baseline and comparable to women in the general population, according to assessments results, and hence there was perhaps little improvement to be made which might explain the lack of significant findings.

Classen *et al.* (2008)

<p>Design: Randomised controlled trial (therapy). Evidence level: 2 Country: United States of America</p>
<p>Inclusion criteria: Women with biopsy-proven breast cancer stages I-IIIa Diagnosis not more than 12 months prior to enrolment Completion of initial surgical treatment No detection of disease present Written informed consent</p>
<p>Exclusion criteria: Evidence of metastases beyond adjacent lymph nodes Recurrence if cancer prior to randomisation Diagnosis of other cancer (except BCC skin or CIS cervix) Other major medical problems likely to limit life expectancy to &lt; 10 years History of major psychiatric illness for which patient was hospitalised or medicated (except for anxiety or depression treated for &lt; 1 year) Attendance at a cancer support group for &gt; 2 months</p>
<p>Population: Number of patients = 350</p>
<p>Interventions: Intervention (n=178): Education material comprising a brief videotape on self-examination and pamphlets from the American Cancer Society covering numerous topics of a practical nature but avoiding issues of emotional expression, coping or social support.</p> <p>Unstructured supportive-expressive group therapy. Groups, comprising up to 10 members, met weekly for 12 weeks. Each meeting lasted for 90 minutes and was led by two co-therapists. Women attended an average of 8/12 meetings.</p> <p>Therapists included 10 nurses, 11 social workers and 3 psychologists all of whom were specifically trained for this project on a 2-day workshop, studying a treatment manual and facilitating a pilot group. The training included examinations and supervision throughout the study by an expert in the intervention.</p> <p>Control (n=179): Educational material only (as above).</p>
<p>Outcomes: Relief of psychological distress across time. Outcomes were measured using the Profile of Mood States questionnaire (POMS) to which responses were recorded on 5-point Likert scales resulting in a score for mood disturbance.</p> <p>Secondary outcomes were measured on the Hospital Anxiety and Depression Scale (HADS), Mini-Mental Adjustment to Cancer Scale (MAC) Courtauld Emotional Control Scale, Impact of Event Scale (IES) Stanford Self-Efficacy Scale for Serious Illness, CARES Medical Interaction Subscale, Family Relations Index, Sleep Measure, Pain measure and Yale Support Index.</p> <p>Data were analysed on a modified intention to treat basis.</p>
<p>Follow up: Final assessments were completed in June 1998. Baseline assessments were</p>

repeated at 3, 6, 12, 18 and 24 months thereafter. A baseline score of 37 on the POMS scale was taken as an indication as a high initial level of distress

In the intervention group, 18 women provided no follow-up due to: refusal (n=3) refusing the group (n=4) being unable to attend the group (n=4) moving away (n=1) giving no response (n=5) or about whom no information was available (n=3).

In the control group, 9 women provided no follow-up due to: refusal of further participation (n=2) illness (n=1) finding the educational material unhelpful (n=1) death (n=2) disappointment at allocation (n=1) giving no response (n=1) or about whom no information was available (n=1).

159/178 of the intervention group and 167/179 of the control group provided baseline and at least one other follow-up for data analyses.

#### Results:

There were no significant differences between study arms for demographic or medical variables with the exception of disease stage since more women in the control arm had stage III disease (15 vs 6).

After removing an outlier with extreme distress (causing the subject to leave the trial) there was no significant difference in POMS scores between study arms using any data modelling and there were no differences either between arms for any secondary outcome measures.

#### General comments:

This paper describes the findings from a RCT comparing a short course of supportive-expressive therapy and provision of education material with education material only. Women were recruited at two academic sites and nine oncology centres across the USA between February 1994 and May 1996. Central randomisation was by a biased coin method and patients were stratified according to surgery type, nodal involvement, age and hormone receptor status.

Baseline levels of distress were not equal across the multiple sites which adversely affected the analysis of variance and these data were omitted subsequently. It was of note that the majority of women did not have high initial levels of psychological distress which may have reduced the ability of the intervention to have had much impact on this parameter. Using baseline distress as a stratification variable may, therefore, have been preferable to using prognostic variables more commonly associated with clinical trials.

The authors concluded that highly distressed women would be unlikely to benefit from the intervention. Therapist training and experience were not associated with any treatment effect and hence there was no evidence that distress was alleviated by brief supportive-expressive group therapy. They hypothesised that an intervention which was existentially oriented might not suit patients who, having potentially curable disease, may perhaps have had more pragmatic concerns.

## Chapter 3 – Operable breast cancer

### 3.1 What is the optimal tumour-free tissue margin to achieve in patients who undergo wide local excision for (DCIS)?

#### Short Summary:

The best available evidence for this question was drawn from observational studies (Bijker *et al.* 2001; Boland *et al.* 2001, 2003; Boyages *et al.* 1999; Cabioglu *et al.* 2007; Chan *et al.* 2001; Cheng *et al.* 1997; Denoux *et al.* 2001; Dillon *et al.* 2007; Goldstein *et al.* 1999; Goldstein *et al.* 2000; Goldstein *et al.* 1998; Hetelekidis *et al.* 1999; Holland *et al.* 1998; Kell *et al.* 2005; Macdonald *et al.* 2005, 2006; Neuschatz *et al.* 2001,2002; Ratanawichitrasin *et al.* 1999; Rodrigues *et al.* 2002; Sahoo *et al.* 2005; Sigal-Zafrani *et al.* 2004; Silverstein *et al.* 1994, 1997, 1999, 2003; Solin *et al.* 2005; Tunon-de-Lara *et al.* 2001; Vargas *et al.* 2005; Vicini *et al.* 2001; Wong *et al.* 2006; Yau *et al.* 2006). There is no consistency regarding the optimal tumour-free tissue margin. Most existing studies agree that margins containing tumour cells are associated with local recurrence or bear the risk of residual cancer. There is consistency that the risk of local recurrence is reduced with very wide margins, e.g. more than 10mm of tumour-free tissue. Several studies reported a linear correlation between margin widths and recurrence. There is conflicting evidence regarding whether wide margins can and whether they should replace radiotherapy. There is also disagreement regarding which of the two should most be avoided. The included studies varied in more than the factor margin widths (i.e. co-treatment, lengths of follow-up) and results are therefore difficult to compare. Studies varied in their definition of 'wide'.

#### PICO

Population	Intervention	Comparison	Outcomes
Patients with DCIS	<ul style="list-style-type: none"> <li>Wide Local Excision</li> <li>Breast Conserving Surgery</li> </ul>	Different margin widths: <2mm 2-5mm 5-10mm >10mm	<ul style="list-style-type: none"> <li>Local Recurrence Rate</li> <li>Disease Free Survival</li> <li>Overall Survival</li> <li>Cosmetic result</li> <li>Psychological morbidity</li> <li>Health Economics</li> </ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

#### Evidence Summary

There is a considerable body of observational studies looking at margin width, although one RCT is included, however the patients were not randomly assigned to margin widths but to excision alone versus adjuvant radiotherapy. The majority of the studies aimed to demonstrate a connection between margins and recurrence. None of the identified studies were designed to answer the question 'what is a minimum safe margin?' and only one study reported cosmetic outcomes.

There is no consistency regarding the optimal tumour-free tissue margin.

There is consistency that the risk of local recurrence is reduced with very wide margins, e.g. more than 10mm of tumour-free tissue. Several studies reported a linear correlation between margin widths and recurrence.

There is conflicting evidence regarding whether wide margins can and should replace radiotherapy.

The included studies varied in more than the factor margin widths (i.e. co-treatment, lengths of follow-up) and results are therefore difficult to compare. Studies varied in their definition of 'wide'.

The majority of studies investigated 'recurrences' without distinguishing true recurrence, marginal miss, treatment failure or similar so the evidence statement cannot differentiate these cases either.

Few studies reported survival data and not in all studies was it possible to attribute the outcome to the excision width as reexcisions could result in other treatment decisions such as mastectomies. There were too few clear descriptions of the margin width measurement method or pathology variables to allow the pursuit of this factor and its influence on the results.

### **General association margin width and clinical outcomes**

The case series published by Macdonald et al. (2005), Chan et al. (2001), Neuschatz et al. (2001), Boland et al. (2003), Dillon et al. (2007), Silverstein and Buchanan (2003), Boland et al. (2001), Yau et al. (2006), Neuschatz et al. (2002), Holland et al. (1998), Sigal-Zafrani et al. (2004), Vargas et al., (2005), Tunon-de-Lara et al. (2001), Solin et al. (2005), and Silverstein et al. (1994) reported a linear correlation between margin widths and local recurrence or residual cancer or statistically significant differences between subgroups. This was also highlighted in a risk factor analysis of an RCT (Bijker et al., 2001) and in a meta-analysis by Boyages et al. (1999). It is noteworthy that the correlation was reported in both, studies that included positive and negative margins as well as studies comparing different negative margin widths, and the effect was found in uni- as well as multivariate analyses. These publications concluded in the majority that margin width is an important or the most important predictor for local recurrence or residual cancer.

Contrarily, Goldstein et al. (2000, 1998) concluded from two (in parts overlapping) case series that margin status (ranging from multifocal positive to >2cm negative margins) is not associated with local recurrence. Rodrigues et al. (2002) concluded from a case series with many missing data on margin status that positive or close margin status was not a significant predictor of local relapse. The difference in local recurrence rates in the case series by Hetelekidis et al. (1999) was not statistically significant. Denoux et al. (2001) found no statistically significant correlation between margin width and local recurrence but highlighted that none of the patients with margins  $\geq 10$ mm in the case series developed a local recurrence.

Macdonald et al. (2005) concluded that increasing margins decrease the risk for local recurrence, Silverstein et al. (1997) reported that the probability of local recurrence decreases as margin width increases, Boland et al. (2003) concluded that excision width is the most important predictor of local recurrence, Silverstein and Buchanan (2003) reported that as margin width increases the probability of local recurrence decreases, Boland et al. (2001) concluded that close resection margins are an even better predictor than the Van Nuys prognostic index for DCIS recurrence, Yau et al. (2006) concluded that wide

excisions plus radiotherapy appear to be a reasonable alternative in the treatment of DCIS, Ratanawichitrasin et al. (1999) did not find a statistically significant difference between >2mm and <2mm margins with regard to residual disease. The difference in local recurrence rates in the case series by Hetelekidis et al. (1999) was not statistically significant. Denoux et al. (2001) found no statistically significant correlation between margin width and local recurrence but highlighted that none of the patients with margins  $\geq 10$ mm in the case series developed a local recurrence. Chan et al. (2001) found a significant difference when comparing >1mm and  $\leq 1$ mm margins but subgroups beyond 1mm margins did not differ regarding recurrence free survival. Cheng et al. (1997) found no statistically significant difference between smaller or equal to 1mm negative margins compared to >1mm.

### **Positive margins**

Macdonald et al. (2005), Sahoo et al. (2005), Tunon-de-Lara et al. (2001), Neuschatz et al. (2002), Goldstein et al. (1999; 1998), Silverstein et al. (1994), Ratanawichitrasin et al. (1999), Cheng et al. (1997), Vargas et al. (2005), Solin et al. (2005), showed in case series that positive margins are linked to local recurrence or residual cancer. A risk factor analysis of an RCT that included some data on margin status (Bijker et al., 2001) also demonstrate this link and a meta-analysis by Boyages et al. (1999) stated that most recurrences occur in the immediate vicinity of primary surgical site suggesting that recurrences arise from remaining tumour cells, i.e. incomplete surgical excision and that the presence of positive or close margins increases the risk of local recurrence even irrespective of radiation therapy. Sigal-Zafrani et al. (2004) showed that the presence of residual tumour correlated strongly with initial margin status and patients with greater involvement were more likely to end up with a mastectomy. Cabioglu et al. (2007) reported that patients with negative margins had a better 5yr ipsilateral recurrence free survival rate than patients with persistent positive / close margins after completion of all surgical treatment.

Goldstein et al. (1999) reported that multifocal positive margins were associated with the presence of residual DCIS in reexcision specimen but unifocal positive margins versus negative or close margins not and there was also no significant difference between negative versus close or positive margins. Vicini et al. (2001) showed that positive combined with close margins compared to >2mm margins differ significantly in ipsilateral breast failures and true recurrences / marginal miss, however, the authors concluded that margin status alone may be suboptimal in defining excision adequacy. Goldstein et al (2000) concluded from a case series that margin status (ranging from multifocal positive to >2cm negative margins) is not associated with local recurrence. Rodrigues et al. (2002) conclude in a case series with few analysable data that positive or close margin status was not a significant predictor of local relapse.

### **Specific negative margins and cancer related outcomes**

Neuschatz et al. (2002) reported 41% of patients showed a tumour at re-excision. Boland et al. (2003) reported 38% recurrence. Boland et al. (2001) reported a 37% ipsilateral recurrence rate. Macdonald et al (2005) reported a local recurrence rate of 34%; with a 63% probability of remaining recurrence free at 5 years and 58% at 8yrs. Silverstein et al. (1999) reported a local recurrence rate of 30% with a probability of a recurrence within 8 years of 0.58 or 0.30 depending on the addition of radiation therapy. Silverstein et al. (1997) reported a 25% recurrence rate. Denoux et al. (2001) reported a 20% local recurrence rate, 93% of patients are without local recurrence at 5 years and 82% at 10 years.

Sigal-Zafrani et al. (2004) show that 44% of patients with  $\leq 1$ mm margins had a residual tumour at reexcision and 21% of the patients subsequently had a mastectomy. Chan et al. (2001) reported a recurrence rate of 38% for margins between 0.1 and 1mm. Holland et al. (1998) reported a 36% recurrence rate for  $\leq 1$ mm. Neuschatz et al. (2001) reported for  $\leq 1$ mm margins a 25% crude local failure rate and 30% 5yr local failure. Hetelekidis et al. (1999) reported a value of 25% actuarial 5 year local recurrence for  $\leq 1$ mm. Cheng et al. (1997) reported 19% with residual disease for margins of  $\leq 1$ mm. Dillon et al. (2007) reported a 60% residual disease rate although this is likely to include patients with positive margins as well. Silverstein & Buchanan (2003) stated that 1mm wide margins are inadequate when it comes to complete removal of DCIS, surgeons commonly leave residual disease.

Sahoo et al. (2005) reported 8% local recurrences for patients receiving adjunct radiation therapy.

MacDonald et al. (2005) reported a 34% rate of local recurrences with a probability of remaining without recurrence at 5 years between 63% and 73% depending on the cut-off category and 58% / 49% at 8 years. Ratanawichitrasin et al. (1999) reported 31% residual disease. Yau et al. (2005) achieved a 15% local failure rate with 77% 5 year actuarial local failure free rate for patients with adjuvant radiotherapy. Dillon et al. (2007) report 64% residual disease for margins 1 to 2mm and 60% for 0 to 1mm margins and concluded that patients with margin distances of  $\leq 2$ mm are at high risk of residual disease and propose a 5mm margin width. Neuschatz et al. (2002) reported that 31% of patients with margins between 1 and 2mm had a tumour at reexcision, 41% for 0 to 1mm. Goldstein et al. (1998) reported a 19% true recurrence rate and 6% recurrences elsewhere for patients receiving adjuvant radiation therapy and concluded that DCIS may be in inadequately excised if atypical ductal hyperplasia and DCIS or cancerisation of lobules and DCIS are near the margin. Rodrigues et al. (2002) reported a 14% recurrence rate for patients with  $\leq 2$ mm margins and adjuvant radiation therapy. Vargas et al. (2005) reported 13% ipsilateral recurrence or true recurrence or marginal miss at 5 years and 22% at 10 years but these data include patients with positive margins and margins equal to 2mm. Goldstein et al. (2000) reported an 8% true recurrence or marginal miss rate and a 4% rate of carcinoma elsewhere for patients receiving also radiation therapy and concluded that margin status is not associated with the analysed outcomes.

Goldstein et al. (1998) reported a 4% true recurrence and 3% recurrence elsewhere rate in a sample of consecutive patients treated with local excision plus radiation therapy. Vargas et al. (2005) report the same values for a larger sample (it is possible that there is overlap). Rodrigues et al. (2002) reported a 5% recurrence rate for patients receiving radiotherapy in addition. Goldstein et al. (2000) report a 5% recurrence rate, 2% for carcinomas elsewhere, for patients also receiving radiotherapy. Margins of more than 2mm in conjunction with radiotherapy showed better results (7% ipsilateral breast failure at 5 years, 9% at 10 years) than close or positive margins in a case series by Vicini et al. (2001). Yau et al. (2006) concluded that final resection margins of more than 2mm (mean and upper limit unclear) appears to be a reasonable alternative to mastectomy in view of a 100% 5 year survival rate and a 98% failure free rate. Neuschatz et al. (2002) found no tumours at reexcision in margins 2 to 10mm wide. The review by Kell and Morrow (2005) stated that radiotherapy with a margin of 2mm can achieve excellent local control. The data by Macdonald et al. (2005) showed that even without radiotherapy a local recurrence rate of only 11% was achieved. Ratanawichitrasin et al. (1999) reported 17% with residual disease, radiotherapy was not reported. Although Dillon et al. (2007) showed a high rate of successful breast conserving therapy without the need for mastectomy (88%, follow up

period unclear, radiotherapy co-treatment unclear) in patients with >2mm the authors recommend a 5mm resection margin.

Neuschatz et al. (2002) reported a 0% tumour rate at reexcision for margins between 2 and 10mm, the study did not report that the patients also received adjuvant radiotherapy. Goldstein et al. (1998) reported a 4% true recurrence rate and a 2% risk of a carcinoma elsewhere for patients treated with adjuvant radiation therapy. Goldstein et al. in a further publication (2000) reported a 5% recurrence rate and a 2% risk of a carcinoma elsewhere; the patients were also treated with radiation therapy. Vargas et al. (2005) reported 4% ipsilateral recurrence at five years, 9% at ten years, 3% true recurrences / marginal miss at five years, 7% at 10 years. Vicini et al. (2001) reported 9% ipsilateral breast failure, true recurrences or marginal miss rate at five and at ten years for patients treated with adjuvant radiation therapy. Chan et al. (2001) reported a 3.5% rate of patients with recurrences for margins between 1.1 and 5mm, several of the patients received adjuvant therapies, e.g. radiation or tamoxifen. Sahoo et al. (2005) showed a 10% local recurrence rate for margins between 1 and 5mm for patients receiving adjuvant radiation therapy, this study was also cited in the review by Kell and Morrow (2005). Yau et al. (2006) reported a 2% rate of local failure for margins above 2mm and in conjunction with radiotherapy and / or tamoxifen. Rodrigues et al. (2002) reported a 5% rate of recurrences for margins above 2mm in conjunction with radiotherapy. It is also possible to draw on those selected studies that report beneficial results for smaller margins to substantiate this statement, i.e. Neuschatz et al. (2001), Boland et al. (2003), Denoux et al. (2001), Boland et al. (2001), Holland et al. (1998) and Sahoo et al. (2005) report recurrence rates of under 10% for margins of  $\geq 1$ mm. Dillon et al. (2007) showed a 17% rate of residual disease, adjuvant therapies were not reported. Ratanawichitrasin et al. (1999) reported a 17% rate of residual disease at reexcisions; there was no information on adjuvant therapy. Macdonald et al. (2005) showed a 21% rate of recurrences for margins between 3 and 5.9mm for patients treated with excision alone.

Dillon et al. (2007) recommend a 5mm resection margin and indicated that in none of the patients with this margin distance residual disease was found, the role of adjuvant therapies is unclear. Sahoo et al. (2005) reported a 4% local recurrence rate for margins >5mm for patients receiving adjuvant radiation therapy, the study was also highlighted in the review by Kell and Morrow (2005). Vicini et al. (2001) reported a rate of 7% ipsilateral breast failure at five years, 9% at 10 years with only 3% true recurrences at five years, 5% at ten years, the patients received also radiotherapy. Chan et al. reported a 7% recurrence rate for patients with margins of 5.1 to 10mm, with a 6% recurrence rate were all events at  $\geq 5$ mm considered; the patients received adjuvant therapy.

It is also possible to draw on those selected studies that report beneficial results for smaller margins to substantiate this statement, i.e. Neuschatz et al. (2001), Boland et al. (2003), Denoux et al. (2001), Boland et al. (2001) and Holland et al. (1998) report recurrence rates of under 10% for margins of  $\geq 1$ mm, Yau et al. (2006), Neuschatz et al. (2002), Goldstein et al. (2000), Goldstein et al. (1998), Rodrigues et al. (2002) and Vargas et al. (2005) report recurrence rates of under 10% for margins of  $\geq 2$ mm.

Macdonald et al. (2005) data show that a margin of 6 to 9.9mm only carried a risk of 5% local recurrence for patients treated with excision alone. Dillon et al. (2007) reported no case of residual disease for margins above 5mm margins. Sahoo et al. (2005) reported a 4% local recurrence rate for margins above 5mm for patients also receiving radiation therapy. Vicini et al. (2001) found only a rate of 7% for ipsilateral breast failure and 3% true recurrence at five years for margins beyond 5mm. None of the 10 patients with margins of

2 to 10mm in Neuschatz et al. (2002) had a tumour at reexcision (follow up unclear). Chan et al. reported a 7% recurrence rate for patients with margins of 5.1 to 10mm. The review by Kell and Morrow (2005) stated that there is no difference between 10mm margins and 1 to 10mm margins and cited Silverstein et al. (1999).

Neuschatz et al. (2001) reported 3.7% crude local failure and 30% five year local failure rates for margins above 1 and 10mm. Boland et al. (2003) reported 6% recurrence for margins between 1 and 9mm in a group where some were only treated with excision. Denoux et al. (2001) reported a 7% recurrence rate. It is also possible to draw on those selected studies that report beneficial results for smaller margins to substantiate this statement, i.e. Boland et al. (2001) and Holland et al. (1998) report recurrence rates of under 10% for margins of  $\geq 1$ mm, Yau et al. (2006), Goldstein et al. (2000), Goldstein et al. (1998), Rodrigues et al. (2002) and Vargas et al. (2005) report recurrence rates of under 10% for margins of  $\geq 2$ mm. Silverstein et al. (1999) reported a local recurrence rate of 17% for a group where a subgroup did not receive radiotherapy and a rate of 15% in a further publication (Silverstein et al., 1997).

Denoux et al. (2001) found no local recurrence in this margin group (plus radiation therapy). Silverstein et al. (1999) reported a 2% local recurrence rate in a group where only some patients were treated with radiation therapy. Silverstein et al. (1997) showed a recurrence rate of 3% for a median follow up of 90 months. Boland et al. (2003) reported a 3% rate, only some patients received radiation therapy. Silverstein & Buchanan (2003) also report a 3% rate in a group where only some patients received radiation therapy. Macdonald et al. (2005) reported a 5% local recurrence rate for patients treated with excision alone. Chan reported a 5% recurrence rate; some patients received different adjuvant treatments. Macdonald et al. (2006) reported that a subgroup of excision alone patients showed a rate of 6% recurrences. Neuschatz et al. (2001) reported 7% crude local failure, 10% five year local failure, some patients received adjuvant treatment.

Wong et al. (2006) closed their study on patients receiving only wide excisions to accrual because the number of local recurrences exceeded a prespecified limit; they also reported a 2% first site treatment failure.

### **Cosmetic outcomes**

Kell and Morrow (2005) stated that large margins lead to a greater deformity of the breast and patients will suffer a worse cosmetic outcome.

Only one case series (Yau et al., 2006) with 75 women living in Hong Kong reported cosmetic results and came to the conclusion that even final resection margins of more than 2mm (mean and upper limit unclear) achieve good to excellent cosmetic results in physician ratings (range only reported for whole sample).

### **Consideration of clinical and cosmetic outcomes**

The case series by Yau et al. (2006) with 75 women in Hong Kong evaluated local recurrence and cosmetic results and came to the conclusion that final resection margins of more than 2mm (mean and upper limit unclear) appears to be a reasonable alternative to mastectomy regarding local recurrence rates and five year survival while achieving good to excellent cosmetic results in physician ratings.

### **Implications for co-interventions**

Silverstein & Buchanan (2003) concluded from a case series that included 10 participants with  $\geq 10$ mm that there were so few local recurrences in these patients that the effect of

radiation therapy is of little practical importance. Cheng et al. (1997) concluded from their case series that although small tumours with clear margins of >1mm carry a low risk of local failure and can be treated with lumpectomy that large tumours pose a risk of residual disease independently of margin status and additional adjuvant therapy may be indicated. Hetelekidis et al (1999) report only a 8% actuarial five year local recurrence for margins above 1mm in patients treated without radiation therapy. Neuschatz et al. (2002) reported no tumours at reexcision for margins above 2mm; adjuvant therapy was not mentioned in the publication. Macdonald et al. (2006) showed a 6% rate of any recurrence for a group in which only some patients were additionally treated with radiation therapy. Wong et al. (2006) closed to accrual because the number of local recurrences met the predetermined stopping rules. Kell and Morrow (2005) approach the topic differently and stated radiotherapy may make the use of very wide margins redundant.

The European EORTC 10853 trial (Bijker et al., 2001) concluded that radiotherapy cannot compensate for positive margins although it should be noted that this is the result of a subgroup analysis and the trial did not randomise to margin status. Tunon-de-Lara et al. (2001) reported an 11% relapse rate for involved margins compared to 53% when radiotherapy is given, the corresponding rate for free margins and radiotherapy was 7.5%; the authors concluded that there is a need for clear margins but also emphasised that breast cancer mortality is extremely low regardless of the treatment method. Chan et al. (2001) compared the recurrence rates of the included subgroups and concluded that radiotherapy does not compensate for inadequate surgical clearance.

**MacDonald HR, Silverstein MJ, Mabry H et al. (2005). Local control in ductal carcinoma in situ treated by excision alone: incremental benefit of larger margins. American Journal of Surgery, 190 (4), 521-525.**

**Design** Case series (multivariate analysis) **Evidence level** 3 **Country** USA

**Population** N=445 patients with DCIS and known margin widths

**Intervention** excision alone

**Margin** closest single distance between DCIS and inked margin; 0mm (tumour transected), 0.1-0.9mm, 1-1.9mm, 2-2.9mm, 3-5.9mm, 6-9.9mm and ≥10mm as established by direct measurement or ocular micrometry

**Follow up** median: 57 months, median time to local recurrence: 26 months

### Results

Margin	Results	Author's conclusion
overall	Margin width was associated with local recurrence in univariate ( $p < .001$ ) and multivariate analyses ( $p < 0.00001$ ) and was the most important predictor of local recurrence (relative HR 0.42). After adjusting for all other predictors the likelihood of local recurrence for patients with margins $\leq 10$ mm was 5.39 times as much for patients with 10mm or more (CI: 2.68-10.64)	
positive	15/32 with local recurrence 48% probability of remaining free at 5yrs, 39% at 8yrs 0mm vs $\geq 10$ mm: HR 7.69	Margin width is the single most important predictor of local recurrence, increasing margins decreases the risk for local recurrence.
0.1-0.9mm	18/53 with local recurrence [34%] 63% probability of remaining free at 5yrs 58% at 8yrs HR compared to 0mm: .61	
1-1.9mm	7/20 with local recurrence [35%] 73% probability of remaining free at 5yrs, 49% at 8yrs HR compared to 0mm: .58	
[<2mm]	[25/73 with local recurrence, 34%]	
2-2.9mm	20/82 with local recurrence [24%] 81% probability of remaining free at 5yrs, 78% at 8yrs HR compared to 0mm: .21	
[>2mm]	[39/340 with local recurrence, 11%]	
3-5.9mm	8/39 with local recurrence [21%] 64% probability of remaining free at 5yrs, 64% at 8yrs HR compared to 0mm: .35	
[>6mm]	[11/219 with local recurrence, 5%]	
6-9.9mm	2/22 with local recurrence [9%] 91% probability of remaining free at 5yrs, 61% at	

	8yrs HR compared to 0mm: .20
≥10mm	9/197 with local recurrence [5%] 93% probability of remaining free at 5yrs, 91% at 8yrs HR compared to 0mm: .07
<b>General comments</b> some patients may overlap with Macdonald et al (2006) and Silverstein et al. (1999)	

Updated 2018

**Chan KC, Knox WF, Sinha G et al. (2001). Extent of excision margin width required in breast conserving surgery for ductal carcinoma in situ. Cancer, 91(1), 9-16.**

**Design** Case series **Evidence level** 3 **Country** UK

**Population** N=244 patients receiving breast conservative surgery for DCIS with a the maximum tumour diameter of 40mm and available margin information

**Intervention** wide local excision with the goal of obtaining clear margins and cavity shavings, tamoxifen (20mg, 5yrs), radiotherapy, tamoxifen + radiotherapy; involved margins or cavity shavings resulted in reexcision

**Margin** histologic margins measured by ocular micrometer, clear: >1mm, close: DCIS ≤1mm from inked margin, close: DCIS ≤ 1mm from any inked margin; involved: DCIS at any inked margin

**Follow up** at least 1 year for each patient

**Results**

Margin	Results	Author's conclusion
overall	The recurrence rates were different for margins of >1mm and ≤1mm (p<0.001), this was also true for the subgroup excision alone (P<0.001) and excision + tamoxifen (p<0.05) but not for excision + radiotherapy or excision + radiotherapy + tamoxifen (n.s.) Close margin width significantly predicted recurrence in uni- and multivariate analyses  Recurrence free survival was different for margins >1mm and ≤1mm (p<0.001), but subgroups (1.1-5mm, 5.1-10mm, 10.1-40mm) of clear margins did not differ (n.s.)	Close margins were associated with a high risk of local recurrence, radiotherapy did not compensate for inadequate surgical clearance.
0.1-1mm	37.9% patients with recurrences, 22/66 DCIS, 3/66 invasive ductal carcinoma	
1.1-5mm	3.5% patients with recurrences, 2/89 DCIS, 2/89 invasive ductal carcinoma	
5.1-10mm	7.1% patients with recurrences, 2/28 DCIS, 0/28 invasive ductal carcinoma	
10.1-40mm	4.5% patients with recurrences, 0/22 DCIS, 1/22 invasive ductal carcinoma	
[≥5mm]	[3/50, 6% with recurrence]	
≤1mm	48.7% of nuclear grade 3 DCIS patients with recurrences, 15/37 DCIS, 3/37 invasive ductal carcinoma	
>1mm	7.9% of nuclear grade 3 DCIS patients with recurrences, 5/89 DCIS, 3/37 invasive ductal carcinoma	

**General comments** it is possible that some of the patients are also included

in Boland et al. (2003, 2001)

**Neuschatz AC, DiPetrillo T, Safaii H et al. (2001). Margin width as a determinant of local control with and without radiation therapy for ductal carcinoma in situ (DCIS) of the breast. International Journal of Cancer, 96, 97-104.**

**Design** Case series **Evidence level** 3 **Country** USA

**Population** N=125 patients with DCIS, (microinvasion excluded)

**Intervention** excision with rim of uninvolved tissue, excision + radiation therapy, mastectomy, (no tamoxifen)

**Margin** differentiation  $\leq 1$  vs  $> 1$  and  $\leq 1$ mm vs 1-10mm vs  $> 10$ mm; reexcision for margins  $\leq 2$ mm

**Follow up** 5 years

**Results**

Margin	Results	Author's conclusion
overall	Final margin status of $\leq 1$ mm as compared to 1mm was associated with local failure (p=0.01) $\leq 1$ mm vs 1-10mm vs $> 10$ mm: p=0.04* there were significant differences in local failure for different margin widths combined with different lesion diameters the addition of adjuvant radiotherapy suggested a delay to local failure in lesions with margins $\leq 1$ mm	Large diameters ( $> 15$ mm) and close surgical margins ( $\leq 1$ mm) are dominant risk factors for local recurrence.
$\leq 1$ mm	25% crude local failure, 30% 5yr local failure	
$> 1$ -10mm	3.7% crude local failure, 5% 5yr local failure	
$> 10$ mm	7.3% crude local failure, 9.7% 5yr local failure	
$> 1$ mm	5.9% crude local failure, 8% 5yr local failure	

**General comments** \*as reported in table 2; no formal statistical tests for interaction, rest not detailed

**Design** Case series (multivariate analysis) **Evidence level** 3 **Country** UK

**Population** N=237 patients with breast conserving surgery for DCIS and known margin measurements, (microinvasion excluded)

**Intervention** excision, some plus radiation therapy, some plus tamoxifen, some with all 3

**Margin** ocular micrometer measurement, clear: >1mm, close: DCIS ≤ 1mm from inked margin, involved: DCIS at any inked margin; involved margins resulted in reexcision and further shavings

**Follow up** median: 47 months, range: 12-197 months

**Results**

Margin	Results	Author's conclusion
overall	Excision margin was associated with recurrence in uni- and multivariate analyses (p<0.001)	
<1mm	38% with recurrence RR in comparison to ≥1mm: 9.8 RR in comparison to ≥10mm: 21	Excision width is the most important predictor of local recurrence.
≥1mm	5% with recurrence	
1-9mm	6% with recurrence RR in comparison to ≥10mm: 2.4	
≥10mm	3% with recurrence	

**General comments** it is possible that the patients from Boland et al. (2001) are also included in this analysis, overlap with Chan et al. (2001) is also possible

**Dillon MF, Dermott EW O'Doherty A et al. (2007). Factors affecting successful breast conservation for ductal carcinoma in situ. Annals of surgical Oncology, 14(5), 1618-1628.**

**Design** Case series (multivariate analysis) **Evidence level** 3 **Country** Ireland

**Population** N=135 patients undergoing initial breast conserving procedures for DCIS, not all with definitive preoperative diagnosis

**Intervention** diagnostic or therapeutic operation, reexcision or mastectomy

**Margin** pathology margins, compromised (foci of DCIS found within 10mm) vs clear, ≤2mm, ≤2mm vs >2mm, 0mm vs 0-1mm vs 1-2mm vs 2-5mm vs >5mm

**Follow up** study period 6 years

**Results**

Margin	Results	Author's conclusion
overall	Underestimation of pathological size by mammography by >1cm occurred in more patients with compromised margins than in those with clear margins in univariate analyses (p=0.02) but the factor was not significant in a multivariate analysis  Residual disease on re-operation and DCIS margin distance were associated (p=0.006) Margin width ≤2mm compared to >2mm was a predictor of residual disease in univariate (OR: 11.464, p<0.0001) and multivariate (OR: 6.694, p=0.032)  DCSI margin distance affected the likelihood of whether breast conservation was successful or not (p<0.001)	Patients with margin distances of ≤2mm are at high risk of residual disease; a 5mm margin width is recommended.
0	64% with residual disease	
0-1mm	60% with residual disease	
1-2mm	64% with residual disease	
≤2mm	Of all people with residual disease 95% were in this margin group  Of all patients with a successful breast conserving therapy, 33% were in this margin group, 88% of all patients with unsuccessful breast conserving therapy	
2-5mm	17% with residual disease	
>2mm	Of all the people with residual disease 5% were in this margin group	

Of all patients with a successful breast conserving therapy, 67% were in this margin group, 12% of all patients with unsuccessful breast conserving therapy

0% with residual disease

>5mm

**General comments** very different reporting compared to literature

**Population** N=660 patients with DCIS treated with breast conserving therapy, typically with lesions  $\leq 40$ mm and clear margins  $\geq 1$ mm

**Intervention** excision alone, excision plus radiation therapy (40-50 Gy)

**Margin**  $< 1$ mm, 1-  $< 10$ mm,  $\geq 10$ mm, patients with reexcision without DCIS were scored as 10mm

**Follow up** mean: 88 months

**Results**

Margin	Results	Author's conclusion
overall	The differences between the local disease free survival curves for the 3 margins are significant ( $p < 0.0001$ ) Margin width is the most important predictor of the USC/VNPI score / excellent predictor of local recurrence	As margin width increases, the probability of local recurrence decreases, 1mm margins are inadequate to ensure complete removal of DCIS, there are so few local recurrences in patients with margins of $\geq 10$ mm that the effect of radiation therapy is of little practical importance.
$< 1$ mm	Different local recurrence free survival depending on treatment ( $p < 0.0001$ ); 2.6fold increased risk of recurrence	
1-9mm	Different local recurrence free survival depending on treatment ( $p < 0.03$ ); 2-fold increase in risk of local recurrence for patients with excision alone compared to plus radiation	
$\geq 10$ mm	No different local recurrence free survival depending on treatment (n.s.) 6/214 with local recurrence RR of local recurrence: 6%, relative risk of local recurrence decreased to 3% by adding radiation therapy (but n.s.) Tumour size groups and age groups n.s. differences	

**General comments** publication contains 24 graphs but few raw data, table 4 not extracted as unclear what was depicted / compared. It is possible that there is overlap with the patients reported in Silverstein et al. (1999)

**Denoux Y, Marnay J, Crouet et al (2001). Evaluation of predictive factors, particularly the Van Nuys index, of local recurrence in ductal carcinoma in situ of the breast: study of 166 cases with conservative treatment and review of the literature. Bulletin du Cancer, 88(4), 419-425.**

**Design** Case series **Evidence level** 3 **Country** France

**Population** N=166 patients with DCIS

**Intervention** lumpectomy + radiotherapy (6 patients lumpectomy only)

**Margin** excision presumably aiming at 10mm, histological slides and shames analysed, <1mm, 1-9mm, ≥10mm as proposed by the Van Nuys index

**Follow up** median: 75 months, range: 16-263, 5yr, 10yr

**Results**

Margin	Results	Author's conclusion
overall	Margin width did not predict local recurrence (n.s.)	Margin width was not a statistically significant predictor of recurrence but it should be noted that none of the patients with margins ≥10mm developed a local recurrence.
<1mm	16/82 with local recurrence [20%] 93% without local recurrence at 5yrs 82% without local recurrence at 10yrs	
1-9mm	5/70 with local recurrence [7%]	
≥10mm	0/14 with local recurrence 100% without local recurrence at 5yrs 1%(?) without local recurrence at 10yrs*	

**General comments** published in French; \*as reported in table II, 100% is more likely; there appear to be several values missing in table II

Updated 2020

**Silverstein MJ, Lagios MD & Groshen S (1999). The influence of margin width on local control of ductal carcinoma in situ of the breast. New England Journal of Medicine, 340(19), 1455-1461.**

**Design** Cohort study **Evidence level** 2 **Country** USA

**Population** N=469 patients with DCIS treated with breast conserving therapy

**Intervention** excision alone, excision plus radiation therapy; treatment depending on patient and physician's choice

**Margin** <1mm, 1- <10mm, ≥10mm as established by direct measurement or ocular micrometry

**Follow up** mean: 81 months

**Results**

Margin	Results	Author's conclusion
<1mm	34/112 experience local recurrence [30%] probability of recurrence within 8yrs for excision alone: 0.58, excision plus radiation: 0.30 RR excision alone vs plus radiation: 2.54 (p=0.01)	Radiation does not lower the recurrence rate among patients with wide margins (≥10mm).
[≥1mm]	[41/357, 11%]	
1- <10mm	38/224 experience local recurrence [17%] probability of recurrence within 8yrs for excision alone: 0.20, excision plus radiation: 0.12 RR excision alone vs plus radiation: 1.49 (n.s.)	
≥10mm	3/133 experience local recurrence [2%] probability of recurrence within 8yrs for excision alone: 0.03, excision plus radiation: 0.04 RR excision alone vs plus radiation: 1.14 (n.s.)	

**General comments** 2 sites. It is possible that there is overlap with the patients reported in Silverstein & Buchanan (2003); the patients with ≥10mm are followed up in Macdonald et al. (2006)

**Silverstein MJ, Beron P & Lewinsky BS (1997). Breast conserving therapy for ductal carcinoma in situ: The Van Nuys experience with excision plus radiation therapy. Breast Journal, 3(3 suppl), 36-41.**

**Design** Case series **Evidence level** 3 **Country** USA

**Population** N=185 patients with DCIS treated with local excision and radiation therapy

**Intervention** excisional biopsy, reexcision became routine, radiation therapy

**Margin** <1mm, 1-9mm, ≥10mm

**Follow up** median: 90 months

**Results**

Margin	Results	Author's conclusion
<1mm	25% with recurrence	Local recurrence probability decreases as margin width increases, narrow margins amongst other factors may aid in selecting which patients benefit from radiation therapy.
[≥1mm]	[15/124, 12% with recurrence]	
1-9mm	15% with recurrence	
≥10mm	3% with recurrence	

**General comments** 2 sites. It is possible that there is overlap with the patients reported in Silverstein et al. (1999). Cosmetic results were assessed but not reported

Updated 2018

**Boland G, Chan KC, Knox WF & Bundred NJ (2001). Comparison of margin status with van Nuys index to predict recurrence of ductal carcinoma in situ after breast conserving surgery. British Journal of Surgery, 88, 41.**

**Design** Case series (regression) **Evidence level** 3 **Country** UK

**Population** N=228 patients treated with breast conserving surgery for unifocal DCIS

**Intervention** breast conserving surgery

**Margin** close: <1mm, not close: >1mm

**Follow up** median: 48 months

**Results**

Margin	Results	Author's conclusion
overall	Excision margin was associated with ipsilateral recurrence (p<0.001)	Close resection margins are a better predictor than the Van Nuys prognostic index for DCIS recurrence.
<1mm	36.9% with ipsilateral recurrence	
>1mm	5.8% with ipsilateral recurrence	

**General comments** Abstract only. It is possible that these patients are also part of Boland et al. (2003) and in parts of Chan et al. (2001)

Updated 2018

**Hetelekidis S, Collins L & Manola J (1999). Predictors of local recurrence following excision alone for ductal carcinoma in situ. Cancer, 85 (2), 427-431.**

**Design** Case series (multivariate analysis) **Evidence level** 3 **Country** USA

**Population** N=59 patients diagnosed with DCIS and negative margins of excision on review

**Intervention** excision alone, re-excision, (no radiation therapy)

**Margin** histologic slides, negative (>1mm), close (≤1 mm), (positive margins excluded)

**Follow up** median: 95.5 months, range: 34-141

**Results**

Margin	Results	Author's conclusion
overall	Margin size – local recurrence: n.s.	Margin status and nuclear grade may be useful to identify patients with DCIS who can be managed with excision alone.
≤1mm	25% actuarial 5yr local recurrence	
>1mm	8% actuarial 5yr local recurrence	

**General comments** -

Updated 2018

**Yau TK, Chan K, Chan M et al. (2006). Wide local excision and radiotherapy for the treatment of ductal carcinoma in situ of the breast: The Hong Kong experience. Clinical Oncology, 18, 447-452.**

**Design** Case series (regression) **Evidence level** 3 **Country** China

**Population** N=75 consecutive women with DCIS treated with wide local excision and radiotherapy

**Intervention** excision + radiotherapy, tamoxifen possible but not standard (no interstitial brachytherapy, no regional node irradiation, no chemotherapy)

**Margin** close ( $\leq 2$ mm but negative) vs  $> 2$ mm

**Follow up** median: 5.1 years, range: 2-10.7

**Results**

Margin	Results	Author's conclusion
overall	Both groups differed in 5-yr actuarial local failure free rate ( $p=0.02$ )  At 5yr follow-up all patients were still alive  All women had good to excellent cosmetic scores (physician rating)	Wide local excision and radiotherapy appears a reasonable alternative, efforts are needed to achieve cosmetically acceptable tumour free margins greater than 2mm.
$\leq 2$ mm	3/20 patients with local failure [15%] 77% 5yr actuarial local failure free rate HR 9.083 ( $p=0.056$ )	
$> 2$ mm	1/55 patients with local failure [2%] 98.2% 5yr actuarial local failure free rate	

**General comments** mean and upper limit of applied margins unclear

**Kell MR & Morrow M (2005). An adequate margin of excision in ductal carcinoma in situ: 2mm plus radiotherapy is as good as a bigger margin. BMJ, 331(7520), 789-790.**

**Design** Non-systematic review **Evidence level** 4 **Country** USA

**Population** patients with DCIS, entire review on margins

**Intervention** excision + radiotherapy

**Margin** clear vs positive, 2mm vs >10mm, 0-1mm, 1-2mm, ≥2mm, 5mm, 1-10mm also cited

**Follow up** treatment failure, 10yrs

**Results**

Margin	Results	Author's conclusion
overall	<ul style="list-style-type: none"> <li>-Definitions of negative vary, e.g. no tumour cells on the ink, 2mm free</li> <li>- Excisions of 5mm free seem unlikely to leave DCIS, even in patients with discontinuous growth, smaller margins may be appropriate for poorly differentiated DCIS</li> <li>- further disease is related to resection margin (Neuschatz et al. 2002 cited)</li> <li>- there is no difference between patients with 10mm margins and 1-10mm margins when treated with surgery and radiotherapy (Silverstein et al., 1999 cited)</li> <li>- the only benefit of &gt;10mm could be in low risk patients in whom radiotherapy may be avoided but this is not empirically confirmed (Wong et al., 2003 cited)</li> <li>- radiotherapy reduces the risk of local recurrence even in studies that only look at negative margins without specifying margin width (3 studies cited including the EORTC trial)</li> <li>- Radiotherapy with a margin of 2mm can achieve excellent local control (Solin et al., 2005)</li> <li>- there is no convincing evidence that larger margins confer better rates of local control [presumably] than radiotherapy</li> <li>- large margins lead to a greater deformity to the breast and patients will suffer a worse cosmetic outcome (1 study cited)</li> </ul>	<p>Free margins should be obtained, when radiotherapy is given ≤2mm is as good as &gt;10mm; there is an extremely low risk of death due to breast cancer associated with DCIS.</p>

**General comments** doesn't cite the American consensus conference but cites other studies from 1999

**Neuschatz AC, DiPetrillo T, Steinhoff M et al. (2002). The value of breast lumpectomy margin assessment as a predictor of residual tumor burden in ductal carcinoma in situ of the breast. American Cancer Society, 94(7), 1917-1924.**

**Design** Case series (multivariate analysis) **Evidence level** 3 **Country** USA

**Population** N=253 patients with DCIS treated with lumpectomy and reexcision, (microinvasion excluded)

**Intervention** initial excision, lumpectomy or reexcision, reexcisions typically for margins  $\leq 2\text{mm}$ ; excision with normal margin of 5mm or more

**Margin** closest initial excision margin to DCIS specimen edge as measured by micrometer; positive focal margin (single microscopic focus in one histologic section), positive minimal (involvement in one low power field or 2-4 sections at one geographic edge), positive moderate (2-4 LPF / present in 5-7 sections), positive extensive ( $\geq 5$  LPF /  $\geq 8$  sections), negative 0-1mm, negative 1-2mm, negative  $>2\text{mm}$

**Follow up ?**

**Results**

Margin	Results	Author's conclusion
overall	Margin status significantly predict the presence of residual tumours in reexcision specimen ( $p < 0.0001$ ) Margins significantly predict the presence of medium / large residual tumours ( $p = 0.003$ , $< 0.0001$ in uni- and multivariate analyses)	Margin status is the most important predictor for the presence and the amount of residual disease.
Positive-extensive	85% with tumour in reexcision	
Positive moderate	68% with tumour in reexcision	
Positive minimal	46% with tumour in reexcision	
Positive focal	30% with tumour in reexcision	
positive	63% with tumour in reexcision 11% with microscopic, 37% small, 10% medium, 5% large residual tumour	
0-1mm	41% with tumour in reexcision	
$>1-2\text{mm}$	31% with tumour in reexcision	
$>2-10\text{mm}$	0% with tumour in reexcision	
negative	63% no residual tumour, 10% with microscopic, 19% small, 4% medium, 3% large residual tumour	
$[\geq 1\text{mm}]$	$[4/23, 17\% \text{ with tumour in reexcision}]$	

**Goldstein NS, Kestin L & Vicini F (2000). Intraductal carcinoma of the breast. American J of Surgical Pathology, 24(8), 1058-1067.**

**Design** Case series (multivariate analysis) **Evidence level** 3 **Country** USA

**Population** N=132 consecutive patients with mammographically detected DCIS and inked final specimen margins treated with breast conserving therapy

**Intervention** local excision + radiation

**Margin** slide review, unknown (specimen fragmented or edges not inked), negative (all DCIS ducts more than 0.2cm away from inked margin edge), close (at least one DCIS duct within 0.2cm but margin did not transect DCIS duct), focally positive (margin edge transected DCIS duct), multifocal positive (margin transected by  $\geq 2$  DCIS separated by  $\geq 5$ cm or positive margin on  $\geq 2$  slides)

**Follow up** median: 84 months, range: 9-170.4, 78% followed for at least 5 years, 22% followed for at least 10 years

**Results**

Margin	Results	Author's conclusion
Overall	Margin status was not associated with true recurrences or marginal miss or 5yr actuarial recurrence rates in uni- or multivariate analyses (n.s.) No difference in true recurrences or marginal miss between patients with negative, close or positive final margins for patients with $\geq 5$ DCIS ducts or terminal duct lobular units with cancerisation of lobules near final margin (n.s.)	Margin status is not associated with the analysed outcomes.
Multifocal positive	0/11 patients with recurrence 1 with carcinoma elsewhere	
Unifocal positive	1/5 patients with recurrence 0 with carcinoma elsewhere	
positive	1/16 patients with recurrence 1 with carcinoma elsewhere	
>0-2mm	2/25 patients with recurrence [8%] 1 with carcinoma elsewhere [4%]	
>2mm	4/88 patients with recurrence [5%] 2 with carcinoma elsewhere [2%]	
unknown	2/3 patients with recurrence 0 with carcinoma elsewhere	

**General comments** data may be open to alternative interpretation: there were only few patients with recurrences that could enter the analyses, close margins have almost twice the recurrence rate compared to wide margins (8% vs 4.5%). The patients may also be included in parts in Goldstein et al. (1998) and Goldstein et al (1999)

**Goldstein NS, Lacerna M & Vincini F (1998). Cancerization of lobules and atypical ductal hyperplasia adjacent to ductal carcinoma in situ of the breast: Significance for breast conserving therapy. American J of Clinical Pathology, 110(3), 357-367.**

**Design** Case series **Evidence level** 3 **Country** USA

**Population** N=94 consecutive patients with mammographically detected DCIS treated with breast conserving therapy

**Intervention** local excision + radiation

**Margin** final pathology margin; unknown (specimen fragmented or edges not inked), negative (all DCIS ducts more than 0.2cm away from inked margin edge), close (at least one DCIS duct within 0.2cm but margin did not transect DCIS duct), focally positive (margin edge transected DCIS duct), multifocal positive (margin transected by ≥2 DCIS separated by ≥5cm or positive margin on ≥2 slides)

**Follow up** median: 78 months, range: 9-146, 70% followed for ≥ 5 years, 22% followed for ≥ 10 years

**Results**

Margin	Results	Author's conclusion
overall	Final margin status was not associated with true or recurrence elsewhere	
positive	No recurrence	
>0-2mm	3/16 patients with true recurrence, 1/16 with recurrence elsewhere [19%, 6%] 3/6 patients with in whom a true recurrence / marginal miss recurrent carcinoma developed were in this group 2/3 patient with recurrence elsewhere was in this margin group	DCIS may be inadequately excised if atypical ductal hyperplasia and DCIS or cancerisation of lobules and DCIS are near the margin.
>2mm	3/69 patients with true recurrence, 2/69 with recurrence elsewhere [4%, 3%] 3/6 patients with in whom a true recurrence / marginal miss recurrent carcinoma developed were in this group 2/3 patients with recurrence elsewhere were in this margin group	

**General comments** it is likely that these patients are also included in Goldstein et al. (2000), there may be overlap with Goldstein et al. (1999)

**Holland P, Gandhi A, Knox WF et al. (1998). The importance of complete excision in the prevention of local recurrence of ductal carcinoma in situ. British Journal of Cancer, 77(1), 110-114.**

**Design** Case series **Evidence level** 3 **Country** UK

**Population** N=129 women with localised screen-detected DCIS (including microcalcifications, mammographic mass lesions, in the majority impalpable) treated with breast conserving surgery

**Intervention** excision, involved margins underwent reexcision regardless of cavity shavings, some received also tamoxifen or breast irradiation or a combination of the two

**Margin** specimen or cavity shavings, clear (DCIS >1mm from any inked margin), involved (DCIS at any inked margin), close (DCIS ≤1mm from any inked margin)

**Follow up** every 3 months in the first year then annually, study period 58 months

**Results**

Margin	Results	Author's conclusion
overall	Ipsilateral recurrence was related to margin status (p<0.001)	Local relapses often represent residual DCIS rather than true recurrence, cavity shavings are ineffective in ensuring complete excision, 10mm margins around screen detected lesions are recommended.
positive	No recurrence	
≤1mm	36% with recurrence  of all 12 recurrences 10 occur in these patients	
>1mm	2% with recurrence  Of all recurrences 2/12 occur in these patients	

**General comments**

**Cheng L, Al-Kaisi NK, Gordon NH et al. (1997). Relationship between the size and margin status of ductal carcinoma in situ of the breast and residual disease. Journal fo the National Cancer Institute, 89(18) 1356-1360.**

**Design** Case series (multivariate) **Evidence level** 3 **Country** USA

**Population** N=232 consecutive patients diagnosed with mammary DCIS initially presenting with mammographic abnormality, palpable mass or other symptoms

**Intervention** excision, subsequent mastectomy, some with reexcision, some radiation therapy

**Margin** positive (tumour extending to or transacted by inked margin), close (tumour  $\leq 1$ mm or transacted by inked margin), negative ( $>1$ mm from margin) in histologic biopsy specimen

**Follow up** median: 45 months, range: 3-171

**Results**

Margin	Results	Author's conclusion
overall	Residual disease was associated with positive margins in univariate ( $p < 0.001$ ) and multivariate analyses ( $p = 0.04$ ); OR for risk of residual disease 2.2 for patients with positive margins (CI: 1.02-4.55) compared to $\leq 1$ mm or $>1$ mm margins residual disease risk for $\leq 1$ mm margins was not different from that of $>1$ mm (n.s.)  positive margins and tumour size appear to be positively correlated	Size of DCIS and margin status are independent predictors of residual disease, small tumours with negative margins carry a low risk of local failure and can be treated with lumpectomy, large tumours pose a risk of residual disease independently of margin status and additional adjuvant therapy may be indicated.
positive	39% with residual disease	
$\leq 1$ mm	19% with residual disease	
$>1$ mm	14% with residual disease	

**General comments**

**Sahoo S, Recant WM, Jaskowiak N et al. (2005). Defining negative margins in DCIS patients treated with breast conservation therapy: The University of Chicago experience. The Breast Journal, 11(4), 242-247.**

**Design** Case series (multivariate analysis) **Evidence level** 3 **Country** USA

**Population** N=103 consecutive patients with DCIS treated with breast conserving therapy and radiation therapy

**Intervention** excisional biopsy and external beam radiation (46 GY median plus boost therapy)

**Margin** final margins on slide review, positive (DCIS focus touched or was transected at inked margin), close (<1mm, 1-5mm, >5mm of uninvolved breast tissue from inked margin), free (negative but distance not known)

**Follow up** 63 months, range: 7-191, 5yrs

**Results**

Margin	Results	Author's conclusion
overall	Of the 13 patients that showed a recurrence, 5 had positive margins, 3 margins <1mm, 2 free margins, 2 with 1-5mm margins, 1 with >5mm  Positive margin status was a predictor of local recurrence (p=0.008) compared to all other in univariate analyses, the survival curves of patients with positive margins compare to negative margins differed significantly; positive margin compared to all negative was a predictor in multivariate analyses with HR: 0.16 (CI: 0.04-0.63, p=0.009)	Excellent local control can be achieved by obtaining microscopically negative margins and radiation therapy.
positive	31% with local recurrence	
Clear but unknown	20% with local recurrence	
<1mm	8% with local recurrence	
1-5mm	10% with local recurrence	
>5mm	4% with local recurrence	
[≥1mm]	[3/42, 7%]	

**General comments**

**Vicini FA, Kestin LL, Goldstein NS et al. (2001). Relationship between excision volume, margin status, and tumor size with the development of local recurrence in patients with ductal carcinoma in situ treated with breast conserving therapy. Journal of Surgical Oncology, 76, 245-254.**

**Design** Case series (multivariate) **Evidence level** 3 **Country** USA

**Population** N=146 patients treated for DCIS with lumpectomy followed by radiation therapy with complete pathological review (no invasive carcinoma, no microinvasion)

**Intervention** excision + breast irradiation, reexcision due to close ( $\leq 2\text{mm}$ ), positive, or uncertain margins

**Margin** pathology margin; unknown (specimen fragmented or not inked), negative (no DCIS within 0.2cm of inked margin), close (DCIS within 0.2cm but margin did not transected), unifocal positive (single DCIS duct transected at margin), multifocal positive (margin transected by  $\geq 2$  ducts separated by  $\geq 5\text{cm}$  or positive margin on  $\geq 2$  slides)

**Follow up** 5yr, 10yr; every 3 months for 2 years, 6-monthsly after

**Results**

Margin	Results	Author's conclusion
overall	<p>close or positive margins combined and close, positive or uncertain margins combined differed in ipsilateral breast failures compared to <math>&gt;2\text{mm}</math> margins in univariate analyses (<math>p=0.24</math>, <math>p=0.09</math>) but not multivariate analyses (n.s.)</p> <p>Close or positive margins compared to <math>&gt;2\text{mm}</math> was associated with a HR of 4.47 (<math>p=0.03</math>) for true recurrences / marginal miss in a multivariate analysis, the corresponding values for all negative margins were HR of 2.59 (<math>p=0.07</math>) for ipsilateral breast failure, n.s. for true recurrences / marginal miss</p> <p>Close, positive or uncertain margins differed in true recurrences / marginal miss compared to <math>&lt;5\text{mm}</math> (<math>p=0.24</math>, <math>p=0.09</math>)</p> <p>Patients with reexcision and negative margin differed from patients with reexcision and close or positive margins in ipsilateral breast failure incidences (<math>p=0.02</math>) and true recurrences (<math>p=0.003</math>)</p>	Margin status alone may be suboptimal in defining excision adequacy.
Close or positive	<p>11.6% with ipsilateral breast failure at 5yrs, 14.7% at 10yrs, 9.5% true recurrence at 5yrs, 12.6% at 10yrs;</p> <p>Patients with reexcision: 23.4% with ipsilateral breast failure at 5yrs, 32% at 10yrs, 23.4% true recurrence at 5yrs, 32% at 10yrs</p>	
Close / positive / uncertain	<p>15.9% with ipsilateral breast failure at 5yrs, 18.7% at 10yrs, 14% true recurrence at 5yrs, 16.9% at 10yrs</p>	

>2mm	7.4% with ipsilateral breast failure at 5yrs, 9.3% at 10yrs, 4.4% true recurrence at 5yrs, 6.3% at 10yrs; Patients with reexcision 7% with ipsilateral breast failure at 5yrs, 9.4% at 10yrs, 4.3% true recurrence at 5yrs, 6.8% at 10yrs
2-5mm	9.1% with ipsilateral breast failure at 5yrs, 9.1% at 10yrs, 9.1% true recurrence at 5yrs, 9.1% at 10yrs
>5mm	6.8% with ipsilateral breast failure at 5yrs, 9.1% at 10yrs, 2.7% true recurrence at 5yrs, 5% at 10yrs
other	Negative margins at reexcision showed 7% ipsilateral breast failure at 5yrs, 9.4% at 10yrs, 4.3% true recurrence at 5yrs, 6.8% at 10yrs; Close or positive margins at reexcision showed 23.4% ipsilateral breast failure at 5yrs, 32% at 10yrs, 23.4% true recurrence at 5yrs, 32% at 10yrs

**General comments** these data have to be regarded with caution - due to the various groupings of patients and varying definitions of margin status and multiple subgroup analyses mistakes in the data extraction cannot be ruled out

Updated 2019

**Rodrigues N, Carter D, Dillon D et al. (2002). Correlation of clinical and pathologic features with outcome in patients with ductal carcinoma in situ of the breast treated with breast conserving surgery and radiotherapy. International Journal of Radiation Oncology, Biology, Physics, 54(5), 1331-1335.**

**Design** Case series **Evidence level** 3 **Country** USA

**Population** N=230 patients with DCIS treated with breast conserving surgery plus radiotherapy, margin status was only known for 42% of the patients

**Intervention** local excision + radiotherapy, 9% also hormonal therapy

**Margin** positive (DCIS extended to margin edge), close (DCIS present ≤2cm from margin edge), negative (DCIS >0.2cm from margin edge or no tumour in reexcision)

**Follow up** median: 8.2 years; 3-6 months for 2-3 years then every year

**Results**

Margin	Results	Author's conclusion
overall	Ipsilateral breast tumour recurrence rate did not differ between patients with close / positive margins compared to negative / unknown margins	Positive or close margin status was not a significant predictor of local relapse.
unknown	9/97 with recurrence	
positive	0/8 recurrences	
≤2mm	3/22 with recurrence [14%]	
>2mm	5/103 with recurrence [5%]

**Vargas C, Kestin L, Go N et al. (2005). Factors associated with local recurrence and cause specific survival in patients with ductal carcinoma in situ of the breast treated with breast-conserving therapy or mastectomy. Int. J. Radiation Oncology Biol. Phys, 63(5), 1514-1521.**

**Design** Case series (multivariate) **Evidence level** 3 **Country** USA

**Population** N=405 patients with DCIS

**Intervention** lumpectomy alone, lumpectomy + radiation therapy (median 45Gy), subsequent mastectomy, subsequent radiation therapy

**Margin** recorded for initial biopsy and reexcision, positive or close ( $\leq 2$ mm from margin), negative ( $> 2$ mm from margin), uncertain (not inked or fragmented specimen)

**Follow up** median: 7 years, mean: 6.1 years

**Results**

Margin	Results	Author's conclusion
overall	Margin status was related to an increase in ipsilateral recurrences ( $p=0.02$ ) and true recurrences / marginal miss ( $p=0.004$ ), positive / $\leq 2$ mm was also a risk factor in multivariate analyses with a HR of 3.65 ( $p=0.007$ ); using the categories positive, close, negative, or widely negative was also a predictor in multivariate analysis (HR1.82 per group, $p=0.04$ )	Close or positive margins are associated with ipsilateral breast tumour recurrence, local therapy optimisation is crucial to improve local control and cause specific survival.
positive / $\leq 2$ mm	13% with ipsilateral recurrence or true recurrence / marginal miss at 5yrs, 22% at 10yrs	
$> 2$ mm	4% with ipsilateral recurrence at 5yrs, 9% at 10yrs; 3% true recurrence / marginal miss at 5yrs, 7% at 10yrs	

**General comments** data extraction under the assumption that these were initial margin data; it is possible that some of the included patients were also part of Goldstein et al. (1998)

**Tunon-de-Lara C, deMascarel I, MacGrogan G et al. (2001). Analysis of 676 cases of ductal carcinoma in situ of the breast from 1971 to 1995. Am J Clin Oncol, 24(6), 531-536.**

**Design** Case series (includes 4 distinct cohorts) **Evidence level** 3 **Country** France

**Population** N=676 patients with DCIS, (contralateral infiltrative carcinoma excluded)

**Intervention** surgical biopsy / gross excision of primary tumour alone or excision + radiation therapy (50Gy), mastectomy, subsequent mastectomy, subsequent axillary lymph node dissection, subsequent radiation, subsequent lumpectomy

**Margin** histological sections analyses, free vs invaded margins

**Follow up** median: 86 months, range: 8-164, in subgroups median follow up 85.7, 78.8, 237\*, 67.6 months

**Results**

Margin	Results	Author's conclusion
overall	Invaded margin status was predictive of recurrence (p=0.0073)	
free	38/312 relapses lumpectomy alone (n=192): 14.5% relapses (16 noninvasive, 12 invasive), 25 local recurrences, 3 axillary node recurrences, 0 metastasis 8-144 months delay breast cancer specific death: 0.52% 5yr local recurrence free rate: 89%, 10yr: 83% 10yr overall survival: 95.3% lumpectomy + radiation (n=120): 7.5% relapses (4 noninvasive, 6 invasive), 9 local recurrences, 0 axillary node recurrences, 0 metastasis 10-156 months delay breast cancer specific death: 0 5yr local recurrence free rate: 98.1%, 10yr: 87.8% 10yr overall survival: 96.9%	The data emphasize the need for clear margins; breast cancer mortality is extremely low regardless of the treatment method.
invaded	12/51 relapses lumpectomy alone (n=15): 53% relapses (3 noninvasive, 5 invasive), 8 local recurrences in same quadrant as original lesion, 0 axillary node recurrences, 0 metastasis 8-60 months delay breast cancer specific death: 13% 5yr local recurrence free rate: 51.4%, 10yr: - 10yr overall survival: 100% lumpectomy + radiation (n=36): 11% relapses (2 noninvasive, 2 invasive), 4 local recurrences in same quadrant as original lesion, 0 axillary node recurrences,	

0 metastasis

10-31 months delay

breast cancer specific death: 0

5yr local recurrence free rate: 89%, 10yr: -

10yr overall survival: 100%

**General comments** 12% of patients also included in EORTC trial; \*as stated in table 6; the survival data cannot be attributed to the treatments excision alone or excision + radiation as patients received further treatments (including mastectomies) when recurrences occurred

**Solin LJ, Fourquet A, Vivini FA et al. (2005). Long-term outcome after breast-conservation treatment with radiation for mammographically detected ductal carcinoma. Cancer, 103(6), 1137-1146.**

**Design** Case series (multivariate analysis) **Evidence level** 3 **Country** USA

**Population** N=1003 women with unilateral mammographically detected DCIS (no microinvasion)

**Intervention** breast conserving surgery, definitive breast irradiation ( $\geq 4000\text{cGy}$ ), (no adjuvant systemic chemotherapy or hormonal treatment)

**Margin** final pathology margin from reexcision or excision, reexcision in 47% (most commonly for positive margins or residual microcalcifications), negative (no tumour identified  $>2\text{mm}$  or  $\geq 2\text{mm}$ ); positive (tumour identified), close ( $\leq 2\text{mm}$ ,  $<2\text{mm}$  2-3mm or 3mm as defined at individual institution)

**Follow up** median: 8.5 years, mean: 9 years, range: 0.2-24.6, 873/1003 alive and available at 5yrs, 363/1003 at 10yrs, 68/1003 at 15 years

**Results**

Margin	Results	Author's conclusion
overall	Final pathology margin status is associated with local recurrence in univariate ( $p=0.024$ ) as well as multivariate analyses ( $p=0.0026$ ); negative margin was associated with fewer local recurrence ( $p=0.0026$ )	Age $\geq 50$ yrs and negative margins are associated with a decreased risk of local failure.
negative	4% local failure at 5yrs, 8% at 10yrs	
close	7% at 5yrs, 13% at 10yrs HR 1.90 for local failure compared to negative margin ( $p=0.027$ )	
positive	11% at 5yrs, 15% at 10yrs HR 3.35 for local failure compared to negative margin ( $p=0.00035$ )	
unknown	6% at 5yrs, 14% at 10yrs	

**General comments** multi-site with varying margin cut-offs

**Bijker N, Peterse JL, Duchateau L et al. (2001). Risk factors for recurrence and metastasis after breast conserving therapy for ductal carcinoma in situ: Analysis of European Organization for Research and Treatment of Cancer Trial 10853. Journal of Clinical Oncology, 19(8), 2263-2271.**

**Design** RCT (not randomised to margin status) **Evidence level** 1- **Country** Europe

**Population** N=1010 women from 46 institutes enrolled in EORTC DCIS

**Intervention** excision alone vs excision + radiotherapy (47-55 Gy); excision was performed often together with reexcision of the biopsy cavity after diagnostic excision by shaving, margins were considered free if no DCIS was found in the multiple reexcision specimen

**Margin** pathology report, free with or without further specifications, close/involved; inking was mentioned in 25% of specimen

**Follow up** median: 5.4yrs

**Results**

Margin	Results	Author's conclusion
overall	Margin status was associated with local recurrence in univariate ( $p < 0.0223$ ) and multivariate analyses ( $p = 0.0008$ ) HR for unknown / close / involved margins compared to free margins: 2.07 (CI: 1.35-3.16, multivariate analysis)  The time to local recurrence differed between the 4 groups excision+radiation-free margin, excision-free margin, excision+radiation-involved/nonspecified margin, excision-involved/nonspecified margin ( $p = 0.0003$ , Kaplan-Meier curves)	Involved, close, or nonspecified margins are related to the risk of recurrence; radiotherapy cannot compensate for involved margins.
free	15% local recurrence with further specified margins, 13% for free margins but not further specified, HR: 1.36 and 1.07 the group receiving excision only 18% or 14% experienced local recurrences, the excision + radiotherapy group had a 12% recurrence rate	
Close / involved	24% local recurrence, HR: 2.01 the group receiving excision only 32% experienced local recurrences, the excision + radiotherapy group had a 16%* recurrence rate	
unknown	28% local recurrence, HR: 2.11 the group receiving excision only 33% experienced local recurrences, the excision + radiotherapy group had a 22% recurrence	

rate

**General comments** multi-site; \* the discussion implied that the recurrence rate was 20%; more information on excision and margin definitions were taken from the excluded paper by Bijker, Rutgers et al. (2001)

Updated 2018

**Goldstein NS, Kestin L. & Vicini F (1999). Pathologic features of initial biopsy specimens associated with residual intraductal carcinoma on reexcision in patients with ductal carcinoma in situ of the breast referred for breast conserving therapy. American Journal of Surgical Pathology, 23(11), 1340-1348.**

**Design** Case series (multivariate analysis) **Evidence level** 3 **Country** USA

**Population** N=98 patients with pure DCIS undergoing biopsy and reexcision with available inked initial biopsy specimen

**Intervention** biopsy, reexcision

**Margin** negative / close, unifocal positive or multifocal positive in initial biopsy

**Follow up** median: 84 months, range: 9-170.4, 78% followed for at least 5 years, 22% followed for at least 10 years

**Results**

Margin	Results	Author's conclusion
overall	<p>negative, close or unifocal positive margins vs multifocal positive margin showed differences in the presence of DCIS (<math>p &lt; 0.01</math>)</p> <p>there was no difference between negative or close versus unifocal positive margins (n.s.)</p> <p>there was no difference between negative versus close or positive margins (n.s.)</p> <p>multifocal positive margins was associated with increasing number of slides with DCIS on reexcision (<math>p &lt; 0.01</math>; only in univariate analysis)</p>	<p>Multifocal positive margins are associated with the presence of and an increasing amount of residual DCIS in reexcision specimens; the more DCIS and near the margin, the greater the chance of increasing amounts of DCIS in the adjacent breast.</p>
multifocal positive	79% with DCIS at reexcision	
unifocal positive	33% with DCIS at reexcision	
close or positive	56% with DCIS at reexcision	
negative, close or unifocal positive	42% with DCIS at reexcision	
negative or close	45% with DCIS at reexcision	
negative	43% with DCIS at reexcision	

**General comments** The patients may also be included in parts in Goldstein et al. (1998; 2000)

**Silverstein, MJ, Gierson ED, Colburn WJ, et al. (1994). Can intraductal breast carcinoma be excised completely by local excision? Clinical and pathological predictors. Cancer, 73(12), 2985-2989.**

**Design** Case series **Evidence level** 3 **Country** USA

**Population** N=181 patients with DCIS and excisional biopsy and subsequent reexcision or mastectomy

**Intervention** biopsy designed to remove lesion with excision leaving a rim of normal appearing tissue, subsequently reexcision or mastectomy

**Margin** microscopically differentiated between clear and positive

**Follow up** study period 14 years

**Results**

Margin	Results	Author's conclusion
overall	Positive initial biopsy margins can predict whether residual DCIS can be found at reexcision or mastectomy (p<0.0001) Tumour size was a predictor for DCIS independently of margin status	Inadequate excision may be the most important cause of local failure.
positive	76% with residual DCIS	
clear	43% with residual DCIS	

**General comments**

Updated 2018

**Wong JS, Kaelin CM, Troyan SL (2006). Prospective study of wide excision alone for ductal carcinoma in situ of the breast. Journal of Clinical Oncology, 24 (7), 1031-1036.**

**Design** Case series **Evidence level** 3 **Country** USA

**Population** N=158 patients with grade 1 or 2 DCIS

**Intervention** wide excision with or without reexcision, (no chemotherapy or tamoxifen)

**Margin** histologic margin  $\geq 1$ cm or a totally negative reexcision, reexcision if initial margins  $< 1$ cm or not assessable

**Follow up** study closed after 3 years of recruiting, 477 patient years

**Results**

Margin	Results	Author's conclusion
$\geq 10$ mm	Study was closed to accrual at 158 patients because the number of local recurrences exceeded 7 before a total combined follow-up time of 100 patient years 2.4% first site treatment failure per patient-year (5 year rate 12%); recurrence of DCIS: in 69% of patients, recurrence with invasive disease: 31%	Despite margins of at least 10mm, local recurrence rate is substantial when treated with excision alone, the use of radiation therapy and / or tamoxifen should be assessed.

**Macdonald HR, Silverstein MJ, Lee LA et al. (2006). Margin width as the sole determinant of local recurrence after breast conservation in patients with ductal carcinoma in situ of the breast. The American Journal of Surgery, 192, 420-422.**

**Design** Case series (includes 2 distinct cohorts) **Evidence level** 3 **Country** USA

**Population** N=272 patients diagnosed with DCIS and treated with breast conservation and margins of  $\geq 10$ mm, (microinvasion excluded)

**Intervention** excision alone, excision plus radiation therapy (no tamoxifen or other hormone therapy)

**Margin**  $\geq 10$ mm, determined by direct measurement or ocular micrometry, patients without DCIS at reexcision were scored  $\geq 10$ mm

**Follow up** median: 53 months

**Results**

Margin	Results	Author's conclusion
$\geq 10$ mm	12/212 excision alone patients experienced any recurrence, [6%] 3 invasive recurrences 13.9% probability of any recurrence at 12yrs, 3.4% for invasive recurrence 1/60 excision plus radiation patients experienced an invasive recurrence; 2.5% probability at 12yrs	Local recurrence compares favourably in patients treated with excision alone with margins of 10mm or greater to patients with nontransected margins and treated with radiation; the risk of invasive recurrence is extremely low.

**General comments** most patients also included in Silverstein et al. (1999), some overlap with Macdonald et al. (2005) and / or Silverstein & Buchanan (2003) possible

**Cabioglu N, Hunt KK, Sahin AA et al. (2007). Role for intraoperative margin assessment in patients undergoing breast conserving surgery. Annals of Surgical Oncology, 14(4), 1458-1471.**

**Design** Case series **Evidence level** 3 **Country** USA

**Population** sample of N=64 women diagnosed with DCIS undergoing primary tumour excision included in population

**Intervention** wide local excision including complete primary tumour removal plus adjuvant external beam radiation therapy, some received doxorubicin, tamoxifen, reexcision mainly for positive or close margins, subsequent mastectomy, level I and II axillary lymph node dissection with or without sentinel lymph node biopsy

**Margin** intraoperative assessment of gross tissue inspection, specimen radiography with or without frozen section

**Follow up** median: 6.4 years, range: 0.6-9.4; 5 years

**Results**

Margin	Results	Author's conclusion
Overall	DCIS patients with negative margins had a better 5yr ipsilateral recurrence free survival rate than patients with persistent positive / close margins after completion of all surgical treatment (86% versus 98%, p=0.017)	Intraoperative assessment assisted in identifying positive / close margins and enabled intraoperative reexcision and resulted in excellent local control.

**General comments** table 3 not extracted as number of patients with particular margin width missing

### 3.2 What is the role of mastectomy in patients with localised Paget's disease of the nipple?

#### Short Summary

There is a small volume of literature relating to Paget's disease of the nipple, with evidence comprising of mostly small retrospective, non-comparative case series.

11 observational studies provide data on breast cancer recurrence in patients treated with mastectomy or breast conserving surgery for Paget's disease (Sutton *et al.* 1999; Bijker *et al.* 2001; Dixon *et al.* 1991; Duff *et al.* 1998; Howard *et al.* 1989; Nicolosai *et al.* 1996; Polgar *et al.* 2002; Zurrida *et al.* 1993 Estabrook *et al.* 1996; Marshal *et al.* 2003). These data appear to show higher rates of recurrence following breast conserving surgery compared to mastectomy, but no study provided a statistical analysis.

In 3 out of 4 studies in which survival data were reported for both mastectomy and breast conserving surgery, post-mastectomy breast cancer-specific survival was superior (Dixon *et al.* 1991; Howard *et al.* 1989; Polgar *et al.* 2002; Sutton *et al.* 1999).

A single study statistically compared survival following mastectomy or breast conserving surgery and found no statistical difference in breast cancer-specific survival at 15 years following treatment (Chen *et al.* 2006).

Cosmesis was assessed in one study only (Marshall *et al.* 2003). The treating radiation oncologist assessed cosmesis in 31 patients. These were rated as: excellent, 10 (32%; 4 patients underwent nipple reconstruction); good, 18 (58%); fair, 3 (10%). No data was identified for quality of life, based on assessment with a specific instrument, as an outcome in patients treated for Paget's disease by mastectomy or breast conserving surgery.

#### PICO

Population	Intervention	Comparison	Outcome
Patients with localized Paget's disease of the nipple	<ul style="list-style-type: none"> <li>• Wide Local Excision (WLE)</li> <li>• Mastectomy</li> </ul>	Versus each other	<ul style="list-style-type: none"> <li>• Recurrence</li> <li>• Disease Free Survival</li> <li>• Overall survival</li> <li>• Cosmesis</li> <li>• Patient Acceptability</li> <li>• Quality of Life</li> </ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

#### Evidence Summary

There appears to be a relatively small literature base on Paget's disease of the nipple and for this reason no arbitrary threshold criteria were applied in selecting studies for appraisal.

The studies were predominantly small retrospective, non-comparative case series of which 15 reported on fewer than 50 cases. There was considerable heterogeneity in the included studies in terms of population size, follow-up intervals, methods of reporting disease recurrence and patient survival. For these reasons the results should be interpreted cautiously.

Of the outcome measures specified for this topic, recurrence (local/regional and distant metastases) and/or survival (disease-specific and overall) were addressed by all studies. Minimal information was reported on cosmesis (1 study) or post-operative complications relevant to patient quality of life (1 study; protracted chest wall pain, chronic breast infection and radiation dermatitis). No data were reported on patient acceptability.

The data appears to show higher rates of recurrence following breast conserving surgery compared to mastectomy, but no study provided a statistical analysis.

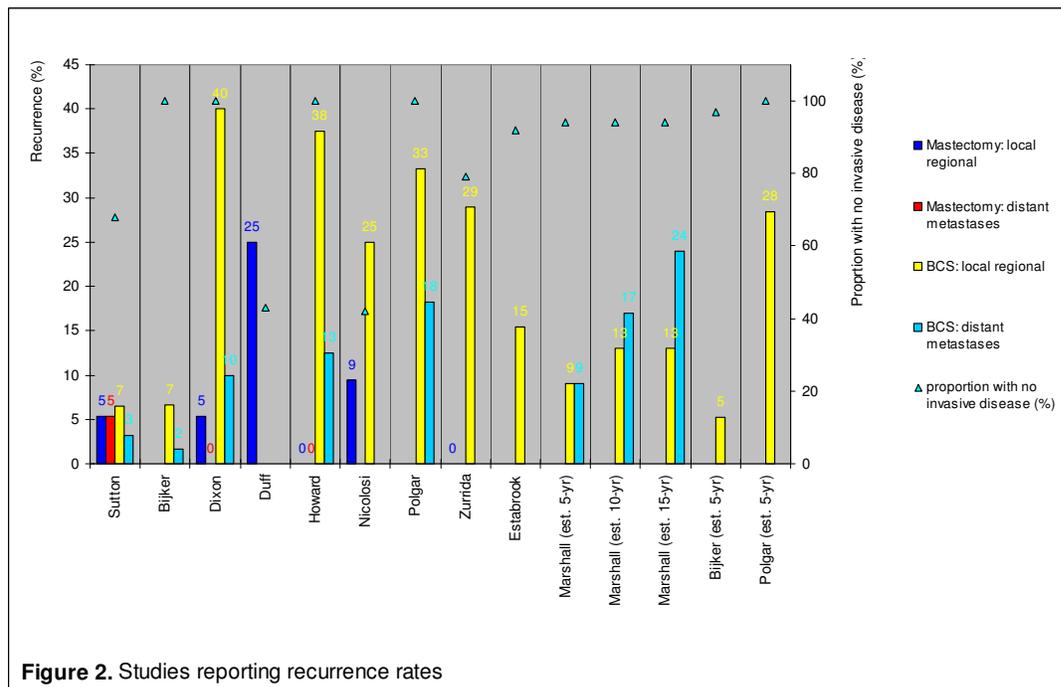

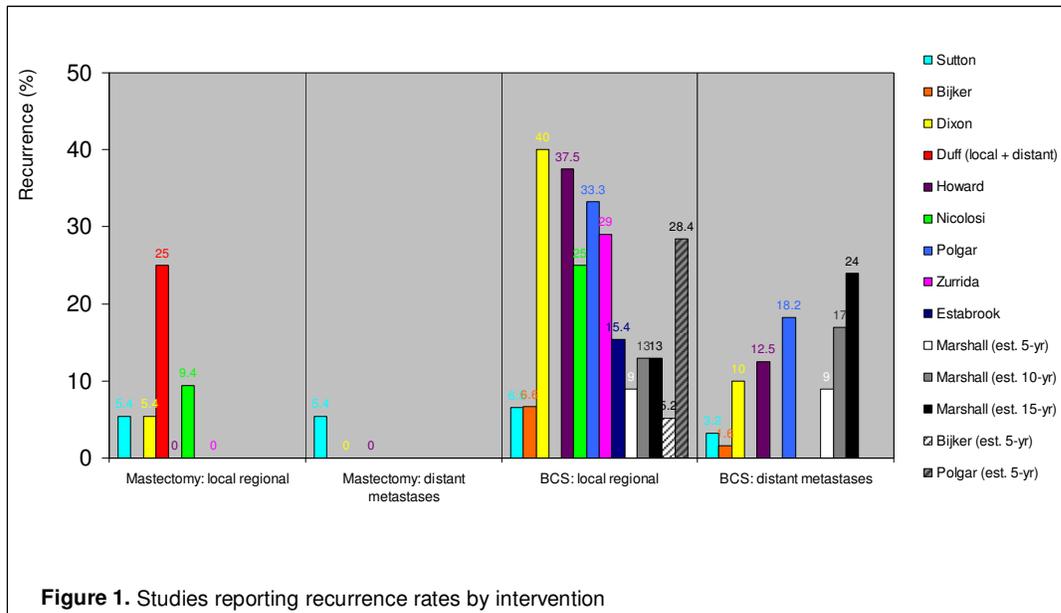

Data on crude rates of survival following mastectomy or breast conserving surgery in patients with Paget's disease comes from nine observational studies. In three of four studies that provided data on both procedures, survival was better in patients treated with mastectomy. However there is no other visible trend in the data and no conclusions on survival can be reliably made.

Disease-related events following surgical treatment for Paget's disease of the nipple

### **Disease recurrence**

Eleven observational studies provide data on breast cancer recurrence in patients treated with mastectomy or breast conserving surgery for Paget's disease (Figure 1, Figure 2). These data appear to show higher rates of recurrence following breast conserving surgery compared to mastectomy, but no study provided a statistical analysis. Study size is small; 9 of the 11 observational studies comprised less than 50 cases. Therefore due to the poor quality of the data; no conclusions can be reliably drawn.

Eleven studies reported local and distant metastatic disease recurrence rates following surgery for Paget's disease of the nipple (Figure 1, Figure 2). All these studies reported recurrence rates following breast conserving surgery and six following mastectomy. In general the proportion of patients presenting with no evidence of underlying invasive breast cancer - therefore meeting the population criteria for this topic - was high (median = 92%, range, 42%-100%). The largest study in the series reported recurrence data comparing outcomes following mastectomy (n=74) and wide local excision (WLE, n=31) (Sutton *et al.* 1999). The data revealed similar but not statistically evaluated rates of local disease recurrence for mastectomy and WLE (5.4% vs. 6.5% respectively), but a higher distant metastatic disease recurrence rate following mastectomy (5.4% vs. 3.2%). Follow-up in this study was for 84 months and 60 months for mastectomy and WLE, respectively. In contrast, an earlier study (Dixon *et al.* 1991) reported local and distant disease recurrence rates markedly higher in patients who had undergone WLE (40%, 10%, respectively) compared with mastectomy (5.4%, 0%). However, although the follow-up interval for WLE was similar (56 months), follow-up for mastectomy was limited to 40 months, less than half the follow-up period reported by Sutton *et al.*

### Disease recurrence in patients with Paget's disease of the nipple and no palpable underlying mass

One retrospective study analysed recurrence in the subgroup of patients with Paget's disease and no underlying palpable lump (Sutton 1999). In this study the crude rate of local recurrence was 1.9% following mastectomy and 6.9% following breast conserving surgery. Respective rates of distant recurrence were 5.7% and 3.4% respectively. With no statistical analysis and small numbers of patients, the data do not permit conclusions to be reliably drawn (Table 1).

Table 1. Post-operative breast cancer local and distant recurrence according to pre-existence/absence of a palpable mass

Study	Underlying palpability	Recurrence	Mastectomy				Breast conserving surgery			
			n <sup>1</sup>	d <sup>2</sup>	Recurrence n÷d (%)	Follow-up <sup>3</sup> (months)	n <sup>1</sup>	d <sup>2</sup>	Recurrence n÷d (%)	Follow-up <sup>3</sup> (months)
Sutton (1999)	Palpable lump	Local	3	21	14.3	84	0	2	0	60
	No palpable lump	Local	1	53	1.9	84	2	29	6.9	60
	Palpable lump	Distant	1	21	4.8	84	0	2	0	60
	No palpable lump	Distant	3	53	5.7	84	1	29	3.4	60

<sup>1</sup> number of patients with disease recurrence

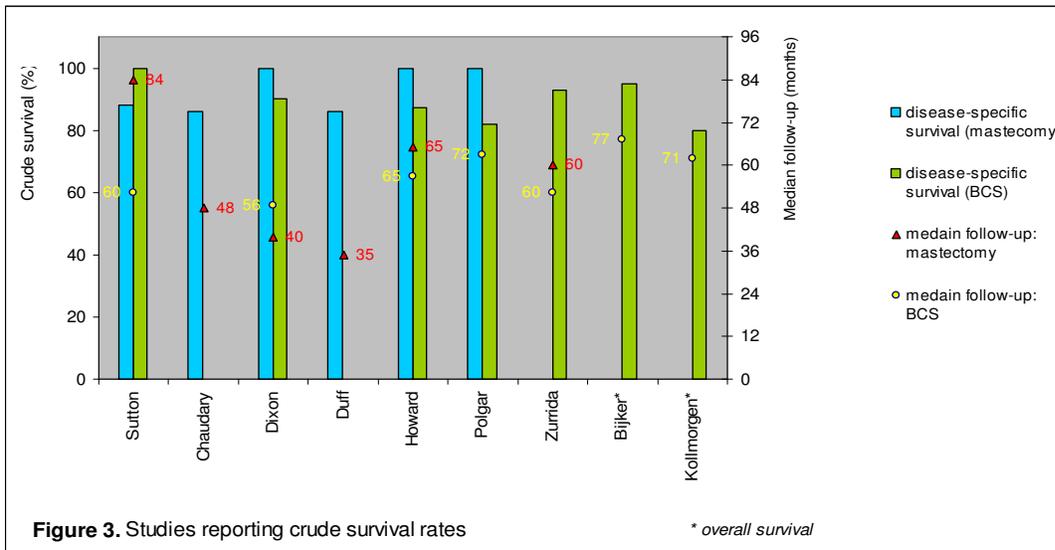

<sup>2</sup> number of patients followed-up

<sup>3</sup> median follow-up

#### Patient survival - crude rates

Data on crude rates of survival following mastectomy or breast conserving surgery in patients with Paget's disease comes from nine observational studies (Figure 3). In three of four studies that provided data on both procedures, survival was better in patients treated with mastectomy. However there is no other visible trend in the data and no conclusions on survival can be reliably made.

Nine studies reported crude survival rates following either mastectomy or breast conserving surgery (BCS; Figure 3). Seven of these reported crude breast cancer-specific survival and 2 reported overall survival. The median follow-up period over which survivals were reported was 35-84 months for mastectomy and 56-77 months for BCS. In 3 out of 4 studies in which survival data were reported for both mastectomy and BCS, post-mastectomy breast cancer-specific survival was superior (figure 3) (Dixon et al. 1991; Howard et al. 1989; Polgar et al. 2002; Sutton et al. 1999). Sutton et al reported 100% (n = 29) patient survival at 84 months follow-up for patients with no pre-existing palpable mass who had received breast conserving surgery (Sutton et al. 1999). Likewise 100% survival was reported for patients who presented with a palpable mass although only 2 patients fell into this subgroup.

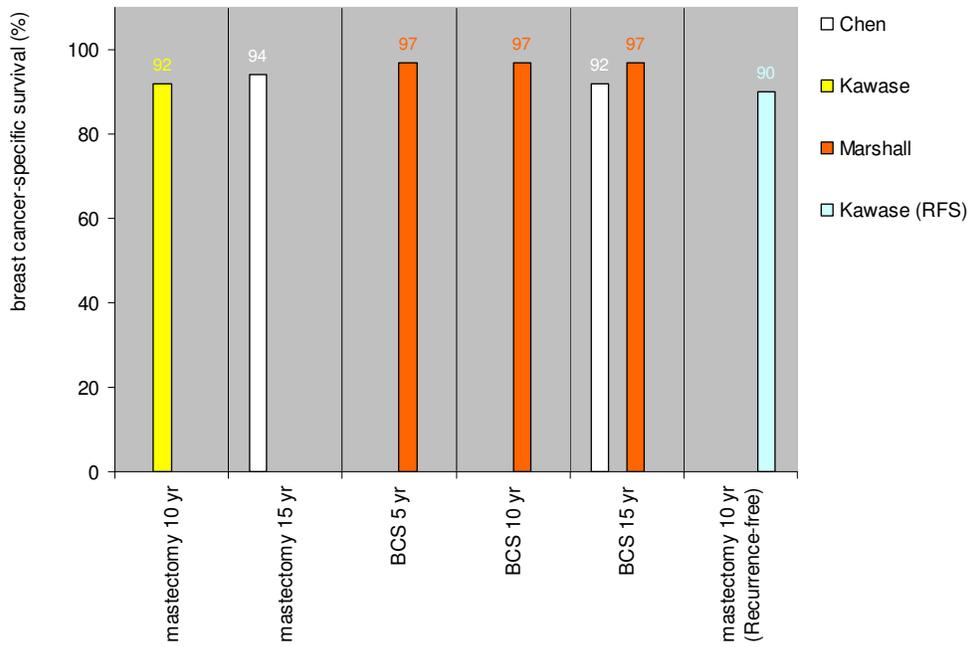

### Patient survival - actuarial data

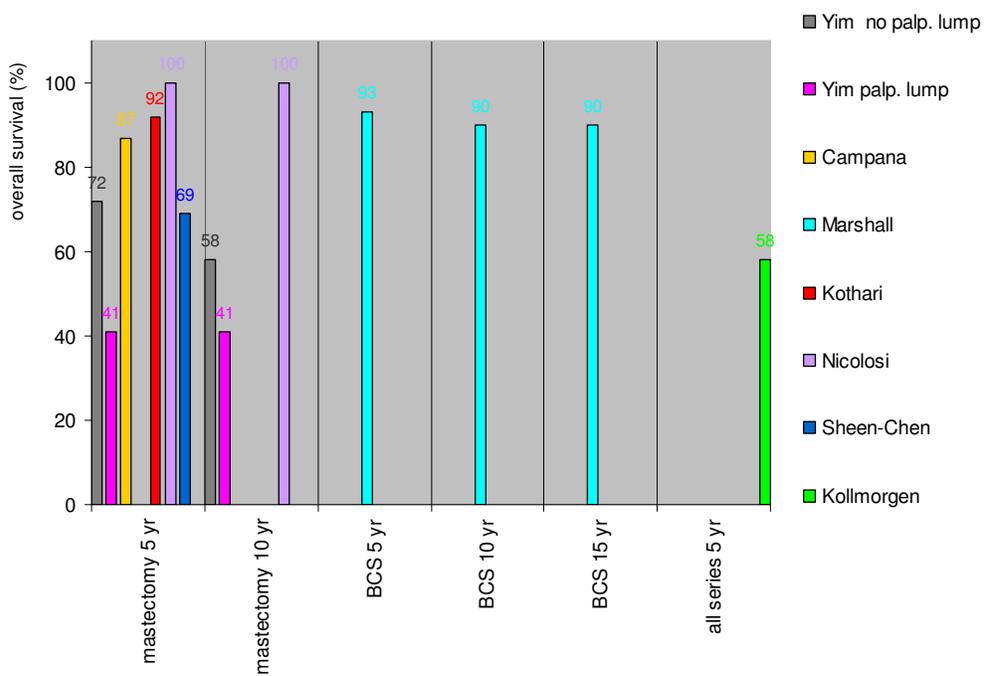

Nine observational studies provide estimated survival rates in patients with Paget's disease treated with mastectomy or breast conserving surgery based on time-to-event analyses (Figure 4). The only study that statistically compared survival following these procedures found no difference in breast cancer-specific survival at 15 years following treatment (Chen et al. 2006). The data from the remaining studies do not permit conclusions on the superiority of breast conserving surgery or mastectomy in terms of either breast cancer-specific survival or overall survival.

Nine studies reported actuarial (estimated) survival data for patients after mastectomy or breast conserving surgery. The results are presented for breast cancer-specific survival and for overall survival (Figure 4). The largest and most recently published study reported estimated breast-cancer specific survival rates for 350 mastectomies and 196 breast conserving surgery cases followed-up for 15 years (Chen *et al.* 2006). All patients were free of invasive disease at clinical presentation. Breast cancer-specific survival was not significantly different for the two treatment modalities (mastectomy, 94% [95% CI 88%-96%]; breast conserving surgery, 92% [95% CI 84%-96%], *P* not significant, log rank test). There is no visible pattern in the rate of breast cancer-specific survival following mastectomy compared to breast conserving surgery in the remaining studies reporting this outcome (Figure 4, a).

No study provided an analysis of overall survival, comparing mastectomy with breast conserving surgery, and the data are inadequate to indicate any difference in rates of survival arising from mastectomy or breast conserving surgery at respective follow-up periods (5-year, 10-year etc; Figure 4, b).

(a) Breast cancer-specific survival (BSS) and Recurrence-free survival

(b) Overall survival

Figure 4: Studies reporting estimated (actuarial) survival rates grouped by intervention

## Cosmesis and patient quality of life

### Cosmesis

Very few data were identified for cosmesis as an outcome measure. One small, retrospective case series study found that in 31 patients treated with predominantly complete excision of the nipple-areolar complex, cosmetic outcomes were assessed by the treating radiation oncologist as 'excellent' or 'good' in 90% of the series (Marshall *et al.* 2003).

Cosmesis was assessed in one study only (Marshall *et al.* 2003). The treating radiation oncologist assessed cosmesis in 31 patients. These were rated as: Excellent, 10 (32%; 4 patients underwent nipple reconstruction); Good, 18 (58%); Fair, 3 (10%).

#### Quality of life

No data was identified for quality of life, based on assessment with a specific instrument, as an outcome in patients treated for Paget's disease by mastectomy or breast conserving surgery.

No study evaluated quality of life using a specific assessment instrument. However post-operative complications relevant to patient quality of life were reported for 3 patients including protracted chest wall pain, chronic breast infection and radiation dermatitis (Marshall *et al.* 2003). Complications were assessed in 32 patients, of whom 29 (91%) had no long-term complications. Post-operative complications relevant to patient quality of life were reported for 3 patients including protracted chest wall pain, chronic breast infection and radiation dermatitis (Marshall *et al.* 2003).

#### Further Details

A retrospective case series study compared survival rates between women with Paget's disease of the breast treated by mastectomy or breast conserving surgery (BCS) (Chen *et al.* 2006). From 1704 patients with Paget's disease 546 included for study had no evidence of underlying invasive cancer and had undergone surgery. Of these 350 (64%) received mastectomy and 196 (36%) received BCS of varying types including partial mastectomy, lumpectomy, quadrantectomy, wedge resection, nipple resection and excisional biopsy. Estimated 15-year breast cancer-specific survival (Kaplan-Meier method) for mastectomy was 94% (95% CI 88%-96%) and 92% (95% CI 84%-96%) for BCS. Estimated 15-year breast cancer-specific survival by disease status was 94% (95% CI 89-97) for Paget's disease with DCIS and 88% (95% CI 77%-94%) for Paget's disease alone.

A retrospective case series study compared crude rates of local/regional disease recurrence, distant metastases, and disease specific deaths in 105 patients with histologically confirmed Paget's disease of the nipple treated either by mastectomy (n=74) or breast conserving surgery (BCS) (n=31) (Sutton *et al.* 1999). Patients were identified from a larger cohort treated within the years 1975-1997. Of these, 71/105 (68%) had no evidence of underlying invasive disease distributed between the 2 treatment intervention groups; 47/74 (64%) of mastectomy and 24/31 (77%) of BCS patients. Breast conserving surgery comprised wide local excision plus a wedge of underlying breast tissue. 14/31 BCS patients received post-operative radiotherapy (RT). Median follow-up was 7 years (mastectomy group) or 5 years (BCS group). Crude local and distant recurrence rates, and breast cancer-specific death rate following mastectomy were 5.4%, 5.4% and 12.2%, respectively and 6.5%, 3.2% and 0%, respectively following BCS. Recurrence and death rates were further stratified by presence or absence of palpable tumour at presentation (28% of mastectomy patients and 2% of BCS patients). Local or distant recurrence, and disease-specific death rates respectively were: (i) for mastectomy patients with no palpable mass; 1.9%, 5.7% and 9.4%, respectively; (ii) for BCS patients with no palpable

mass; 6.9%, 3.4% and 0%; (iii) for mastectomy patients with a palpable mass; 14.3%, 4.8% and 19%; and (iv) for BCS patients with a palpable mass; 0% throughout. Data presented were based on small subgroups and no statistical testing of the data was reported.

A prospective case series study assessed the feasibility of combined breast conserving surgery and radio-therapy for Paget's disease in 61 patients who had no associated invasive breast cancer (Bijker *et al.* 2001). All patients underwent cone excision of the nipple-areolar complex and subareolar breast tissue followed by 50 Gy X-rays in 25 fractions (no boost). Patients were followed-up for local recurrence (Kaplan-Meier method), distant disease recurrence, and breast cancer-specific deaths (median follow-up 6.4 years). At 5 years the estimated local recurrence rate was 5.2% (95% CI 1.8%-14.1%). Crude local and distant recurrence rates and disease-specific death rate were; 6.6%, 1.6% and 1.6%, respectively. The study group was carefully selected in terms of their suitability for breast conserving surgery, the majority of patients having no evidence of DCIS on preoperative mammography.

A prospective case series study reported comparative data on disease-specific and recurrence-free survival in 104 patients with Paget's disease of the nipple treated either by mastectomy (88%) or breast conserving surgery (BCS) (12%) within the years 1949-1993 (Kawase *et al.* 2005). 40% of patients had no invasive breast cancer of whom 15% had Paget's disease alone and 85% with associated DCIS). All patients treated by BCS and 20% of mastectomy patients received radiotherapy post-operatively. Kaplan-Meier estimated 10-year disease-specific survival and recurrence-free survival rates in patients with stage 0 (non-invasive disease) were 92% (95% CI 80%-100%) and 90% (95% CI 78%-100%), respectively. For the entire series disease-specific survival was 79% (95% CI 70%-88%) following mastectomy and 67% (95% CI 13%-100%) following breast conserving surgery ( $P=0.697$ , log rank test). Recurrence-free survival was 75% (95% CI 66%-84%) (mastectomy) and 61% (95% CI 10%-100%) (BCS) ( $P=0.953$ , log rank test).

A retrospective series of 37 cases of Paget's disease of the nipple treated by mastectomy (97%) or quadrantectomy (3%) reported survival rates over 150 months for patients with or without an associated palpable mass (Yim *et al.* 1997). 46% of patients presented with no associated palpable mass. Kaplan-Meier estimated overall survival rates at 5 years by presence/absence of a palpable mass were 41% (present) and 72% (absent). 10-year survival rates were 41% (present) and 58% (absent). There was a significant difference in overall survival between patients with or without a palpable mass on presentation ( $P<0.05$ , F test).

A retrospective case series reported survival data for 31 patients with Paget's disease of the nipple without an associated palpable mammary tumour who were treated by mastectomy between 1960 and 1984 (Campana *et al.* 1987). Estimated 5-year overall survival (Kaplan-Meier method) was 87% (median follow-up 7.5 years). 22 of the 31 patients (71%) in this series were confirmed as having no invasive disease on presentation.

A retrospective case series reviewed pathology and post-operative disease-related events for 35 women with biopsy-proven Paget's disease of the nipple treated between 1974 and 1984 (Chaudary *et al.* 1986). Of the 35 patients, 14 (41%) had Paget's disease with DCIS but no invasive disease. 32/35 (91%) of patients were treated by mastectomy, 2 by radiotherapy alone and 1 received no treatment. The crude survival rate (mean follow-up

48 months) for the series was 83% (29/35) and 86% (12/14) for patients with Paget's disease and associated DCIS.

A retrospective case series compared post-operative recurrence and survival for 48 patients with Paget's disease of the nipple who had no underlying palpable tumour and treated with either mastectomy or breast conserving surgery (Dixon *et al.* 1991). 39 patients (81%) who received surgery had no invasive component to their disease. 37 (77%) patients underwent mastectomy while 10 (21%) received breast-conserving wide local excision of the nipple-areolar complex including cone excision of underlying breast tissue. Patients were followed-up for a median 40 months post-mastectomy, or 56 months post-breast conserving surgery (BCS). Crude local/regional recurrence rates were 5.4% following mastectomy and 40% after BCS. Crude distant metastasis rates for the two groups were 0% and 10%, respectively and crude death rates were 0% and 10%, respectively.

A retrospective series of 28 histologically confirmed cases of Paget's disease of the nipple compared crude rates of recurrence and breast cancer-specific survival after mastectomy or breast conserving surgery (Duff *et al.* 1998). Patients were treated between 1983 and 1996 and followed-up over a mean period of 35 months. 12 (43%) patients had no associated invasive cancer and 12 (43%) patients had an associated palpable mass. 25 (89%) patients elected to undergo mastectomy, 1 received breast conserving surgery and 2 had no surgery. The crude recurrence rate was 25% for all patients, 50% for those with a palpable mass, and 6% with no palpable mass. The crude survival rate was 86% (all patients), 67% (palpable mass), and 100% (no palpable mass).

A small retrospective series of 13 cases of Paget's disease of the Breast, treated between 1990 and 1995, reported crude local recurrence data following surgical treatment (Estabrook *et al.* 1996). No patients had associated palpable masses or lymphadenopathy although 1 patient was recorded as having an associated invasive ductal breast carcinoma. Thus 12/13 (92%) of cases met the population criteria for this topic. All patients received breast conserving surgery (local excision) with 5 (38%) receiving post-operative radiotherapy. Crude local recurrence at a mean follow-up of 17.8 months was 2/13 (15.4 %); both being reported as ipsilateral recurrences.

A small retrospective case series reported crude 5-year and 10-year overall survival rates for patients with histologically proven Paget's disease of the breast treated during the period 1949 to 1972 (Freund *et al.* 1977). Of 29 patients 19 (66%) had no associated palpable lump and thus met the population criteria for this topic. 3/29 patients were reported to have no nipple abnormalities but had a breast tumour. 25/29 patients elected for mastectomy (21 radical Halstead's procedure, 4 simple mastectomy), and 4 received only radiotherapy due to the advanced stage of their cancer. 27 patients were available for follow-up. Overall survival at 5 years for the full cohort was 74%, falling to 69% at 10 years. When stratified by the presence/absence of a palpable mass there was a statistically significant improvement in survival for patients with no associated palpable mass at presentation; 40% (present) vs. 94% (absent) at 5 years; and 33% (present) vs. 91% (absent) at 10 years ( $P < 0.001$ , Fisher exact test).

A retrospective case series studying 17 patients with Paget's disease of the nipple (identified from a cohort of 78 patients with *in situ* breast carcinoma) treated between 1973 and 1985 reported post-operative recurrence and survival data over a mean follow-up period of 65 months (Howard *et al.* 1989). Nine patients (53%) elected to have simple mastectomy the remaining 8 having breast-conserving cone excision surgery. Crude rates

of local recurrence for the two treatment groups were 0% (mastectomy) and 37.5% (cone excision); Crude rates of distant metastases were 0% and 12.5%, respectively; and crude disease-specific survival rates were 100% and 12.5% respectively. No data on tumour palpability or invasive disease was provided.

A retrospective case series of 68 patients with Paget's disease of the nipple treated between 1963 and 1996 reported comparative data on survival rates for patients who elected for mastectomy or breast conserving surgery (lumpectomy or nipple excision/biopsy) (Kollmorgen *et al.* 1998). 25 patients (45%) had no associated invasive cancer on presentation. 58 patients underwent mastectomy and 10 had BCS and were followed-up for a median 61 months. The 5-year estimated survival rates (Kaplan-Meier method) were; 58% (entire series, n = 68), 35% (patients with a palpable mass at diagnosis, n = 30), and 75% (patient with no palpable mass, n = 38). Median survival for patients with palpable tumours was statistically significantly shorter than for those without (126 months;  $P=0.007$ , log rank test). Data was not reported for survival specific to histological evidence of invasive disease at diagnosis.

A retrospective study of 70 cases of histologically confirmed Paget's disease of the nipple treated between the years 1971 and 1999 reported survival data for patients who elected for treatment by mastectomy (Kothari *et al.* 2002). 23 patients (33%) presented with clinically apparent invasive disease and 15 (21%) presented with focal nodularity. 30 patients (43%) were reported as having no invasive disease, 29 of these having Paget's disease with associated DCIS. 2 patients were unfit for mastectomy and were therefore treated by local excision surgery. Estimated overall survival at 5 years (Kaplan-Meier method) for patients with DCIS (n = 29) was 92%. Although the number of patients with Paget's disease and DCIS who underwent mastectomy was not reported, that only 2/70 had conservative surgery indicates that between 93-100% would have received mastectomy.

A retrospective case series reported long-term follow-up of patients with Paget's disease of the breast without a palpable or mammographically identified mass and treated with combined breast conserving surgery and radiotherapy between 1980 and 2000 (Marshall *et al.* 2003). Of 36 patients with histologically proven Paget's disease 2 were classified as having associated invasive or microinvasive breast cancer, and therefore 34 (94%) met the population criteria for this topic. All patients received breast conserving surgery, either: complete excision of the nipple areolar complex (25/36); partial excision (9/36); or biopsy alone (2/36). All patients received post-operative radiotherapy of 50 Gy and boost radiation to the tumour bed in the majority of cases. Actuarial 5, 10 and 15 year local recurrence rates were reported in two ways; (i) as only site of first recurrence: 5 years = 9% [95% CI 0%-20%]; 10 years = 13% [95% CI 1%-25%]; 15 years = 13% [95% CI 1%-25%]; and (ii) as a component of all recurrences (i.e. includes regional and distant metastasis): 5 years = 9% [95% CI 0%-20%]; 10 years = 17% [95% CI 3%-31%]; 15 years = 24% [95% CI 6%-42%]. Disease-free survival at a median follow-up of 9 years was 89 (32/36 patients). This included patients with successfully treated recurrences. 2/4 patient deaths were not breast cancer-specific. Actuarial disease-specific and overall survival data were reported at 5, 10 and 15 years: (i) cause-specific survival (scores only breast cancer deaths as events): 5 years = 97% [95% CI 90%-100%]; 10 years = 97% [95% CI 90%-100%]; 15 years = 97% [95% CI 90%-100%]; and (ii) overall survival: 5 years = 93% [95% CI 84%-100%]; 10 years = 90% [95% CI 78%-100%]; 15 years = 90% [95% CI 78%-100%]. Cosmesis was assessed in 31 patients by the treating radiation oncologist: Excellent = 10 (32%; 4 patients underwent nipple reconstruction); Good = 18 (58%); Fair = 3 (10%). Complications were assessed in 32 patients, of whom 29 (91%) had no long-

term complications. Post-operative complications relevant to patient quality of life were reported for 3 patients including protracted chest wall pain, chronic breast infection and radiation dermatitis.

A retrospective case series study reported local recurrence rates and overall survival rates for patients with Paget's disease of the breast treated between 1973 and 1994 (Nicolosi *et al.* 1996). Of 38 patients included in the study, 16 (42%) had no histological evidence of invasive breast cancer and therefore met the population criteria for this topic. The majority of patients (32/38, 84%) underwent mastectomy, 4 (11%) elected for breast conserving surgery, and 2 (5%) received primary radiotherapy alone. Median follow-up was not reported but 5-year and 10-year actuarial overall survival of 100% was reported for patients with no invasive disease on presentation. Crude rates of local recurrence for the whole series were 9.4% (3/32) following mastectomy, and 25% (1/4) following breast conserving surgery.

A retrospective case series study of patients with Paget's disease of the nipple with no invasive disease and treated during the period 1980-1996 investigated the rate of local recurrence following cone excision breast conserving surgery (Polgar *et al.* 2002). Of 33 patients 30 (91%) had no palpable mass and in 30 evidence of limited DCIS was reported. No patients had invasive disease. All patients underwent breast conserving surgery (cone excision alone). Patient follow-up was for a median 6 years. The crude local recurrence rate was 33.3% (11/33) with 10/11 recurrences manifesting as invasive disease. This was compared with data from Bijker (Bijker *et al.* 2001) who reported a crude local recurrence rate of 6.6% ( $P=0.0012$ , Fisher exact test). Again comparing their data with that of Bijker *et al.*, The 5-year estimated local recurrence rates were 28.4% (this study) vs. 5.2% (Bijker). For distant recurrence the rates were 18.2% (this study) vs. 1.6% (Bijker) ( $P=0.007$ ). Actuarial cancer-specific deaths were 18.2% (this study) vs. 1.6% (Bijker) ( $P=0.007$ ).

A retrospective case series study of 31 patients for Paget's disease of the breast treated between 1986 and 1997 reported survival rates following mastectomy (Sheen-Chen *et al.* 2001). Fifteen patients (48%) had histological evidence of invasive disease, the remainder having either Paget's disease alone (4 = 13%) or co-presenting with DCIS (12 = 39%). Therefore 16/31 (52%) of patients met the population criteria for this topic. No palpable underlying tumour was found in 19 (61%) of patients. Each patient underwent mastectomy and was followed-up for a mean duration of 58 month. Estimated 5-year overall survival rates (Kaplan-Meier method) were: (i) 69% for all patients; and (ii) by tumour palpability: 19% (present) vs. 94% (absent) ( $P<0.01$ , log rank test). Patients with no palpable underlying tumours had significantly higher incidences of underlying non-invasive breast cancer than those with underlying palpable masses (73% vs. 8%,  $P<0.01$ , Chi square test).

A retrospective case series study of 35 patients with Paget's disease of the breast, identified from a larger cohort of 2261 breast cancer patients surgically-treated between 1989 and 1995 reported data on crude local and distant recurrence and survival rates following either radical mastectomy or breast conserving surgery (Stanislawek *et al.* 2002). Of 35 patients 28 (80%) had underlying intraductal breast cancer not classified as invasive, the remaining 8 patients (20%) having an underlying invasive cancer. Twenty nine patients (83%) elected for radical mastectomy and 6 (17%) had breast conserving surgery (type(s) not specified). Follow-up intervals were not reported for local recurrence, however, crude local recurrence rates by clinical presentation were reported: 1/28 (3.6%) for patients with no preoperative invasive disease, and 4/7 (57%) for patients with

infiltrating disease. Similarly, lymph node metastatic recurrence was reported: 0/29 (no invasive disease) and 4/7 (57%) (with invasive disease). No recurrence data were reported by intervention type. Crude 5-year survival rates by clinical presentation were reported but not defined as either disease-free, disease-specific or overall. Survival for patients with no preoperative invasive disease was 90%, and for patients with infiltrating disease survival was 49%.

A retrospective case series study of patients with Paget's disease of the breast treated between 1975 and 1989 reported follow-up recurrence and death rate data following either mastectomy or breast-conserving wide local excision surgery (Zurrida *et al.* 1993). Ten patients were reported as having involved focal areas of underlying nipple ducts but whether these were invasive disease was not specified. The remaining 39 (76%) patients had no associated invasive breast cancer. Pre-operative biopsy was used to confirm the presence of Paget's disease in 27/27 instances. Mastectomy was performed on 18/49 (37%) patients and wide local excision on 31 (63%), two of whom received post-operative radiotherapy. Patients were followed-up for a median 60 months. Crude rates of locally invasive cancer were 0/18 following mastectomy and 9/31 (29%) following wide local excision, one of the latter recurring in a patient who had received post-operative RT. Crude rates of death due to breast cancer were 0/18 following mastectomy and 2/31 (6.5%) following wide local excision.

## Evidence Tables

Retrospective comparative study

Chen, Sun & Anderson . Paget disease of the breast: Changing patterns of incidence, clinical presentation, and treatment in the U.S. *Cancer* 107[7], 1448-1458. 2006.

### Design

Design: Retrospective comparative study (therapy), evidence level: 3  
Country: USA, setting: Secondary care

### Inclusion criteria

1704 women with Paget's disease of the nipple registered on the US Surveillance, Epidemiology and End Results (SEER) database in the period January 1988 - December 2002.

Distribution of histology:

Paget's disease + invasive ductal: 859 (50.4%)

Paget's disease + DCIS: 618 (36.3%)

Paget's disease alone: 227 (13.3%)

### Exclusion criteria

Men with Paget's disease;

Patients with a history of any type of previous cancer;

Cases of Paget's disease of the nipple with underlying tumour other than ductal carcinoma (e.g. lobular carcinoma) since these cases were registered according to the underlying tumour and were not recorded as Paget's;

Cases of Paget's disease alone or Paget's disease with DCIS presenting with positive lymph nodes i.e. biologically questionable (n=34).

### Population

number of patients = 845, median age = 64 years.

### Interventions

Aim: to compare retrospectively survival between women with Paget's disease treated by mastectomy compared to women with Paget's disease treated by breast conserving surgery.

Of 845 patients with Paget's disease and no underlying invasive disease 546 (64.6%) were recorded as undergoing surgery:

Mastectomy: 350 (64%)

Breast conserving surgery: 196 (36%)

### Outcomes

15-year breast cancer-specific survival (Kaplan-Meier method)

### Follow up

Median not reported; study reports 15-year breast cancer-specific survival.

**Results**

Estimated 15-year breast cancer-specific survival:  
Paget's disease + DCIS: 94% [95% CI 89%-97%]  
Paget's disease alone: 88% [95% CI 77%-94%]

Estimated 15-year breast cancer-specific survival in patients with Paget's disease and no underlying invasive cancer by surgery performed:  
Mastectomy: 94% [95% CI 88%-96%]  
Breast conserving surgery: 92% [95% CI 84%-96%]  
(p value not significant; log rank test)

**General comments**

A total of 845 patients represent the population of this question (for survival data), of whom 546 were recorded as undergoing surgery (for comparison of mastectomy versus breast conserving surgery).

'Breast conserving surgery' refers to a wide variety of procedures and includes nipple excisional biopsy: partial (less than total) mastectomy (including segmental mastectomy, lumpectomy, quadrantectomy, tylectomy, wedge resection, nipple resection, excisional biopsy and partial mastectomy).

Sutton, Singh, Baker & Sacks . Is mastectomy overtreatment for Paget's disease of the nipple? Breast 8[4], 191-194. 1999.

### **Design**

Design: Retrospective comparative study (therapy), evidence level: 3  
Country: UK, setting: Secondary care

### **Inclusion criteria**

105 patients with histologically proven Paget's disease of the nipple, identified from a larger series treated within the years 1975-1997 (see exclusion criteria).

No. patients with a history of previous breast cancer:

Mastectomy group: 5 (6.8%)

Breast conserving surgery group: 3 (9.7%)

Presence of palpable lump:

Mastectomy group: 21 (28%)

Breast conserving surgery group: 2 (6.5%)

Presence of mammographic abnormality:

Mastectomy group: 40 (54%)

Breast conserving surgery group: 11 (36%)

Underlying pathology:

Mastectomy group:

DCIS: 46 (62%)

Invasive carcinoma: 27 (36%)

No histological abnormality: 1 (1%)

Wide local excision group:

DCIS: 22 (71%)

Invasive carcinoma: 7 (23%)

No histological abnormality: 2 (6%)

Therefore in this series, 71/105 = 68% of all patients had no histological evidence of underlying invasive disease.

### **Exclusion criteria**

Men: 5

No surgical treatment: 6

Metastatic disease at presentation: 10

Medical records untraceable: 14

Occurrence of Paget's after previous mastectomy: 6

Total: 41

### **Population**

number of patients = 105, age range 24 to 94 years, median age = 57 years.

### **Interventions**

Two groups were defined retrospectively according to surgical treatment:

Mastectomy group (n=74).

Breast conserving surgery group (n=31): underwent wide local excision plus excision of a wedge of underlying breast tissue. 14 patients in this group underwent RT in addition.

### **Outcomes**

Crude rates of:

Breast recurrence;

Distant metastasis;

Breast cancer-related deaths [presented by subgroup according to tumour palpability]

### **Follow up**

Mastectomy group: median 7 years (4 patients lost to follow-up)

Breast conserving surgery group: median 5 years (range 6 months-10 years)

### **Results**

Incomplete excision:

In the breast conserving surgery group, 4/31 = 13% of tumours were incompletely excised on histological analysis, and were treated with RT.

Results for entire series (n=105)

1. Rate of breast recurrence

Mastectomy group: 4/74 = 5.4%

Breast conserving surgery group: 2/31 = 6.5%

2. Rate of distant metastasis

Mastectomy group: 4/74 = 5.4%

Breast conserving surgery group: 1/31 = 3.2%

3. Rate of breast cancer related deaths

Mastectomy group: 9/74 = 12.2 %

Breast conserving surgery group: 0/31 = 0%

Results for patients without a palpable tumour at presentation:

1. Rate of breast recurrence

Mastectomy group (median follow-up 7 years): 1/53 = 1.9%

Breast conserving surgery group (median follow-up 5 years): 2/29 = 6.9%

2. Rate of distant metastasis

Mastectomy group: 3/53 = 5.7%

Breast conserving surgery group: 1/29 = 3.4%

3. Rate of breast cancer related deaths

Mastectomy group: 5/53 = 9.4%

Breast conserving surgery group: 0/29 = 0%

Results for patients with a palpable tumour at presentation:

1. Rate of breast recurrence

Mastectomy group (median follow-up 5 years): 3/21 = 14.3%

Breast conserving surgery group (median follow-up 5 years): 0/2 = 0%

2. Rate of distant metastasis

Mastectomy group: 1/21 = 4.8%

Breast conserving surgery group:  $0/2 = 0\%$

3. Rate of breast cancer related deaths

Mastectomy group:  $4/21 = 19.0\%$

Breast conserving surgery group:  $0/2 = 0\%$

### **General comments**

All cases of Paget's disease were confirmed histologically by incision biopsy or scrape cytology of the nipple.

$71/105 = 68\%$  of all patients in this series represent the population specified for this question;  $32\%$  had invasive underlying disease revealed by definitive histology.

Crude rates of disease-related events reported are based on small subgroups. No evidence of statistical testing of differences between groups is provided.

Choice to perform mastectomy or breast conserving surgery (plus or minus RT) was not part of the study design and is likely to have depended heavily on prognostic information; a greater proportion of patients treated with mastectomy had palpable tumours and mammographic abnormalities than those treated by breast conserving surgery.

## Prospective case series

Bijker, Rutgers, Duchateau, Peterse, Julien, Cataliotti & EORTC Breast Cancer Cooperative Group. Breast-conserving therapy for Paget disease of the nipple: a prospective European Organization for Research and Treatment of Cancer study of 61 patients. *Cancer* 91[3], 472-477. 2001.

### **Design**

Design: Prospective case series (therapy), evidence level: 3  
Country: Europe, setting: Secondary care

### **Inclusion criteria**

61 Women with histologically proven Paget's disease of the nipple and no invasive breast cancer:

Palpable mass present : 2 (3%)

Palpable mass absent: 59 (97%)

Histology:

Paget's without DCIS: 4 (7%)

Paget's with DCIS: 57 (93%)

### **Exclusion criteria**

Evidence of invasive breast cancer;

DCIS extending >5cm from the nipple;

Involved margin following surgery;

Age > 75 years;

Pregnancy;

Previous or concomitant malignancy (except treated basal cell carcinoma of the skin or carcinoma in situ of the cervix);

Mental illness or other condition precluding long-term follow-up.

### **Population**

number of patients = 61, age range 31 to 74 years, median age = 58 years.

### **Interventions**

Aim: to assess the feasibility of breast conserving surgery plus RT in patients with Paget's disease of the nipple without associated invasive breast cancer.

All patients underwent:

Surgery: cone excision of the skin with the nipple-areolar complex and subareolar breast tissue (no axillary surgery).

RT: 50Gy to the whole breast in 25 fractions (no boost).

### **Outcomes**

Time to local recurrence (Kaplan-Meier method);

Distant metastasis;

Death due to breast cancer.

### **Follow up**

Median follow-up period: 6.4 years.

Protocol: clinical examination at 1 month, 3 months postoperatively, then 3 monthly for 3 years, 6 monthly until the 10th postoperative year, and annually thereafter.

Patients also received bilateral mammography 6 weeks postoperatively and annually thereafter.

### **Results**

4 of 61 patients developed local recurrence (1 case of recurrent DCIS and 3 cases of recurrent invasive disease).

1 patient developed distant metastasis and died.

2 patients died of other causes than breast cancer.

At 5 years follow-up the estimated local recurrence rate (Kaplan-Meier) was 5.2% [95% CI 1.8%-14.1%].

### **General comments**

Study group is carefully selected to be suitable for breast conserving surgery: extent of DCIS is limited and the majority of patients had no evidence of DCIS on preoperative bilateral mammography.

Surgical specimens were reviewed histologically for exclusion criteria based on tumour size and margin.

Median interval from nipple biopsy to surgery: 22 days (range 0-212 days).

Median interval from surgery to RT: 41 days (range 17-140 days).

Kawase, Dimaio, Tucker, Buchholz, Ross, Feig, Kuerer, Meric-Bernstam, Babiera, Ames, Singletary & Hunt . Paget's disease of the breast: there is a role for breast-conserving therapy. *Ann Surg Oncol* 12[5], 391-397. 2005.

### **Design**

Design: Prospective case series (therapy), evidence level: 3  
Country: USA, setting: Secondary care

### **Inclusion criteria**

104 patients treated with surgery for Paget's disease of the nipple between the years 1949 and 1993.

#### Distribution of histology:

Invasive ductal:	43 (41%)
DCIS:	34 (33%)
Unspecified adenocarcinoma:	19 (18%)
Invasive lobular:	1 (1%)
Paget's alone:	7 (7%)

#### Distribution of stage:

Stage 0:	41 (39%)
Stage I:	23 (22%)
Stage II:	40 (38%).

#### Presence/absence of palpable mass:

Present:	36 (35%)
Absent:	68 (65%)

#### Diagnostic mammography was performed in 81 patients; results:

Normal mammography:	21 (26%)
Abnormality on mammography:	60 (74%)

### **Exclusion criteria**

Patients with involvement of the nipple as part of locally advanced (Stage III) breast cancer (n=9)

### **Population**

number of patients = 104, age range 24 to 90 years, median age = 57 years.

### **Interventions**

Aim: to analyse survival and prognostic factors in patients with Paget's disease of the nipple.

#### Patients underwent surgery as follows:

Mastectomy:	92 (88.5%)
Breast conserving surgery):	12 (11.5%) (minimally, complete excision of the nipple-areolar complex)

30 patients received RT, including all patients treated primarily with breast

conserving surgery.

### **Outcomes**

Estimated 10-year disease-specific and recurrence-free survival (Kaplan-Meier method).

### **Follow up**

Median 7 years (range 10 months to 29 years).

### **Results**

Estimated 10-year disease-specific survival in patients with stage 0 (non-invasive) disease: 92% [95% CI 80%-100%]

Estimated 10-year recurrence-free survival in patients with stage 0 (non-invasive) disease: 90% [95% CI 78%-100%]

For the whole series of patients (including the 61% with underlying invasive disease), 10-year disease-specific survival by type of surgery performed was as follows:

Mastectomy: 79% [95% CI 70%-88%]  
Breast conserving surgery: 67% [95% CI 13%-100%]  
p=0.697, Log rank test.

For the whole series of patients (including the 61% with underlying invasive disease), 10-year recurrence-free survival by type of surgery performed was as follows:

Mastectomy: 75% [95% CI 66%-84%]  
Breast conserving surgery: 61% [95% CI 10%-100%]  
p=0.953, Log rank test.

### **General comments**

Discounting the cases of 'unspecified adenocarcinoma', 41 patients represent the population specified for this question (39% of the series). From data in the paper, these 41 patients appear to be those referred to in survival analyses as 'stage 0'.

Segmental mastectomy classed as breast conserving surgery.

Compared to mastectomy, fewer patients underwent breast conserving surgery; study may be underpowered to detect differences in survival arising from surgical procedure.

Retrospective case series

Yim, Wick, Philpott, Norton & Doherty . Underlying pathology in mammary Paget's disease. Ann Surg Oncol 4[4], 287-292. 1997.

### **Design**

Design: Retrospective case series (therapy), evidence level:  
Country: USA, setting: Secondary care

### **Inclusion criteria**

37 patients with histologically proven Paget's disease of the nipple treated within the years 1979-1995.

Presence/absence of invasive tumour by definitive histology:

Present: 20 (54%)  
Absent: 17 (46%)

Presence/absence of palpable mass:

Present: 20 (54%)  
Absent: 17 (46%)

### **Exclusion criteria**

1 patient who underwent local resection of the nipple, with no assessment of underlying histology.

### **Population**

number of patients = 37, age range 28 to 88 years, median age = 63 years.

### **Interventions**

Aim: to report on pathology and survival in patients treated for Paget's disease of the nipple.

Patients underwent surgery as follows:

Mastectomy: 36 (97%)  
Quadrantectomy: 1 (3%)

### **Outcomes**

Estimated overall survival (Kaplan-Meier method) by subgroup according to presence/absence of a palpable tumour.

### **Follow up**

No median or mean reported. Range (from Kaplan-Meier curves) 0-150 months.

### **Results**

Estimated 5-year overall survival by presence/absence of a palpable tumour:

Present: 41%  
Absent: 72%

Estimated 10-year overall survival by presence/absence of a palpable tumour:

Present: 41%  
Absent: 58%

Over a follow-up period of 150 months, patients with no palpable tumour had statistically significantly better overall survival than patients with a palpable tumour ( $p < 0.05$ , F test).

**General comments**

46% of patients in this series represent the population of patients specified for this question.

Campana, Vielh, Fourquet, Schlienger, Jullien, Durand, Salmon & Vilcoq . [Paget's disease of the nipple without any associated mammary tumor clinically or radiologically detectable. Apropos of 51 cases treated at the Curie Institute]. [French]. J Gynecol Obstet Biol.Reprod.(Paris) 16[8], 1069-1073. 1987.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: , setting: Secondary care

### **Inclusion criteria**

31 patients with Paget's disease of the nipple and no palpable or mammographic mass, treated with mastectomy between 1960 and 1984.

#### Histology:

Paget's disease alone:	1 (3%)
Paget's + DCIS:	21 (68%)
Paget's + DCIS + microinvasion:	9 (29%)

### **Exclusion criteria**

Study presents data for 20 further patients (total series size 51) treated with RT alone (17 cases) or breast conserving surgery plus RT (3 cases): not cited here.

### **Population**

number of patients = 31, age range 40 to 90 years, median age = 58 years.

### **Interventions**

Aim: to report on treatment and survival for 51 patients with Paget's disease of the nipple.

31 patients underwent mastectomy as primary treatment.

### **Outcomes**

Estimated overall survival (Kaplan-Meier method).

### **Follow up**

Median 7.5 years.

### **Results**

Estimated 5-year overall survival in patients treated by mastectomy: 87%.

### **General comments**

Of the 31 patients, 22 (71%) had no invasive disease and represent the population specified for this question.

Paper written in French; data cited are mostly from English abstract. In the main text, 'carcinome intracanalair' is assumed to represent DCIS, since patients with 'micro-infiltrants' are described separately.

Chaudary, Millis, Lane & Miller . Paget's disease of the nipple: a ten year review including clinical, pathological, and immunohistochemical findings. Breast Cancer Research & Treatment 8[2], 139-146. 1986.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: UK, setting: Secondary care

### **Inclusion criteria**

35 women with biopsy-proven Paget's disease of the nipple treated between 1974 and 1984.

Histology of the underlying breast tissue was available for 34 of 35 patients:

Paget's + pure DCIS: 14 (41%)  
Paget's + DCIS + invasion: 20 (59%)

### **Exclusion criteria**

Patients with Paget's disease as an incidental histological finding after mastectomy, but with no clinically apparent Paget's disease,

### **Population**

, age range 31 to 88 years, mean age = 56 years.

### **Interventions**

Aim: to review pathology and outcomes in a series of 35 patients with biopsy-proven Paget's disease of the nipple.

Patients received treatment as follows:

Mastectomy: 32 (91%)  
RT alone: 2 (6%)  
No treatment: 1 (3%)

### **Outcomes**

Disease-related events.

### **Follow up**

Mean 48 months (range 1-98 months).

### **Results**

Crude rate of mortality due to breast cancer:

All patients:  $6/35 = 17\%$   
Patients with Paget's disease + pure DCIS:  $2/14 = 14\%$   
(2 deaths due to breast cancer in this latter subgroup followed mastectomy)

### **General comments**

14 patients (41% of the series) had no evidence of underlying invasive disease and represent the population specified for this question.

1 patient received no radical treatment owing to general poor health.

All patients received either nipple biopsy or biopsy of the palpable breast lump, if present.

Study provides a very small amount of useful data for this question and results are highly susceptible to the effects of small sample size.

Dixon, Galea, Ellis, Elston & Blamey . Paget's disease of the nipple. Br J Surg 78[6], 722-723. 1991.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: UK, setting: Secondary care

### **Inclusion criteria**

48 patients with Paget's disease of the nipple no palpable underlying tumour, who were treated between the years 1973 and 1989.

#### Histology:

DCIS + invasive component: 8 (17%)

DCIS: 37 (79%)

No tumour: 2 (4%)

(1 patient received no surgery)

Pre-operative mammography was performed in 37 patients with results as follows:

Suspicious: 21 (57%)

Normal: 13 (35%)

Not reported: 3 (8%)

### **Exclusion criteria**

Patients with Paget's disease in association with a palpable tumour.

### **Population**

number of patients = 48, age range 35 to 85 years, median age = 62 years.

### **Interventions**

Mastectomy: 37 (77%)

Wide local excision of nipple/areolar complex including a cone of underlying breast tissue: 10 (21%)

No surgery (tamoxifen alone) 1 (2%)

### **Outcomes**

Incidence of disease related events.

### **Follow up**

For patients treated by mastectomy: median 40 months (range 7-124 months);

For patients treated by breast conserving surgery: median 56 months (range 18-96 months).

### **Results**

Crude rate of local-regional recurrence (breast or axilla):

Following mastectomy:  $2/37 = 5.4\%$

Following breast conserving surgery:  $4/10 = 40\%$

Crude rate of distant metastasis:

Following mastectomy:  $0/37 = 0\%$   
Following breast conserving surgery:  $1/10 = 10\%$

Crude rate of death due to breast cancer:  
Following mastectomy:  $0/37 = 0\%$   
Following breast conserving surgery:  $1/10 = 10\%$

**General comments**

Of 48 patients in the series, 39 (81%) represent the population specified in the question, of which 38 underwent surgery.

Results are subject to the effects of small sample size and in particular, low event rates.

Duff, Hill, Shering, Nugent, Kennedy, McDermot & O'Higgins . Paget's disease of the nipple - A 14 year experience. Ir.Med J 91[4], 131-132. 1998.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Ireland, setting: Secondary care

### **Inclusion criteria**

29 patients with histologically confirmed Paget's disease of the nipple treated between the years 1983-1996.

#### Histology:

Paget's disease alone:	4 (14%)
Paget's + DCIS:	8 (28%)
Paget's + LCIS:	1 (4%)
Paget's + invasive:	15 (54%)

#### Presence/absence of palpable mass:

Present:	12 (43%)
Absent:	16 (57%)

### **Exclusion criteria**

1 patient who received treatment at a different centre.

### **Population**

number of patients = 28, age range 30 to 74 years, mean age = 54 years.

### **Interventions**

Aim: to report on presentation, treatment and outcomes for a series of patients treated for Paget's disease of the nipple.

#### Patients underwent surgery as follows:

Mastectomy:	25 (89%)
Breast conserving surgery:	1 (4%)
No surgery:	2 (7%)

### **Outcomes**

Disease-related events.

### **Follow up**

Mean 35 months (range 7-134 months).

### **Results**

#### Crude rate of recurrence (any anatomical site):

All patients:	7/28 = 25%
Palpable mass:	6/12 = 50%
No palpable mass:	1/16 = 6%

#### Crude rate of deaths due to breast cancer:

All patients:	4/28 = 14%
---------------	------------

Palpable mass: 4/12 = 33%

No palpable mass: 0/16 = 0%

**General comments**

A total of 12 patients represent the population specified for this question (i.e. non-invasive disease, discounting 1 case of LCIS; 43% of the series). All 12 patients were treated with mastectomy.

2 patients underwent no surgery due to detection of disseminated disease at diagnosis. It is unclear whether these patients occur within the 6 cases of recurrent disease or 4 cases of mortality that were reported during the follow-up period.

Results reported are highly susceptible to the effect of small sample size.

Estabrook, Banerjee, Hibshoosh, Hans, Schnabel, Krementz & Kinne .  
Conservative management of Paget's disease of the breast. Breast Cancer  
Research & Treatment 37[Suppl], 43. 1996.

**Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria**

Patients with Paget's disease of the breast with no associated palpable breast  
lump or lymphadenopathy, treated between 1990 and 1995.

Paget's disease + focal intraductal breast Ca: 6/13 (46%)

Paget's disease + multifocal intraductal Ca: 6/13 (46%)

Paget's disease + invasive ductal Ca: 1/13 (8%)

**Exclusion criteria**

None specified.

**Population**

number of patients = 13, age range 45 to 87 years, mean age = 71 years.

**Interventions**

Breast conserving surgery (local excision): 8/13 (62%)

Breast conserving surgery (local excision) + Radiotherapy: 5/13 (38%)

**Outcomes**

Local disease recurrence rate.

**Follow up**

Mean 17.8 months (range 3-48 months)

**Results**

Crude local recurrence rate 15.4% (2/13) - 1 invasive ductal, 1 invasive  
lobular, both ipsilateral.

**General comments**

Poster session abstract: small retrospective comparative case series with a  
short mean follow-up period, 12/13 (92%) cases match the population criteria  
for this topic.

Freund, Maydovnik, Laufer & Durst . Paget's disease of the breast. J Surg Oncol 9[1], 93-98. 1977.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Israel, setting: Secondary care

### **Inclusion criteria**

Women with histologically proven Paget's disease of the breast, treated during the period 1949 and 1972.

Nipple changes only 19/29 (66%)  
Nipple changes + palpable lump 7/29 (24%)  
Breast tumour only 3/29 (10%)

### **Exclusion criteria**

None specified

### **Population**

number of patients = 29, age range 30 to 75 years, mean age = 54 years.

### **Interventions**

Mastectomy: radical (classical Halsted) 21/29 (72%); simple 4/29 (14%)

RT only: 4/29 (due to advanced disease)

### **Outcomes**

Crude overall survival rate at 5 years and 10 years

### **Follow up**

Up to 10 years for 27 available patients

### **Results**

Crude overall survival:

	n=	5 years (%)	10 years (%)
No palpable mass	17	94	91
Palpable mass	10	40	33
Total	27	74	69

Significant difference in survival rates between patients with or without a palpable mass at presentation ( $P < 0.01$ , Fisher exact test).

### **General comments**

Small retrospective case series comparing survival rates between Paget's disease patients presenting with or without a palpable lump. Three patients had no nipple reported changes. The results are highly susceptible to the effects of a small sample size.

The authors also present tabulated 5 and 10 year survival data from previous studies of surgical interventions for Paget's disease from 1954 to 1970.

Howard, Locker, Dowle, Ellis, Elston & Blamey . In situ carcinoma of the breast. Eur J Surg Oncol 15[4], 328-332. 1989.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: UK, setting: Secondary care

### **Inclusion criteria**

17 Patients with Paget's disease of the nipple, identified retrospectively within a larger series of 78 patients with only in situ disease, treated between 1973 and 1985.

Mammography was performed in 8/17 patients with Paget's disease, with result as follows:

Indicative of DCIS: 4/8 = 50%

No abnormality: 4/8 = 50%

### **Exclusion criteria**

Patients with invasive tumour revealed by histology.

### **Population**

number of patients = 17, age range 28 to 81 years, mean age = 54 years.

### **Interventions**

Aim: to review histological factors, method of treatment and outcomes in a series of patients treated for in situ breast cancer, including 17 patients with Paget's disease of the nipple.

17 patients with Paget's disease were treated with surgery as follows:

Simple mastectomy: 9 (53%)

Cone excision: 8 (47%)

### **Outcomes**

Disease related events

### **Follow up**

In the larger series: mean 65 months (range 18-144 months).

2 patients were lost to follow-up.

### **Results**

Crude rate of local recurrence:

Following mastectomy: 0/9 = 0%

Following cone excision: 3/8 = 37.5%

Crude rate of distant metastases:

Following mastectomy: 0/9 = 0%

Following cone excision: 1/8 = 12.5%

Crude rate of deaths due to breast cancer:

Following mastectomy:  $0/9 = 0\%$

Following cone excision:  $1/8 = 12.5\%$

**General comments**

Tumour palpability is not reported for patients with Paget's disease.

Results are highly susceptible to the effects of small sample size and low event rates.

Kollmorgen, Varanasi, Edge & Carson . Paget's disease of the breast: a 33-year experience. J Am Coll.Surg 187[2], 171-177. 1998.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: USA, setting: Secondary care

### **Inclusion criteria**

68 patients diagnosed with Paget's disease of the nipple between January 1963 and June 1996:

Underlying tumour histology:

Invasive breast cancer:	25 (45%)
DCIS plus invasion:	6 (10%)
DCIS alone:	24 (43%)
Unknown:	1 (2%)

No. (%) of cases with palpable mass at time of diagnosis:

Present: 30 (44%)

Absent: 38 (56%)

Mammograms were available for 27/38 = 71% of patients without palpable tumours. Of these 27 patients 17 had normal mammograms and 10 showed mammographic abnormality.

### **Exclusion criteria**

None reported.

### **Population**

number of patients = 68, age range 23 to 85 years, median age = 57 years.

### **Interventions**

Aim: To review retrospectively survival in patients treated for Paget's disease of the nipple.

Patients received surgery as follows:

58 (85%) patients underwent mastectomy;

5 (7%) patients underwent lumpectomy;

5 (7%) patients underwent nipple excision/biopsy alone.

### **Outcomes**

Overall survival (Kaplan-Meier method).

### **Follow up**

Median 61 months (range 2-288 months).

### **Results**

5-year estimated survival rates:

Whole series (n=68): 58%

Patients with palpable tumours at diagnosis (n=30): 35%

Patients without palpable tumours at diagnosis (n=38): 75%.

The median survival for patients with palpable tumours (42 months) was statistically significantly shorter than for patients without palpable tumours (126 months;  $p=0.007$ , log rank test).

In the 10 patients treated with breast conserving surgery (5) or biopsy (5), 2 recurrences and 2 deaths occurred at a median follow-up of 71 months.

### **General comments**

Study reports on an additional 12 patients in whom Paget's disease was an incidental histological finding after mastectomy; data not cited here. Therefore original series size was 80 patients.

Study does not report mammographic data for patients with palpable breast tumours at the time of diagnosis.

5 (7%) patients underwent nipple excision/biopsy alone, which is likely to be a less extensive procedure than wide local excision.

In this series only 25 (45%) patients had no histological evidence of invasive disease and represent the population specified for this question. Survival data is not reported for this subgroup, therefore applicability to this question is limited.

Kothari, Beechey-Newman, Hamed, Fentiman, D'Arrigo, Hanby & Ryder .  
Paget disease of the nipple: a multifocal manifestation of higher-risk disease.  
Cancer 95[1], 1-7. 2002.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: United Kingdom, setting: Secondary care

### **Inclusion criteria**

70 patients with clinically apparent and histologically confirmed Paget's disease of the nipple treated between the years 1971-1999.

Of the 70 patients, 23 (33%) patients presented with a palpable mass with clinical stage:

T1: 30%

T2: 53%

T3: 17%

A further 15 (21%) patients presented with focal nodularity, therefore 38 (54%) patients had a breast abnormality in addition to signs of Paget's disease.

Of 55 patients with a mammogram available for the time of diagnosis results were:

No abnormality: 12 (22%)

Abnormality present: 43 (78%)

The diagnoses for the whole series of 70 patients were as follows:

Paget's disease with pure DCIS tumour: 29 (41.4%)

Paget's disease with invasive tumour: 40 (57.1%)

Paget's disease with no underlying tumour: 1 (1.4%)

### **Exclusion criteria**

Patients with Paget's disease that was an incidental histologic finding following mastectomy.

### **Population**

number of patients = 29, age range 29 to 88 years, median age = 56 years.

### **Interventions**

Aim: to examine pathologic tumour characteristics and overall survival in patients treated with mastectomy for Paget's disease of the nipple.

### **Outcomes**

Overall survival estimated by Kaplan-Meier method.

### **Follow up**

Median not reported. 5-year overall survival reported.

**Results**

Estimated overall survival at 5 years of patients with Paget's disease and DCIS was 92%.

**General comments**

Relevant information for this question is survival data for 29 patients with Paget's disease and DCIS.

The majority of patients in the larger series underwent mastectomy: 68/70 = 97%. 2 patients in the larger series underwent wide local excision since they were unfit for mastectomy.

Age data shown are for the larger series of 70 patients.

The proportion of patients with Paget's disease and DCIS who underwent mastectomy is not reported, however since only 2 patients in the larger series of 70 patients underwent wide local excision, the proportion with DCIS who received mastectomy must be between 93%-100%.

Marshall, Griffith, Haffty, Solin, Vicini, McCormick, Wazer, Recht & Pierce .  
Conservative management of Paget disease of the breast with radiotherapy:  
10- and 15-year results. Cancer 97[9], 2142-2149. 2003.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: United States, setting: Secondary care

### **Inclusion criteria**

36 patients with histologically proven Paget's disease of the breast without palpable or mammographic mass and treated with breast conserving surgery plus RT between the years 1980-2000.

Stage of disease (n cases):

TisN0M0, Stage 0: (33)

T1N0M0, Stage 1: (2; 1 pure DCIS, 1 microinvasive)

T2N0M0, Stage IIa: (1, i.e. invasive disease).

30 cases (83%) had an underlying breast malignancy.

### **Exclusion criteria**

Follow up period < 12 months (2 patients)

### **Population**

number of patients = 36, age range 33 to 79 years, median age = 51 years.

### **Interventions**

Aim: to report long term follow-up of patients with Paget's disease of the breast treated with breast conserving surgery and RT.

All patients underwent surgery as follows:

Complete excision of nipple-areolar complex in 25 cases (69%);

Partial excision in 9 cases (25%);

Biopsy alone in 2 cases (6%).

All patients received RT to the whole breast: median 50 Gy; the majority received a boost to the remaining nipple or tumour bed.

### **Outcomes**

Local recurrence

Cause-specific survival;

Overall survival.

[Analysis by Kaplan-Meier method, measured from the completion of RT]

### **Follow up**

Median 113 months (range 17-257 months).

### **Results**

Actuarial local recurrence rates:

1. As only site of first recurrence:

5 years: 9% [95% CI 0%-20%]  
10 years: 13% [95% CI 1%-25%]  
15 years: 13% [95% CI 1%-25%].

2. As a component of all recurrence (i.e. includes regional and distant metastasis):

5 years: 9% [95% CI 0%-20%]  
10 years: 17% [95% CI 3%-31%]  
15 years: 24% [95% CI 6%-42%].

Cosmesis:

Cosmesis was assessed in 31 patients by the treating radiation oncologist as follows:

Excellent: 10 (32%; 4 patients underwent nipple reconstruction)

Good: 18 (58%)

Fair: 3 (10%).

Complications were assessed in 32 patients, of whom 29 (91%) had no long-term complications. In 3 patients complications included protracted chest wall pain, chronic breast infection and radiation dermatitis.

Survival:

At a median follow-up of 9 years, 32 of 36 patients were alive with no evidence of disease (includes patients with successfully treated recurrence). 2 patients died of breast cancer and 2 died free of breast cancer.

Cause-specific survival (scores only breast cancer deaths as events):

5 years: 97% [95% CI 90%-100%]

10 years: 97% [95% CI 90%-100%]

15 years: 97% [95% CI 90%-100%]

Overall survival:

5 years: 93% [95% CI 84%-100%]

10 years: 90% [95% CI 78%-100%]

15 years: 90% [95% CI 78%-100%]

### **General comments**

Small, retrospective study with long follow-up.

Of 36 patients, two had invasive disease, therefore 94% of the series represent the specified population for this question.

9 patients had mammographic abnormality: nipple thickening or microcalcifications.

15 patients (42%) underwent axillary surgery; all of whom had no axillary disease.

Method of assessment of cosmesis is cited, but is not accessible in this paper; clinician assessment is arguably less relevant than patient assessment.

Nicolosi, Mallocci, Calo & Tarquini . Paget's disease of the breast. Chirurgia (Bucur.) 9[4], 325-329. 1996.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Italy, setting: Secondary care

### **Inclusion criteria**

38 female patients with Paget's disease, treated between 1973 and 1994.

Histology:

Paget's + invasive: 22

Paget's + DCIS: 7

Paget's alone: 9

### **Exclusion criteria**

Not known.

### **Population**

number of patients = 38, age range 34 to 88 years, median age = 60 years.

### **Interventions**

Aim: to report treatment and disease-related events in 38 patients treated for Paget's disease of the nipple.

Patients underwent treatment as follows:

Mastectomy: 32 (84%)

Breast conserving surgery: 4 (11%)

No surgery/primary RT: 2 (5%)

### **Outcomes**

Disease-related events;

Actuarial overall survival

### **Follow up**

Median not known; 5-year and 10-year actuarial survival reported.

### **Results**

Crude rates of local recurrence (whole series):

Following mastectomy:  $3/32 = 9.4\%$

Following breast conserving surgery:  $1/4 = 25\%$

Actuarial overall survival in patients with no evidence of invasive disease:

5-year: 100%

10 year: 100%

### **General comments**

16/38 = 42% of patients in this series represent the population specified for this question, although survival is reported for this subset.

Paper written in Italian: data cited are mostly from the abstract.

Polgar, Orosz, Kovacs & Fodor . Breast-conserving therapy for Paget disease of the nipple: a prospective European Organization for Research and Treatment of Cancer study of 61 patients<sup>145</sup>. Cancer 94[6], 1904-1905. 2002.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Hungary, setting: Secondary care

### **Inclusion criteria**

33 patients retrospectively identified as treated for Paget's disease of the nipple with limited DCIS between the years 1980-1996 by cone excision without RT.

The 33 patients were selected from a larger series of 62 patients with Paget's disease (see exclusion criteria).

30 patients had no palpable mass and a palpable mass was present in 3 patients.

In 30 patients DCIS was present and 3 patients had no evidence of DCIS.

### **Exclusion criteria**

29 patients with Paget's disease plus extensive DCIS (n=12) or Paget's disease plus invasive disease (n=17).

### **Population**

number of patients = 33, age range 35 to 80 years, median age = 65 years.

### **Interventions**

Aim: to examine the rate of local recurrence in patients treated for Paget's disease (and no invasive tumour) with cone excision alone.

All patients underwent cone excision alone.

### **Outcomes**

Local recurrence;  
Distant metastasis;  
Deaths due to breast cancer.

### **Follow up**

Median 6 years (range 2-14 years)

### **Results**

Local recurrence  
The crude rate of local recurrence was  $11/33 = 33.3\%$ .

In 10 of 11 recurrences the recurrent tumour was invasive disease.

The estimated (actuarial method) 5-year local recurrence rate was 28.4%.

The comparison with the series reported by Bijker et al. 2002 was as follows:

Crude local recurrence rate:

This series: 33.3%

Bijker et al. 6.6% ( $p=0.0012$ , Fisher exact test)

Estimated (actuarial) local recurrence rate:

This series: 28.4%

Bijker et al. 5.2%

Distant metastasis:

This series: 6 (18.2%)

Bijker et al. 1 (1.6%) ( $p=0.007$ )

Deaths due to breast cancer:

This series: 6 (18.2%)

Bijker et al. 1 (1.6%) ( $p=0.007$ )

### **General comments**

All 33 patients (100%) in this series represent the population specified for this question.

Threshold for 'extensive' DCIS (warranting mastectomy) as an exclusion criterion not reported.

Authors focus on a comparison between this series (treated with cone excision alone) and that of Bijker et al. 2001, who were treated with cone excision plus RT.

Whilst the comparison of this series with that of Bijker et al. 2002 is based on similar patient-disease variables (age, median follow-up time, histology and tumour palpability), the two groups represent two distinct, retrospectively defined groups, with possible further unknown differences.

Sheen-Chen, Chen, Chen, Eng, Sheen & Chou . Paget disease of the breast - An easily overlooked disease? J Surg Oncol 76[4], 261-265. 2001.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Taiwan, setting: Secondary care

### **Inclusion criteria**

31 patients with histologically confirmed Paget's disease treated between 1986 and 1997.

#### Histology:

Paget's disease + invasive cancer:	15 (48%)
Paget's disease +DCIS:	12 (39%)
Paget's disease alone:	4 (13%)

#### Presence/absence of palpable underlying tumour:

Present:	12 (39%)
Absent:	19 (61%)

### **Exclusion criteria**

None reported.

### **Population**

number of patients = 31, age range 25 to 72 years, mean age = 51 years.

### **Interventions**

Aim: to report survival rates of patients treated for Paget's disease of the nipple.

All patients underwent mastectomy.

### **Outcomes**

Overall survival (Kaplan-Meier method)

### **Follow up**

Mean 58 months (range 6-156 months).

### **Results**

Estimated 5-year overall survival:  
All patients: 69%

Estimated 5-year overall survival by subgroup for tumour palpability:

Palpable tumour present:	19%
Palpable tumour absent:	94%

( $p < 0.01$ , log rank test)

Proportion of patients with underlying pure DCIS by subgroup for tumour palpability (for 27 patients with an underlying tumour):

Palpable tumour present:	8%
--------------------------	----

Palpable tumour absent: 73%  
( $p < 0.01$ , Chi square test)

**General comments**

Of the whole series 16 patients (52%) represent the population specified for this question.

Stanislawek, Kurylcio & Krasuska . Surgical treatment in Paget's disease of the breast. *Annales Universitatis Mariae Curie-Sklodowska - Sectio d - Medicina* 57[1], 444-448. 2002.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Poland, setting: Secondary care

### **Inclusion criteria**

Identification of Paget's disease of the breast in a larger cohort of 2261 patients with breast cancer treated surgically in the interval 1989-1995

No statement on histopathological confirmation of disease

28/35 (80%) of patients had Paget's disease with underlying intraductal breast cancer (DCIS?)

7/35 (20%) had underlying invasive breast cancer

### **Exclusion criteria**

None stated

### **Population**

number of patients = 35, age range 42 to 71 years, mean age = 53 years.

### **Interventions**

Radical mastectomy 29/35 (83%)

Breast conserving surgery 6/35 (17%)

### **Outcomes**

Rates of local recurrence and lymph node metastasis (after ? years)

Crude 5-year survival

### **Follow up**

Not stated, data presented on 5-year survival

### **Results**

Crude local recurrence rate:

Paget's disease with intraductal (non-invasive) disease : 1/28 (3.6%)

Paget's disease with infiltration (invasive) disease: 4/7 (57%)

Crude lymph node metastatic recurrence rate:

Paget's disease with intraductal (non-invasive) disease: 0/28

Paget's disease with infiltration (invasive) disease: 4/7 (57%)

Crude survival at 5 years:

Paget's disease with intraductal disease (non-invasive): 90%

Paget's disease with infiltration (invasive) disease: 49%

### **General comments**

Retrospective case series of Paget's disease of the breast identified from a

large cohort of surgically-treated breast cancer patients.

Eighty percent of the patients had no underlying invasive disease and therefore met the inclusion criteria for this topic.

Recurrence and survival data are given only by clinical presentation and not by intervention. The follow-up interval for recurrence is not stated. Survival rates are presumed to be overall survival.

Results are highly susceptible to the effects of a small sample size.

Zurrída, Squicciarini, Bartoli, Rovini & Salvadori . Treatment for Paget's disease of the breast without an underlying mass lesion: An unresolved problem. Breast 2[4], 248-249. 1993.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Italy, setting: Secondary care

### **Inclusion criteria**

49 patients clinically diagnosed with Paget's disease between the years 1975 and 1989.

#### Pathology:

Paget's disease alone: 7 (14%)

Paget's plus DCIS: 32 (65%)

Paget's plus involvement of focal areas of breast and underlying nipple ducts: 10 (20%)

42 patients underwent a diagnostic mammography with results as follows:

Mammographic abnormality: 14 (34.2%)

Normal: 28 (68.3%)

### **Exclusion criteria**

None reported.

### **Population**

number of patients = 49, mean age = 60 years, median age = 62 years.

### **Interventions**

Aim: to report on disease-related events in a small series of patients with Paget's disease of the nipple.

Patients received surgery as follows:

Mastectomy: 18 (36.7%)

Wide local excision: 31 (63.3%)

2 patients treated with wide local excision received RT in addition.

### **Outcomes**

Local recurrence

Deaths due to breast cancer

### **Follow up**

Median 60 months (range 20-179 months).

2 patients were lost to follow-up.

### **Results**

Crude rates of locally recurrent invasive tumour:

Following mastectomy: 0/18 = 0%

Following wide local excision:  $9/31 = 29\%$

Of 31 patients who underwent wide local excision, 8 cases of recurrence occurred in the subset of 29 patients who did not receive RT and 1 case of recurrence occurred in the subset of 2 patients who received RT.

Crude rates of death due to breast cancer:

Following mastectomy:  $0/18 = 0\%$

Following wide local excision:  $2/31 = 6.5\%$

### **General comments**

Pre-operative biopsy was performed in 27 patients and confirmed Paget's disease histologically in all 27 cases.

Paper does not make clear whether 10 cases with definitive pathology of 'involvement of focal areas of breast and underlying nipple ducts' is invasive disease or in situ disease. However at least 39 cases (79% of the series) represent the population specified in the question.

Results are subject to the effects of small sample size and in particular, low event rates.

### **3.3 In patients with invasive breast cancer or DCIS when is sentinel lymph node biopsy justified as a staging procedure?**

#### **Short Summary - Invasive breast cancer SLNB versus axillary clearance or axillary sampling**

There is a large volume of evidence on SLNB both from randomised controlled trials (RCTs) and case series studies (Agarwal *et al.* 2005, Blanchard *et al.* 2003, BMJ Clinical Evidence 2005; Carlo *et al.* 2005, Clarke *et al.* 2004, Cody *et al.* 1999, Cox. *et al.* 2000, Cserni *et al.* 2002, Fleissig *et al.* 2006 Giuliano *et al.* 1997, Haid *et al.* 2002, Imoto *et al.* 2004, Julian *et al.* 2004, Katz *et al.* 2006, Kim *et al.* 2006, Kokke 2005, Krag *et al.* 2001 and 2007, Langer *et al.* 2004, Langer *et al.* 2005, Leidenius 2004, Lucci *et al.* 2007, Mansel *et al.* 2006, Naik *et al.* 2004, Purushotham *et al.* 2005, Reitsamer *et al.* 2004, Rietman *et al.* 2003, Ung *et al.* 2004, Veronesi *et al.* 2003 and 2006, Zavagno *et al.* 2005a and 2005b and 2008)

A well conducted systematic review and meta-analysis of 69 studies (of mixed study design) was undertaken by Kim, Giuliano & Lyman (2006) with data from over 8000 patients. The overall sentinel lymph node localisation rate was 96.4%; the pooled estimate of false negative rate was 7.0% and the mean proportion of patients with positive sentinel lymph nodes was 42% and the post test probability negative was 4.6%. From other studies, the sentinel lymph node localisation rate ranged from 81.4% to 100%, (mean 94.0% and median 94.9%) (Agarwal *et al.* 2005, Carlo *et al.* 2005, Clarke *et al.* 2004, Cody *et al.* 1999, Cox. *et al.* 2000, Cserni *et al.* 2002, Giuliano *et al.* 1997, Haid *et al.* 2002, Imoto *et al.* 2004, Julian *et al.* 2004, Krag *et al.* 2001, Langer *et al.* 2004, Langer *et al.* 2005, Naik *et al.* 2004, Reitsamer *et al.* 2004, Ung *et al.* 2004, Veronesi *et al.* 2003).

The false negative rate of SLNB ranges from 0% to 10.7% (mean 5.8%, median 5.9%) (Agarwal *et al.* 2005, Clarke *et al.* 2004, Cody *et al.* 1999, Cox *et al.* 2000, Cserni *et al.* 2002, Giuliano *et al.* 1997, Julian *et al.* 2004, Krag *et al.* 2001, Langer *et al.* 2004, Ung *et al.* 2004, Veronesi *et al.* 2003). The accuracy of SLNB ranges from 94.6% to 100%, (mean 97.7% with a median of 98.3%) (Agarwal *et al.* 2005, Clarke *et al.* 2004, Cody *et al.* 1999, Cserni *et al.* 2002, Giuliano *et al.* 1997, Krag *et al.* 2001, Langer *et al.* 2004, Ung *et al.* 2004, Veronesi *et al.* 2003, Cox *et al.* 2000.) The prevalence of axillary disease has a mean of 39.1%, median 35.4% and a range from 28.8% to 57.6% (Agarwal *et al.* 2005, Clarke *et al.* 2004, Cody *et al.* 1999, Cserni *et al.* 2002, Giuliano *et al.* 1997, Krag *et al.* 2001, Langer *et al.* 2004, Leidenius *et al.* 2004, Ung *et al.* 2004, Veronesi *et al.* 2003 and 2006, Cox *et al.* 2000.)

The evidence on morbidity, including lymphoedema, favours SLNB over axillary clearance. (Mansel *et al.* 2006 and Fleissig *et al.* 2006; Purushotham *et al.* 2005; Lucci *et al.* 2007, Zavagno *et al.* 2008). The ALMANAC RCT (reported by Mansel, 2006 and Fleissig 2006) and the RCT by Purushotham *et al.* (2005) found little evidence, by intention to treat, that a difference exists in psychological morbidity between patients treated by SLNB compared to axillary clearance.

The follow-up periods in the studies ranged from a mean of 24 months from surgery (Blanchard *et al.* 2003) to a median of 60 months by Carlo *et al.* (2005) and up to 78 months as reported by Veronesi *et al.* (2006). The extent of follow-up is therefore immature and results should be interpreted with caution, however, findings showed that patients treated by SLNB do not appear to have poorer rates of: disease free survival or

overall survival, or of axillary recurrence in the short term, compared to patients treated by axillary clearance.

The retrospective review conducted by Katz *et al.* (2006) of SLNB procedures in 1,133 patients, the majority of whom had invasive disease, identified the following factors as risk factors for involvement of the sentinel lymph node: younger age; mastectomy as definitive surgery; larger tumour size; invasive histology; and tumour lymphovascular invasion. In the same study in patients with involved sentinel lymph nodes, the following factors were found to be risk factors for further axillary node involvement revealed by axillary clearance: tumour lymphovascular invasion; higher number of positive sentinel lymph nodes; larger sentinel lymph node deposits; and lower number of uninvolved sentinel lymph nodes. A RCT by Lucci *et al.* 2007 reported that the use of SLNB plus ALND resulted in more wound infections, axillary seromas, and paresthesias than SLNB alone. Lymphoedema was more common after SLNB plus ALND but was significantly different only by subjective report. The use of SLNB alone resulted in fewer complications. Zavagno *et al.* (2008) reported that the analysis of the Psychological General Well Being Index questionnaire showed a statistically more positive outcome in the anxiety domain and in the general index for the sentinel lymph node group.

### **Axillary sampling as staging surgery**

In addition to SLNB, a literature search was performed to identify studies which evaluated axillary sampling as staging surgery in early breast cancer. 15 studies were identified: two RCTs: Chetty *et al.* 2000, Forrest *et al.* 1995 and 13 case series studies: Hadjiminas and Burke 1994, Rampaul *et al.* 2004, Tanaka *et al.* 2006, Thompson *et al.* 1995, Mathew *et al.* 2006, Sato *et al.* 2001; Ishikawa *et al.* 2005; Narredy *et al.* 2006; Macmillan *et al.* 2001; Hoar and Stonelake 2003, Gui *et al.* 2005; Cserni 1999, Kingsmore *et al.* 2003.

Staging performance: Staging data for axillary sampling were identified in five case series studies, most of which were very small in size. From these limited data, axillary sampling appears to have a median false negative rate of 3.6% (range 0%-6.5%) and a median accuracy of 98.5% (range 98%-100%). Although these values appear favourable to those of SLNB<sup>5</sup> they should be interpreted with caution due to the small volume of low quality evidence. However the studies present no evidence that axillary sampling is inferior to SLNB in terms of detecting axillary disease.

Physical morbidity: Evidence from one RCT is suggestive of reduced morbidity from axillary sample over axillary clearance or axillary sample plus radiotherapy, expressed as greater arm flexion at six months from surgery and smaller forearm circumference at three years from surgery. There were no other significant differences in morbidity outcomes, including upper arm circumference and other arm movements. Evidence from three observational studies comparing axillary sampling with axillary clearance favours axillary sample in terms of arm volume increase. Two of these studies suggest that radiotherapy, when used after axillary sampling in patients with disease positive nodes, has an adverse effect on shoulder mobility and arm volume.

---

<sup>5</sup> A meta-analysis by Kim, Giuliano & Lyman (2006) provided a pooled estimate of FNR for SLNB as 7.0% [95% CI 5.2%-8.8%]. In studies of SLNB reviewed for this guideline, the accuracy of SLNB had median 98.3% (range 94.6% to 100%), based on 10 series of patients (three series were within RCTs). The FNR of SLNB had median 5.9% (range 0% to 10.7%) based upon 11 series of patients (four series were within RCTs).

Recurrence and survival: Two RCTs comparing axillary sampling with axillary clearance found no significant difference in terms of survival or recurrence. One retrospective analysis of a large series of patients who were treated in the pre-SLNB era, concluded that survival is significantly improved if four or more nodes are sampled, compared to sampling fewer than four lymph nodes. This effect was demonstrated for patients with metastatic axillary lymph nodes and for patients with no detectable nodal metastases. A second observational study was suggestive of an inverse relationship between survival and the number of positive lymph nodes, with the best survival in patients with no detectable nodal disease.

### **Predictive factors for axillary metastases**

Evidence on the risk factors for axillary metastases in patients with early invasive breast cancer was identified in 16 retrospective analyses. Although some studies represented large series of patients, the retrospective design constitutes poor quality evidence (Anan *et al.* 2000; Barth *et al.* 1997; Brenin *et al.* 2001; Cao *et al.* 2005; Chen *et al.* 2002; Cutuli *et al.* 2001; Giuliano *et al.* 1996; Grube *et al.* 2002; Houvenaeghel *et al.* 2003; Katz *et al.* 2006; Peters-Engl *et al.* 2004; Rivadeneira *et al.* 2000; Specht *et al.* 2005; Tan, Tan *et al.* 2005; Tan, Wu *et al.* 2005; Velanovich and Szymanski 1998).

The overall risk of axillary metastases in each of 13 studies had a median value of 27%. The most commonly reported risk factors for axillary metastases in 12 studies that performed multivariate analyses were larger tumour size (11 studies) presence of lympho-vascular invasion (8 studies), higher histological grade (5 studies) and younger patient age (5 studies), although other risk factors were reported.

The poor quality evidence from these studies does not permit definition of a distinct patient group with risk factors that indicate avoidance of SLNB in favour of axillary clearance.

### **Short Summary - DCIS**

A limited volume of case series studies which address SLNB in patients with DCIS were identified. Ansari *et al.* (2008) conducted a meta-analysis (of observational studies) of the reported data on the incidence of sentinel lymph node metastasis in patients with DCIS. This analysis reported SLNB results in patients with the diagnosis of DCIS. The analysis showed the frequency of sentinel lymph node positivity in patients with a preoperative diagnosis of DCIS ranged from 0 to 16.7%. With an overall positivity incidence of 7.4%. Postoperative overall positivity incidence was 3.7%. The overall frequencies of nodal metastasis between the two groups (preoperative versus definitive diagnosis) were significantly different. Evidence on a subset of patients with a biopsy diagnosis of DCIS who were at high risk of an invasive component was reviewed and suggested that a palpable mass, a mammographic mass, a high-grade DCIS and a large size were associated with a significant risk of invasive disease in the final resection specimen.

In the other case series studies there was general consistency in differentiating between true DCIS, DCIS with microinvasion (DCIS<sub>m</sub>) and invasive disease, usually based upon the definition of DCIS<sub>m</sub> by the American Joint Committee on Cancer (i.e. invasive focus < 1mm in size on definitive histology). The overall rate of sentinel lymph node involvement for true DCIS was 1.8% (Veronesi *et al.* 2005) and 5% (Wilke *et al.* 2005). This evidence was drawn from observational studies which reported rates of detection of positive sentinel lymph nodes in patients with DCIS (with no detectable microinvasion) as 1.8% (Veronesi *et al.* 2005). The median value from 12 included observational studies was 5.4% (range 0% to 22%). Overall rate of sentinel lymph node involvement for DCIS<sub>m</sub> from an

observational study by Wilke *et al.* (2005) showed that the subgroup of patients with DCISm represented only 51 individuals. Among these, the rate of detection of positive sentinel lymph nodes was 14%. The median value from 7 included observational studies is 11.1% (range 9.5% to 29.4%). From all other 16 case series studies the summary statistics for the rate of sentinel lymph node involvement in patients with DCIS (which represent patients with only true DCIS, only DCISm, or either of DCIS/DCISm) were: mean 7.6%; median 6.8%, range 0% to 22%. (Camp *et al.* 2005; Cox *et al.* 1998; Cserni *et al.* 2002; Farkas *et al.* 2004; Intra *et al.* 2003; Katz *et al.* 2006; Kelly *et al.* 2003; Klauber-DeMore *et al.* 2000; Liu, Yang and Chen 2003; Mittendorf *et al.* 2005; Pendas *et al.* 2000; Trisal, Qian and Wagman 2004; Veronesi *et al.* 2005; Wilkie *et al.* 2005; Zavagno *et al.* 2005 and b; and Zavotsky *et al.* 1999).

There was no evidence to suggest that a pattern exists between the rate of positive sentinel lymph nodes and DCIS grade. There was no evidence to suggest that a pattern exists between the rate of positive sentinel lymph nodes and DCIS tumour size. It was not possible to reliably estimate the proportion of patients with DCIS and positive sentinel lymph nodes who have further axillary nodal involvement from the studies identified, because of small numbers of patients in the series.

None of the selected studies (all retrospective) reported changes to treatment plans as a result of staging by SLNB, and all studies were retrospective in nature. However five studies provided data on patients who were upstaged from the stage attributed by primary tumour biopsy, in the light of final, primary tumour histology from definitive surgery: a retrospective case series study (Wilkie *et al.* 2005) provides evidence that 10% of patients staged by biopsy as having DCIS (including DCISm) and who undergo SLNB are found to have invasive disease by primary tumour histology revealed by definitive surgery.

### **Invasive breast cancer SLNB versus axillary clearance or axillary sampling -**

#### **Evidence Summary**

There is a large volume of evidence on SLNB but the vast majority arises from numerous case series. Applicability to the UK is limited due to the variable techniques employed in different centres internationally.

A well conducted systematic review and meta-analysis of 69 studies (of mixed study design) was undertaken by Kim, Giuliano & Lyman (2006) with data from over 8000 patients. This study summarised the staging performance of SLNB as follows:

Overall SN localisation rate = 96.4%

Pooled estimate of FNR = 7.0% [95% CI 5.2%-8.8%, p<0.0001]  
 Mean proportion of patients with positive SNs = 42%

Post test probability negative = 4.6%.

An earlier, smaller systematic review of 12 studies was performed by Cox et al. (2000) but the results are not summarised here since there is apparently overlap with the superior review by Kim, Giuliano & Lyman (2006). Otherwise in our review of the literature, data on the staging performance of SLNB comes from 17 original series of patients as follows:

#### **Sentinel node localisation rate**

The SN localisation rate had range 81.4% to 100%, mean 94.0% and median 94.9%, based upon 17 series of patients (four series were within RCTs):

Agarwal et al. 2005, Carlo et al. 2005, Clarke et al. 2004, Cody et al. 1999, Cox. et al. 2000, Cserni et al. 2002, Giuliano et al. 1997, Haid et al. 2002, Imoto et al. 2004, Julian et al. 2004, Krag et al. 2001, Langer et al. 2004, Langer et al. 2005, Naik et al. 2004, Reitsamer et al. 2004, Ung et al. 2004, Veronesi et al. 2003.

#### **False negative rate**

The FNR of SLNB had range 0% to 10.7% (mean 5.8%, median 5.9%) based upon 11 series of patients (four series were within RCTs):

Agarwal et al. 2005, Clarke et al. 2004, Cody et al. 1999, Cox et al. 2000, Cserni et al. 2002, Giuliano et al. 1997, Julian et al. 2004, Krag et al. 2001, Langer et al. 2004, Ung et al. 2004, Veronesi et al. 2003

Of these 11 studies 10 used axillary clearance as the gold standard and one (Agarwal et al. 2005) used FNS as the gold standard.

#### **Accuracy**

The accuracy of SLNB had range 94.6% to 100%, mean 97.7% and median 98.3% based on 10 series of patients (three series were within RCTs):

Agarwal et al. 2005, Clarke et al. 2004, Cody et al. 1999, Cserni et al. 2002, Giuliano et al. 1997, Krag et al. 2001, Langer et al. 2004, Ung et al. 2004, Veronesi et al. 2003, Cox et al. 2000.

Of these 10 studies 9 used axillary clearance as the gold standard and one (Agarwal et al. 2005) used FNS as the gold standard.

### **Prevalence of axillary disease**

Prevalence of axillary disease had mean 39.1%, median 35.4% and range 28.8% to 57.6% based on 11 series of patients (three series were within RCTs):

Agarwal et al. 2005, Clarke et al. 2004, Cody et al. 1999, Cserni et al. 2002, Giuliano et al. 1997, Krag et al. 2001, Langer et al. 2004, Leidenius et al. 2004, Ung et al. 2004, Veronesi et al. 2003, Cox et al. 2000.

Of these 11 studies 10 used axillary clearance as the gold standard and one (Agarwal et al. 2005) used FNS as the gold standard.

### **Morbidity**

Three RCTs and five observational studies compared morbidity outcomes between SLNB and axillary clearance.

### **Physical Morbidity**

The majority of the evidence from 8 studies comparing physical morbidity, including lymphoedema, favours SLNB over axillary clearance. This was most effectively demonstrated by ITT analyses in two RCTs representing study situations where a proportion of patients randomised to SLNB actually underwent axillary clearance, which attenuates any advantage arising from SLNB (the ALMANAC RCT, reported by Mansel et al. 2006 and Fleissig et al. 2006 and a second RCT by Purushotham et al. 2005):

In Mansel et al. (2006) the ALMANAC trial demonstrated effects that were statistically significant and clinically important in favour of the SLNB arm for the trial outcome index (TOI) which was based on quality of life. Statistically significant effects in favour of SLNB were also demonstrated for arm sensory loss, lymphoedema, use of surgical drains and wound infection, at different time points up to one year post-surgery (RR of any lymphoedema in SLNB group compared to standard treatment group = 0.37 (95% CI 0.23-0.60). A significantly greater proportion of patients in the SLNB arm resumed normal activities within 3 months than did patients in the control arm. Fleissig (2006) demonstrated that patients in the SLNB group of the ALMANAC trial experienced statistically significantly better TOI at longer follow-up of 18 months from surgery. Older patients experienced statistically significantly better TOI than younger patients.

The RCT by Purushotham et al. (2005) also demonstrated significant advantages in favour of SLNB in the first year post-surgery in terms of physical morbidity: smaller mean increases in arm volume and lower odds of sensory loss in five different measurements were observed in the SLNB arm. Only one of five shoulder mobility outcomes were significantly better for the SLNB arm, with no significant differences detected in the remaining four by ITT.

Further evidence of less physical morbidity following SLNB compared to axillary clearance was provided (by non intention-to-treat (ITT) analysis) in the RCT by Veronesi et al. (2003) and also in observational studies by Haid et al. (2002), Blanchard et al. (2003), Langer et al. (2004) and Langer et al. (2005). These studies used a combination of subjective (mostly patient-reported) and objective measures and found that the effect in favour of SLNB was present from the short-term post-operative period, and was demonstrable at a mean follow-up period of 51 months (Langer et al. 2004). Only Rietman et al. (2003) found no significant difference in physical morbidity between SLNB and axillary clearance, at 6 weeks after surgery. Although not identified by the included studies, SLNB also carries a

risk of allergic reaction of 1.8% when blue dye is used (King 2004 cited by BMJ Clinical Evidence 2005b).

### **Psychological Morbidity**

The ALMAMAC RCT (reported by Mansel, 2006 and Fleissig 2006) and the RCT by Purushotham et al. (2005) found little evidence, by ITT, that a difference exists in psychological morbidity between patients treated by SLNB compared to axillary clearance.

Mansel et al. (2006) found no significant difference between groups for a measure of state anxiety at any follow-up point up to 12 months post-surgery and concluded that this demonstrated that patients who undergo SLNB do not experience increased anxiety due to concerns of residual cancer being 'left behind'. Fleissig (2006) demonstrated a similar result that in the same study group considering only patients with positive nodes between randomised groups (non ITT) and also that older patients experienced statistically significantly less anxiety than younger patients.

Purushotham et al. (2005) found few significant differences between groups for psychological outcomes: There was one significant difference in favour of SLNB for a measure of 'clinically significant morbidity', but this did not remain significant when adjusted for trait anxiety.

### **Recurrence and survival**

Twelve of the identified studies provide information on recurrence or survival after SLNB. The follow-up periods in the studies ranged from a mean of 24 months from surgery (Blanchard et al. 2003) to a median of 60 months by Carlo et al. (2005). The extent of follow-up is therefore immature although patients treated by SLNB do not appear to have poorer disease free or overall survival, or rates of axillary recurrence in the short term, compared to patients treated by axillary clearance.

### **Survival**

Only three studies (Veronesi et al. 2003, Carlo et al. 2005 and Imoto et al. 2004) performed analyses using an actuarial method i.e. one which considers the time it takes for patients to reach the endpoints of interest:

The RCT by Veronesi et al. (2003) found no significant difference in overall survival by ITT, between randomised groups (intervention: SLNB with axillary clearance only if positive, versus control: SLNB plus axillary clearance), at a median follow up of 46 months, indicating no survival disadvantage in patients treated by SLNB in its operational setting. In the intervention group 0.8% of patients died of breast cancer compared with 0.4% of the control group ( $p=0.15$ , log rank test).

The case-series study by Carlo et al. (2005) estimated 5-year disease-free survival in patients who successfully underwent SLNB, at 94% (95% CI 91% to 97%). This result was for two patient groups together:

- i) patients with positive sentinel nodes who underwent axillary clearance
- ii) patients with negative sentinel nodes who did not undergo axillary clearance

5-year disease-free survival was significantly longer in patients in the second group (96%), compared to the first (89%,  $p = 0.02$ , log rank test), illustrating the prognostic value of the disease status of the axilla. The case-series study by Imoto et al. (2004) found no significant difference in disease-free survival between patients with negative sentinel nodes who underwent axillary clearance and patients with negative sentinel nodes who did

not undergo axillary clearance. The proportions of patients alive at a median follow-up of 52 months groups were 94% and 93% respectively ( $p=0.78$ , log rank test).

### **Recurrence**

In the studies identified, axillary recurrence occurred with range 0% to 0.96% in patients with negative sentinel nodes who underwent no axillary clearance, with follow up periods ranging from 12 months (Mansel et al. 2006) to a median of 60 months (Carlo et al. 2005). These studies reported simple proportions of patients that had reached the event of interest and should be interpreted with caution due to the variability of follow-up periods.

In the ALMANAC RCT at 12 months from surgery 4 patients in the standard treatment group and 1 patient in the SLNB group experienced axillary recurrence (difference = 2.7%, 95% CI -1.5%-7.8%, Mansel et al. 2006).

In patients with positive sentinel nodes who received subsequent axillary clearance, axillary recurrence occurred with range 0% to 1.4%, with follow up periods ranging from median 31 months (Naik et al. 2004) to median 60 months (Carlo et al. 2005).

In patients with negative sentinel nodes who underwent axillary clearance in centres' validation periods, no axillary recurrences were reported with follow up ranging from a mean of 24 months (Blanchard et al. 2003) to a median of 52 months (Imoto et al. 2005).

Naik et al. (2004) demonstrated a higher proportion of patients with positive sentinel nodes who underwent no axillary clearance experiencing axillary recurrence (1.4%), than all other patients studied i.e. patients with positive sentinel nodes who underwent subsequent axillary clearance plus patients of with negative sentinel nodes, with or without subsequent axillary clearance (0.18%,  $p=0.013$ ).

### **Patient acceptability**

No studies were included that specifically address patient acceptability as an outcome measure.

### **Factors (identified prior to definitive surgery) that are associated with high risk of nodal metastases**

The retrospective review conducted by Katz et al. (2006) of SLNB procedures in 1133 patients, the majority of whom had invasive disease, identified the following factors as risk factors for involvement of the sentinel node: younger age; mastectomy as definitive surgery; larger tumour size; invasive histology; tumour lymphovascular invasion. In the same study in patients with involved sentinel nodes, the following factors were found to be risk factors for further axillary node involvement revealed by axillary clearance: tumour lymphovascular invasion; higher number of positive sentinel nodes; larger sentinel node deposits; lower number of uninvolved sentinel nodes.

### **Axillary sample as staging surgery**

An additional literature search was performed in addition to that for SLNB, on the MEDLINE and EMBASE databases. 15 studies were identified which evaluate axillary sample as staging surgery in patients with early breast cancer; 2 RCTs: Chetty et al. 2000, Forrest et al. 1995 and 13 case series studies: Hadjiminias and Burke 1994, Rampaul et al. 2004, Tanaka et al. 2006, Thompson et al. 1995, Mathew et al. 2006, Sato et al. 2001; Ishikawa et al. 2005; Narredy et al. 2006; Macmillan et al. 2001; Hoar and Stonelake 2003, Gui et al. 2005; Cserni 1999, Kingsmore et al. 2003.

Although all of the identified studies evaluate axillary sampling to stage the axilla, there is a high degree of inconsistency in the detail of the staging interventions (Table 1). Of the total of 15 studies, eight (including two RCTs) report on unguided axillary sample of four axillary nodes as the intended surgical procedure and two report on axillary sample of four nodes, guided by blue dye. In some studies there is an apparent blurring of the boundaries of axillary sample with SLNB (Hoar and Stonelake 2003, Gui et al. 2005).

Table 1. Consistency of axillary sample procedures

Staging intervention	Studies reporting
Unguided sample of a target/minimum of four axillary nodes, by palpation.	Chetty et al. 2000, Forrest et al. 1995, Hadjiminias and Burke 1994, Rampaul et al. 2004*, Tanaka et al. 2006, Thompson et al. 1995*, Mathew et al. 2006, Sato et al. 2001.
Dye assisted four node sample.	Ishikawa et al. 2005, Narredy et al. 2006.
Axillary clearance with retrospective analysis of the staging information provided by different numbers of nodes.	Cserni 1999, Kingsmore et al. 2003.
SLNB, extended to sample a minimum of four axillary nodes, using palpation.	Hoar and Stonelake 2003, Gui et al. 2005.
Unguided four node sample, but with preoperative injection of radiocolloid and analysis <i>ex vivo</i> of nodes identified as sentinel nodes.	Macmillan et al. 2001.

\* Staging technique appears to be unguided sample, but details of the method were not specified.

Since 10 of the 15 studies are of patients treated in the UK (including two RCTs), applicability to the UK should be reasonable, noting inconsistencies discussed above.

**Staging performance of axillary sample:** Five observational studies provided complete staging performance data for axillary sample, compared to axillary clearance as gold standard (Hoar & Stonelake 2003, Ishikawa et al. 2005, Narreddy et al. 2006, Tanaka et al. 2006 and Sato et al. 2001). In general the studies represent small series of patients. For this reason the study by Tanaka et al. 2006 stands out with the largest series size of 237 patients. In this study, unguided axillary sample of four palpable nodes had a false negative rate of 6.5% and an accuracy of 98.3%.

**False negative rate:** The false negative rate of axillary sample had mean 2.9%, median 3.6% and range 0%-6.5% (Hoar & Stonelake 2003, Ishikawa et al. 2005, Narreddy et al. 2006, Tanaka et al. 2006 and Sato et al. 2001). Two studies reported false negative rates of zero (Ishikawa et al. 2005 and Narreddy et al. 2006), but these represented small series of patients (32 patients and 17 patients, respectively).

**Accuracy:** The accuracy of axillary sample had mean 99%, median 98.5% and range 98%-100%. Similar to above, two studies with very small series of patients reported accuracy values of 100% (Ishikawa et al. 2005 and Narreddy et al. 2006).

**Prevalence of axillary disease:** Prevalence of axillary disease as determined by axillary clearance as gold standard had a mean of 43.2%, median 39.8% and range 26.2%-76.5% (Hoar & Stonelake 2003, Ishikawa et al. 2005, Narreddy et al. 2006, Tanaka et al. 2006, Macmillan et al. 2001 and Sato et al. 2001). The highest prevalence of 76.5% was reported by Narreddy et al. 2006, who studied a small, selected series of 17 patients with multifocal breast cancer.

**Other staging information:** The case series study by Gui et al. 2005 studied the staging performance SLNB (with radiocolloid plus, in some cases, blue dye) extended where necessary, to an axillary sample of a minimum of four nodes. The study found that sampling a minimum of four nodes did not reveal, after SLNB, any cases of further positive nodes.

The retrospective review of pathology slides by Cserni 1999 examined the staging information provided by sampling the largest three, four, five and six axillary nodes in patients who underwent axillary clearance. Considering all cases, concordance of staging information with the axillary clearance was as follows:

- 3 nodes: 94-96%
- 4 nodes: 97-98%
- 5 nodes: 98-99%
- 6 nodes: 99%

**Morbidity outcomes for axillary sample:** The RCT reported by Chetty et al. 2000 compared axillary sample versus axillary clearance. Six months following surgery, arm flexion was statistically significantly lower in patients who received axillary clearance ( $p=0.003$  ANCOVA) and in those who received axillary sample plus RT ( $p=0.004$ ) compared to those who underwent axillary sample alone. There were no differences between groups in power to flex the shoulder or abduction, at any time point. There was no significant difference in the upper arm circumference between the three groups. At three years from surgery the forearm circumference was significantly greater after axillary clearance than after node sample ( $p=0.005$ ) or node sample plus RT ( $p=0.04$ ).<sup>6</sup>

The prospective case series study by Thompson et al. 1995 studied arm morbidity up to twelve months after surgery following axillary sample or axillary clearance. A greater proportion (42%) of patients who underwent axillary clearance had an arm volume increase  $>200\text{ml}$ <sup>7</sup> compared to patients who underwent axillary sample (21%; difference 19%, 95% CI 1%-38%). RT was found independently to have a statistically significant adverse impact on shoulder mobility.

The prospective case series study by Hadjiminias and Burke 1994 measured the rate of lymphoedema at a median of 20 months following surgery. Lymphoedema was present in 14% of patients who underwent axillary sample followed by axillary clearance compared to 0% in patients who underwent axillary sample alone ( $p<0.02$ ).

---

<sup>6</sup> Morbidity outcomes were not analysed by intention to treat and although the forearm circumference difference is statistically significant, it is difficult to tell whether the difference is clinically important.

<sup>7</sup> Regarded by the authors as a threshold for clinically important arm morbidity.

Mathew et al. 2006 studied the incidence of lymphoedema in patients who underwent axillary sample (with RT in cases with metastatic nodes) compared to patients who underwent axillary clearance, using two retrospectively defined groups. Axillary clearance was associated with a higher incidence of lymphoedema than axillary sample (12% and 2% respectively,  $p=0.001$ ). This difference remained statistically significant when measured in node-negative patients only (removing the effect of RT), but statistical significance was lost when only node positive patients were analysed.

**Recurrence and survival data for axillary sample:** In the RCT of axillary sample versus axillary clearance after breast conserving surgery reported by Chetty et al. 2000, there was no statistically significant difference between randomised groups for overall survival or disease free survival at a median follow-up of 4.1 years. There was also no significant difference between randomised groups in the rate of axillary recurrence.

An earlier RCT reported by Forrest et al. 1995 compared axillary sample versus axillary clearance after mastectomy. At a median follow-up of 11 years there was no significant difference between groups for disease specific survival (Hazard ratio (HR) 1.11 in favour of axillary clearance; 95% CI 0.80-1.53), distant recurrence (HR 1.05 in favour of axillary clearance; 95% CI 0.74-1.5) or locoregional recurrence (HR 1.35 in favour of axillary sample; 95% CI 0.83-2.19).

Kingsmore et al. 2003 performed a retrospective analysis of a large series of patients who underwent axillary staging surgery in the pre-SLNB era, analysing survival against the number of axillary nodes examined. Patients who had examination of four or more axillary nodes had statistically significantly increased survival compared to patients who had 3 or less nodes examined, when node-negative patients were analysed (HR 1.34; 95% CI 1.09-1.65) and when node-positive patients were analysed (HR 1.20; 95% CI 1.02-1.41).

Rampaul et al. 2004 examined survival in a series of 852 patients who underwent axillary sample, with axillary RT given in cases with positive axillary nodes. At a median follow-up period of 7.5 years, axillary recurrence occurred at a rate of 0.66% per annum. Overall survival by the number of positive nodes was as follows:

- 0 nodes positive: 89%
- 1 nodes positive: 84%
- 2 nodes positive: 75%
- 3 nodes positive: 65%

### **Predictive factors for axillary metastases**

There is a large volume of evidence on SLNB in general. 97 studies that address risk factors for axillary metastases were identified from within the list of studies identified for SLNB. All of the selected studies are retrospective analyses, usually performed by interrogating databases of routinely collected clinical and pathological data. Some of the studies report on large patient samples. However the quality of these studies is generally poor due to their retrospective nature.

There is likely to be inconsistency amongst the studies for the definition of a metastatic axillary node; SLNB is more likely to involve serial sectioning of nodes than is axillary dissection. Immunohistochemistry histology techniques, where used, are likely to be more sensitive than standard techniques. Studies also vary in terms of their methods of analysis and also the variables that authors chose to explore, and how results are presented (e.g. by continuous/categorical variables). Despite this, half or more of the studies report larger

tumour size and presence of tumour lympho-vascular invasion to be significant risk factors for axillary metastasis.

Studies are also inconsistent in the magnitude of risk conveyed by any particular risk factor (see Table 2: OR for axillary metastases by tumour size; Peters-Engl et al. 5004 and Rivadeneira et al. 2000).

**Patient population:**

The patient samples represented in the retrospective studies varied in terms of tumour size. Several studies are restricted to patients with tumour sizes below a stated maximum, notably T1 tumours in five studies (Anan et al. 2000, Barth et al. 1997, Brenin et al. 2001, Giuliano et al. 1996 and Rivadeneira et al. 2000). Other studies aimed to report on entire treated series and accordingly, patients were analysed without tumour size restrictions. Specht et al. 2005 state no T size criteria, but that all patients had clinically palpable axillary nodes. Table 1 provides a description of each patient series in terms of tumour size and also the surgical staging method used. Grube et al. 2002 report only on patients with invasive lobular carcinoma. Tan, Wu et al. 2005 studied only patients with metastatic sentinel nodes, demonstrated by SLNB.

**Table 1 Tumour size and staging method**

Study	T criteria	Staging method
Anan et al. 2000	T1	AC
Barth et al. 1997	T1	AC
Brenin et al. 2001	T1	AC
Cao et al. 2005	T1-2 (25mm or less)	SLNB
Chen et al. 2002	T1-T2	SLNB
Cutuli et al. 2001	T0-2 (3cm or less)	AC
Giuliano et al. 1996	T1	AC
Grube et al. 2002	ILC (size range 0.3-9.0cm)	SLNB
Houvenaeghel et al. 2003	T0-2, 3cm or less	AC
Katz et al. 2006	T1-T3 (upper T limit unknown)	SLNB
Peters-Engl et al. 2004	Largest tumour 8cm in size	SLNB
Rivadeneira et al. 2000	T1a-T1b	AC
Specht et al. 2005	palp nodes, T size range not reported.	SLNB
Tan, Tan et al. 2005	T1-2	AC
Tan, Wu et al. 2005	T1-2, N1	SLNB
Velanovich and Szymanski 1998	T1-3	AC

SLNB: Sentinel lymph node biopsy

AC: Axillary clearance/dissection

**Risk of axillary metastases:**

13 studies reported a prevalence of axillary disease, revealed by staging surgery (Anan et al. 2000, Barth et al. 1997, Brenin et al. 2001, Cao et al. 2005, Chen et al. 2002, Cutuli et al. 2001, Giuliano et al. 1996, Grube et al. 2002, Houvenaeghel et al. 2003, Katz et al.

2006, Rivadeneira et al. 2000, Specht et al. 2005 and Tan, Tan et al. 2005). In these 13 studies, summary statistics for the prevalence of axillary disease are as follows:

Mean: 31.4%  
 Median: 27%  
 Range: 18%-59%

Specht et al. 2005 reported a prevalence of 59%, but in a series of selected patients with clinically palpable axillary nodes. Discounting this value, the summary statistics become:

Mean: 29.1%  
 Median: 27%  
 Range: 18%-50%

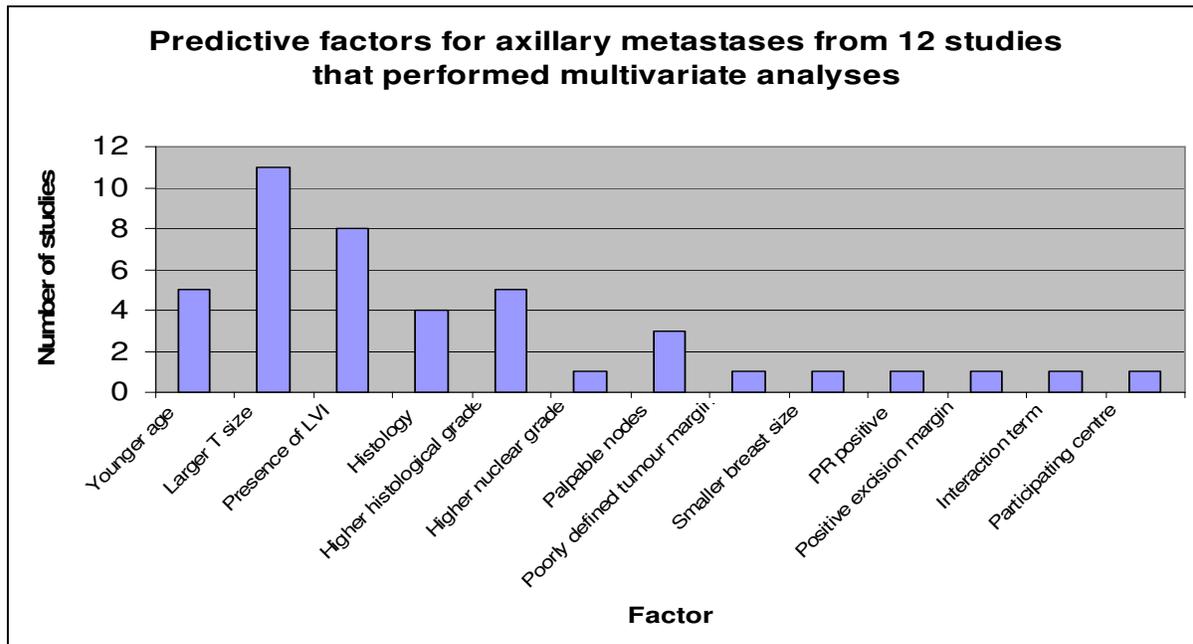

In either case, the mean and median values derived from these studies suggest that approximately 70% of patients who undergo surgical staging for early breast cancer have no axillary disease.

### Predictive factors for metastatic axillary nodes

#### 1. Studies that performed multivariate analysis

12 studies reported risk factors for the presence of any metastatic axillary nodes using multivariate analysis; that is, analysis which considers the action of each risk factor variable, independent of the action of other variables (Anan et al. 2000, Barth et al. 1997, Brenin et al. 2001, Cao et al. 2005, Chen et al. 2002, Cutuli et al. 2001, Houvenaeghel et al. 2003, Katz et al. 2006, Peters-Engl et al. 2004, Rivadeneira et al. 2000, Tan, Tan et al. 2005 and Velanovich and Szymanski 1998). The risk factors identified by multivariate analyses within these 12 studies are shown in Figure 1.

**Figure 1**

#### Tumour size

Larger tumour size was the most frequently identified (by 11 studies) risk factor for axillary metastasis. Odds ratios (OR) or relative risks (RR) for axillary metastasis by tumour size were reported as follows (Table 2):

**Table 2 Tumour size as a risk factor for axillary metastases**

Study	Measure	Value
Brenin et al. 2001	OR (T stage T1c>T1b>T1a)	2.9 [95% CI 1.9-4.3]
Cao et al. 2005	RR (for a 1mm increase in tumour size)	1.065 [95% CI 1.038-1.092]
Peters-Engl et al. 2004	OR (for a 1mm increase in tumour size)	1.06 [95% CI 1.05-1.08]
Rivadeneira et al. 2000	OR (for a 1mm increase in tumour size)	3.58 [95% CI 1.18-11.89]
Tan, Tan et al. 2005	OR (T1a relative to T2) OR (T1b relative to T2) OR (T1c relative to T2)	0.06 [95% CI 0.007-0.5] 0.18 [95% CI 0.065-0.49] 0.38 [95% CI 0.22-0.67]
Velanovich and Szymanski 1998	OR (no criterion reported)	1.5 [no 95% CI reported]

### Lympho-vascular invasion

Presence of lympho-vascular invasion (LVI) was the second most frequently identified (8 studies) risk factor. Odds ratios (OR) or relative risks (RR) for axillary metastasis by LVI status were reported as follows (Table 3):

**Table 3 LVI as a risk factor for axillary metastases**

Study	Measure	Value
Brenin et al. 2001	OR (present:absent)	2.6 [95% CI 1.8-3.64]
Cao et al. 2005	RR (present:absent)	9.8 [95% CI 5.46-17.86]
Tan, Tan et al. 2005	OR (present:absent)	7.7 [95% CI 3.5-17]

Higher histological grade and younger age were equally the third most frequently identified factors (5 studies in each case):

### Histological grade

Odds ratios (OR) for axillary metastasis by histological grade were reported as follows (Table 4):

**Table 4 Histological grade as a risk factor for axillary metastases**

Study	Measure	Value
Brenin et al. 2001	OR (Grade III>II>I)	1.6 [95% CI 1.2-2.1]
Peters-Engl et al. 2004	OR (Grade I:III)	0.55 [95%CI 0.32-0.81]
Rivadeneira et al. 2000	OR (Grade III:I)	2.45 [95% CI 1.27-4.68]

### Age

Odds ratios (OR) for axillary metastasis by age were reported as follows (Table 5):

**Table 5 Age as a risk factor for axillary metastases**

Study	Measure	Value
Peters-Engl et al. 2004	OR (for a 1 year increase in age)	0.98 [95% CI 0.97-0.99]
Rivadeneira et al. 2000	OR (>=50 years:<50 years)	0.61 [95% CI 0.37-1.02]

### Other risk factors

The remaining risk factors for axillary metastasis revealed by the studies included:

- Clinically palpable axillary lymph nodes: this risk factor was reported by three studies: Anan et al. 2000, Barth et al. 1997 and Peters-Engl et al. 2004; the latter study reported an OR (palpable:non-palpable) of 1.77 [95% CI 1.37-2.29].<sup>8</sup>
- Higher nuclear grade (Barth et al. 1997).
- Poorly defined tumour margin (Anan et al. 2000).
- Smaller breast size (Cutuli et al. 2001).
- Progesterone receptor (PR) positive tumour: Tan, Tan et al. 2005 reported OR (positive relative to negative): 1.8 [95% CI 1.0-3.0]
- Positive excision margin: Brenin et al. 2001 reported OR (present:absent) 23.8 [95% CI 5.6-101.2]
- Other factors: three other factors which warrant further explanation were also found to significantly influence the rate of axillary metastases; histological subtype, participating centre and an interaction term:

### Histological subtype

The role of tumour histological type is unclear, based on four studies that found tumour histological type to be significantly associated with axillary metastases:

- Katz et al. 2006 found histology to independently predict SN involvement, but with no discernable pattern between histological subtypes, except for the lowest rate of axillary involvement in patients with DCIS.
- Peters-Engl et al. 2004 found ducto-lobular histology to be predictive of axillary metastasis relative to ductal histology (OR 2.16 [95% CI 1.48-3.16], p=0.0001).
- Tan, Tan et al. 2005 found that 'other' histology tumours (i.e. other than invasive lobular or invasive ductal carcinomas) were predictive of axillary metastases relative to invasive ductal carcinomas (OR 0.26 [95% CI 0.09-0.72], p=0.04).
- Velanovich and Szymanski 1998 found that invasive lobular carcinoma to be strongly predictive of axillary metastases, and tubular or medullary carcinoma to have the opposite effect (OR relative to invasive ductal carcinoma >400000, p=0.02 and OR 0.000006, p=0.02, respectively).

### Participating centre

---

<sup>8</sup> The study by Specht et al. (2005) did not perform multivariate analysis but found that clinical palpation of the axilla had a positive predictive value (PPV) of 59% overall, and a PPV of 77% when only patients with unequivocally suspicious, palpable nodes were analysed.

The multicentre study by Peters-Engl et al. 2004 found that the rate of axillary metastases varied significantly by participating centre, of which there were 12, but with no clear pattern.

**Interaction term**

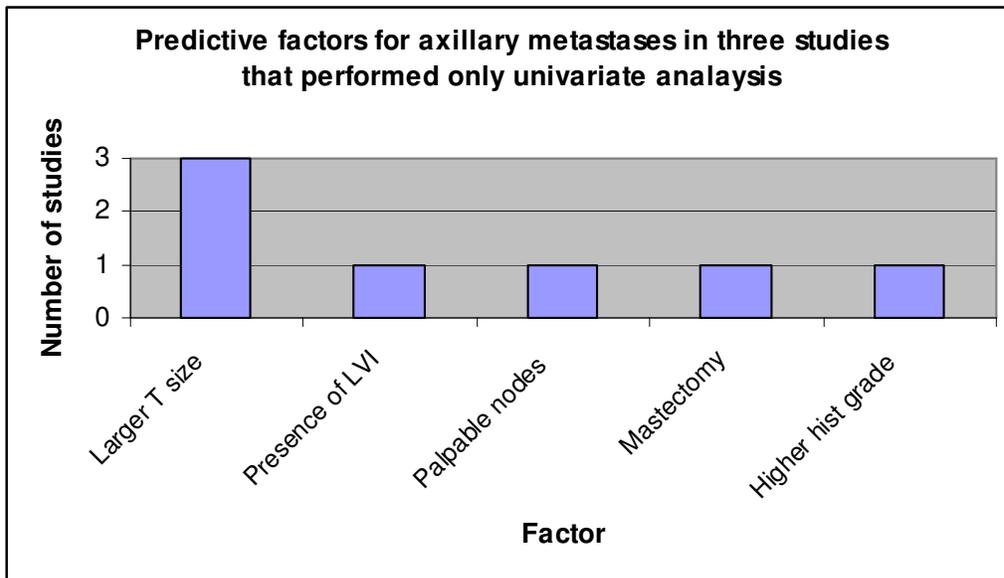

Brenin et al. 2001 modelled an interaction variable for the negative interaction between positive margin and T stage, with OR 0.34 [95% CI 0.2-0.6, p=0.0001]. This indicated that patients with positive margins had risks for axillary metastases largely unaffected by T stage, while increasing T stage conferred an increased risk for patients with negative margins.

**2. Studies that performed only univariate analysis**

Three studies (Giuliano et al. 1996, Grube et al. 2002 and Specht et al. 2005) reported risk factors for the presence of any metastatic axillary nodes using univariate analysis; that is, analysis which considers only one variable at a time. This analysis for risk factors has the disadvantage that the demonstrated effect of one variable will not take account of the effect of other variables which may also influence the outcome.

The risk factors identified by multivariate analyses within these three studies are shown in Figure 2.

**Figure 2**

Although the number of studies is small, larger tumour size remained the most frequently reported risk factor for axillary metastases (Giuliano et al. 1996, Grube et al. 2002 and Specht et al. 2005), with reported rates of axillary disease by tumour size as follows (Table 6):

**Table 6 Incidence of axillary metastases by T stage**

Study	Incidence of axillary disease by T stage
Giuliano et al. 1996	T1a: 10% T1b: 13% T1c: 30% (p<0.002)

Grube et al. 2002	pT1: 24% pT2: 59% pT3: 89% (p=0.001)
-------------------	--

Specht et al. 2005 found that in a series of patients with clinically palpable axillary nodes, mean tumour size was higher in patients with histologically positive axillary nodes compared to those with histologically negative axillary nodes (2.6cm and 1.6cm respectively, p=0.002).

Specht et al. 2005 also demonstrated in the same series that a higher proportion of patients with histologically positive axillary nodes had high grade tumours compared to those with histologically negative axillary nodes (77% and 43% respectively, p=0.002).

In addition to larger tumour size, Grube et al. 2002 found the presence of LVI, clinically palpable nodes and mastectomy surgery (as opposed to breast conserving surgery) to be factors significantly associated with axillary metastases.

### **Risk factors for macrometastatic sentinel nodes**

Tan, Wu et al. 2005 studied risk factors for sentinel node macrometastases (2mm or more in size) in a selected series of patients with metastatic axillary nodes revealed by SLNB. In univariate analysis, the statistically significant risk factors for sentinel node macrometastases were larger tumour size, tubular carcinoma, presence of LVI and two or more positive sentinel nodes.

### **Risk factors for multiple positive axillary nodes**

The study by Velanovich and Szymanski 1998 found, by multivariate analysis, statistically significant risk factors for 10 or more metastatic axillary nodes to be:

Larger tumour size, OR (no increment/category reported)14.8, p=0.026.

Oestrogen receptor (ER) negative tumour: OR 1.1, p=0.05.

### **DCIS - Evidence Summary**

Only a small volume of studies which address SLNB in patients with DCIS were identified (28 studies in total). The best quality evidence comes from a meta analysis of observational studies and a number of case series, all of which provide retrospective analyses.

The meta-analysis showed the frequency of SLN positivity in patients with a preoperative diagnosis of DCIS ranged from 0 to 16.7%. With an overall positivity incidence of 7.4%.

The case series studies vary in their methods of SLNB: six used radiocolloid to identify the sentinel node, nine used radiocolloid plus dye and one study used dye alone. The majority (14) report that immunohistochemistry is used to identify metastases in sentinel nodes. The studies are generally consistent in differentiating between true DCIS, DCISm and invasive disease, usually based upon the definition of DCISm by the American Joint Committee on Cancer: i.e. invasive focus <1mm in size on definitive histology.

No evidence was identified to suggest that a pattern exists between the rate of positive SNs and DCIS tumour grade.

No evidence was identified to suggest that a pattern exists between the rate of positive SNs and DCIS tumour size.

It is not possible to reliably estimate the proportion of patients with DCIS and positive SNs who have further axillary nodal involvement from the studies identified.

## **Rate of sentinel node involvement**

### **1. Overall**

#### **'Pure' DCIS**

Two reasonably sized, observational studies have demonstrated rates of detection of positive SNs in patients with DCIS (with no detectable microinvasion) as 1.8% (Veronesi et al. 2005) and 5% (Wilke et al. 2005). The median value from 12 included observational studies is 5.4% (range 0% to 22%).

#### **DCISm**

Even in one reasonably sized, observational study (Wilke et al. 2005), the subgroup of patients with DCISm represented only 51 individuals. Among these, the rate of detection of positive SNs was 14%. The median value from 7 included observational studies is 11.1% (range 9.5% to 29.4%).

The majority of the studies identified represent small series of patients, with a median series size of only 43.5 patients for all 16 studies. For this reason, the two studies by Wilkie et al. (2005) and Veronesi et al. (2005) stand out with much larger sizes of 675 patients and 508 patients, respectively. These two studies base their estimates of SN involvement on definitive primary tumour histology. Wilke et al. (2005) found the rate of SN involvement to be 5.6% in the whole series of patients, representing a rate of 5% in patients with pure DCIS and 14% in patients with DCISm. Veronesi et al. (2005) found the rate of SN involvement to be 1.8% in patients with pure DCIS.

#### **All series**

In all 17 series of patients the summary statistics for the rate of SN involvement in patients with DCIS are shown below, where the 16 series represent patients with only pure DCIS, only DCISm, or either of DCIS/DCISm:

Mean 7.6%

Median 6.8%

Range 0% to 22%.

[Camp et al. (2005), Cox et al. (1998), Cserni et al. (2002), Farkas et al. (2004), Intra et al. (2003), Katz et al. (2006), Kelly et al. (2003), Klauber-DeMore et al. (2000), Liu, Yang and Chen (2003), Mittendorf et al. (2005), Pendas et al. (2000), Trisal, Qian and Wagman (2004), Veronesi et al. (2005), Wilkie et al. (2005), Zavagno et al. (2005a) and Zavotsky et al. (1999)]

#### **'Pure' DCIS**

In the subgroup of patients without evidence of microinvasion (12 series), the summary statistics for the rate of SN involvement is as follows:

Mean 6.6%

Median 5.4%

Range 0% to 22%.

[Camp et al. (2005), Cserni et al. (2002), Katz et al. (2006), Kelly et al. (2003), Klauber-DeMore et al. (2000), Liu, Yang and Chen (2003), Mittendorf et al. (2005), Pendas et al. (2000), Trisal, Qian and Wagman (2004), Veronesi et al. (2005), Wilkie et al. (2005) and Zavagno et al. (2005a)].

#### **DCISm**

In the subgroup of patients with evidence of microinvasion (7 series), the summary statistics for the rate of SN involvement is as follows:

Mean 14%

Median 11.1%

Range 9.5% to 29.4%.

[Camp et al. (2005), Intra et al. (2003), Katz et al. (2006), Klauber-DeMore et al. (2000), Liu, Yang and Chen (2003), Wilkie et al. (2005) and Zavotsky et al. (1999)]

**2. By tumour grade**

Although a total of nine studies [Camp et al. (2005), Cserni et al. (2002), Intra et al. (2003), Katz et al. (2006), Kelly et al. (2003), Klauber-DeMore et al. (2000), Veronesi et al. (2005), Wilkie et al. (2005) and Zavotsky et al. (1999)] provide some data on the rate of positive SNs and primary DCIS tumour grade, the very small numbers of patients with positive SNs within subgroups based on tumour grade prevents meaningful analysis in the majority of studies.

The three studies that presented the rate of positive SNs for each tumour grade level found no pattern [Katz et al. (2006), Intra et al. (2003) and Veronesi et al. (2005)].

**3. By tumour size**

Similar to the data on DCIS tumour grade above, four studies provided some data on the rate of positive SNs [Katz et al. (2006), Klauber-DeMore et al. (2000), Veronesi et al. (2005) and

Zavotsky et al. (1999)], but the very small numbers of patients with positive SNs within subgroups based on tumour size prevents meaningful analysis in the majority of studies.

Katz et al. (2006) found no statistically significant relationship between the rate of positive SNs and primary DCIS tumour size.

**Rate of further axillary node involvement in patients with positive sentinel nodes**

The studies are inconsistent regarding whether all patients with DCIS and positive SNs underwent axillary clearance, but 9 studies provide data on the involvement of further axillary nodes [Camp et al. (2005), Cserni et al. (2002), Intra et al. (2003), Katz et al. (2006), Klauber-DeMore et al. (2000), Liu, Yang and Chen (2003), Mittendorf et al. (2005), Pendas et al. (2000) and Veronesi et al. (2005)].

The proportion of patients with further involved axillary nodes out of those with positive SNs *who undergo subsequent axillary clearance* is shown in the table below. Although this proportion has mean 0.1, median zero and mode zero, the numbers of patients represented are usually in single figures, so it is not reliable to rely on the data for this purpose.

**Table: Proportion of patients with further involved axillary nodes out of those with positive SNs who undergo subsequent axillary clearance (values refer to number of patients)**

Study	A n(positive SN)	B n(underwent axillary clearance)	C n(with further positive axillary node(s))	Proportion: C/B

Camp et al. (2005)	6	4	0	0
Cserni et al. (2002)	1	1	0	0
Intra et al. (2003)	4	3	0	0
Katz et al. (2006)	10	3	1	0.33
Klauber-DeMore et al. (2000)	12	9	1	0.11
Liu, Yang and Chen (2003)	3	3	1	0.33
Mittendorf et al. (2005)	9	5	1	0.2
Pendas et al. (2000)	5	5	0	0
Veronesi et al. (2005)	9	8	0	0

### Change in treatment decisions

None of the selected studies reported changes to treatment plans as a result of staging by SLNB, and all studies were retrospective in nature. However five studies provided data on patients who were upstaged from the stage attributed by primary tumour biopsy, in the light of final, primary tumour histology from definitive surgery:

### Upstaging to invasive disease by definitive surgery

One single, retrospective case series study [Wilkie et al. (2005)] provides evidence that 10% [95% CI 7.8% to 12.2%]<sup>9</sup> of patients staged by biopsy as having DCIS (including DCISm) and who undergo SLNB are found to have invasive disease by primary tumour histology revealed by definitive surgery.

Five of the selected studies report rates of upstaging by definitive surgery [Wilkie et al. (2005), (Camp et al. (2005), Mittendorf et al. (2005), Liu, Yang and Chen (2003) and Zavotsky et al. (1999)]. These data represent only patients with DCIS who were staged by SLNB, so more reliable data are probably available in the literature, which represent also patients with DCIS who are not staged by SLNB.

The largest series (n=675) in the studies selected is that studied by Wilkie et al. (2005). In this series 10% [95% CI 7.8% to 12.2%]<sup>9</sup> of patients with a biopsy diagnosis of DCIS, including DCISm, were upstaged to invasive disease by definitive surgery.

The other series are much smaller and hence less reliable, but report upstaging from DCIS to invasive disease at rates of 4%, 7.3% and 12.5% [(Camp et al. (2005), Mittendorf et al.

---

<sup>9</sup> 95% CI calculated using a spreadsheet constructed by Newcombe (2006), available online at:[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/index.htm](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/index.htm). Last accessed: 3.10.06

(2005) and Liu, Yang and Chen (2003), respectively]. Liu, Yang and Chen (2003) also report a rate of upstaging from DCIS to DCISm of 12.5% and Zavotsky et al. (1999) report a rate of upstaging from DCISm to invasive disease of 28.6%, but based on only 14 patients.

### **Cost effectiveness**

None of the selected studies reported cost effectiveness as an outcome measure.

### **EVIDENCE UPDATE**

A meta-analysis (Ansari *et al.* 2008) of observational studies detailed reported data on the incidence of SLN metastasis in patients with DCIS. This analysis reported SLN biopsy results in patients with the diagnosis of DCIS.

Twenty-two publications reporting SLN biopsy results in patients with the diagnosis of DCIS were included giving a combined study population of 3166 patients.

- Studies that assessed the frequency of SLN positivity in patients with a preoperative diagnosis of DCIS reported values from 0 to 16.7%
- The test for heterogeneity suggested that these 11 studies were not significantly heterogeneous ( $\chi^2 = 16.07$ , 10 df  $P = 0.098$ ).
- A meta – analysis of the data on SLN positivity from these studies gave an overall positivity frequency (or overall incidence) = 7.4% (95 %CI 6.2 - 8.9)
- There was significant between study heterogeneity in the 11 studies of patients with a definitive (postoperative) diagnosis of DCIS ( $\chi^2 = 27.82$ , 10 df,  $P = 0.002$ ).
- A meta-analysis of the data on SLN positivity from these studies showed an overall positivity frequency (or overall incidence) = 3.7% (95%CI 2.8 – 4.8)
- The overall frequencies of nodal metastasis between the two groups (preoperative versus definitive diagnosis) were significantly different with an odds ratio of 2.11 (95 %CI 1.15-2.93)
- A subset of patients with a biopsy diagnosis of DCIS who were at high risk of an invasive component were presented (from a literature search with some inconsistencies occurring between studies): Most of these studies suggested that a palpable mass; a mammographic mass; a high-grade lesion and a large size were associated with a significant risk of invasive disease in the final resection specimen.

## Evidence Tables

### Invasive breast cancer SLNB versus axillary clearance or axillary sampling

#### Abbreviations:

SLNB technique:

Radiocolloid (R)

Lymphoscintigraphy (L)

Blue dye (D)

Histology technique:

Standard method e.g. Haematoxylin and Eosin, (S)

Frozen section (FS)

Immunohistochemistry (IHC)

#### Randomized controlled trials

Julian . Preliminary technical results of NSABP B-32, a randomized phase III clinical trial to compare sentinel node resection to conventional axillary dissection in clinically node-negative breast cancer patients. 2004.

Design: Randomized controlled trial (therapy), evidence level: 1

Country: United States, setting: Secondary care

**Inclusion criteria** Women with operable invasive breast cancer.

**Exclusion criteria** Not reported

**Population** number of patients = 5210.

**Interventions** NSABP B-32 RCT

Intervention:

SLNB. Patients with disease positive SN were treated with axillary clearance and patients staged as N0 had no further surgery.

Control:

SLNB with immediate conventional axillary clearance.

SLNB technique

R, D.

Histology

FS, S.

**Outcomes** RCT will measure morbidity, recurrence and survival.

**Follow up** Not reported

#### Results

STAGING

Sentinel node localisation rate (all patients) = 97%.

FNR (based on control group) = 9.7%.

**General comments** Staging data represent the performance achieved by 233 surgeons who had previously completed training cases to reach the standard to enrol patients to the RCT.

To date study has only reported preliminary technical results in abstract form.

Insufficient data available to calculate 95% confidence intervals.

Purushotham, Upponi, Klevesath, Bobrow, Millar, Myles & Duffy . Morbidity after sentinel lymph node biopsy in primary breast cancer: results from a randomized controlled trial. Journal of clinical oncology : official journal of the American Society of Clinical Oncology 23[19]. 2005.

Design: Randomized controlled trial (diagnosis, screening), evidence level: 1+  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** Patients with breast cancer tumours of size 3 cm or less.

**Exclusion criteria** Not reported

**Population** number of patients = 298, mean age = 58 years.

**Interventions** Aim: to investigate physical and psychological morbidity following SLNB versus axillary clearance.

Intervention group: underwent SLNB. Patients with disease positive SNs were treated with axillary clearance and patients staged as N0 had no further surgery.

Control group: underwent axillary clearance.

SLNB technique

R, D.

Histology

S, IHC.

### **Outcomes**

Physical morbidity:

Postoperative arm numbness, lymphoedema, paresthesia, swelling, shoulder mobility and seroma formation.

Psychological morbidity:

Beck depression Inventory (BDI)

State - trait anxiety inventory

Brief symptom inventory (BSI) and the closely related global severity index (GSI) to measure presence/absence of clinically significant psychological morbidity.

Mental adjustment to cancer scale (MAC) to measure psychological coping.

SF-36 quality of life scale

Visual analogue scale of quality of life i.e. patients self scored on a continuous scale of 0 to 100.

**Follow up** 12 months

### **Results**

MORBIDITY

Assessment of outcome was taken at 1, 3, 6 and 12 months post-operatively.

**Lymphoedema:**

At 12 months follow-up the SLNB group had smaller mean increases in objectively measured arm volume than the axillary clearance group; at 12 months this difference was 37.8 ml in favour of SLNB ( $p=0.004$ ).

**Seroma:**

The odds of seroma formation between groups were not statistically significantly different: the OR for seroma formation in SLNB group relative to axillary clearance group was given as 0.60 (95% CI 0.33 - 1.11) and  $p=0.1$ .

**Sensory outcomes:**

Patients in the SLNB group were statistically significantly less likely to experience numbness (OR 0.32, 95% CI 0.19 - 0.51), loss of sensation to pinprick (OR 0.38, 95% CI 0.22 - 0.64), loss of light touch (OR 0.39, 95% CI 0.23 - 0.65) and paresthesia (OR 0.36, 95% CI 0.20 - 0.66) in the year following surgery than patients in the axillary clearance group.

**Shoulder mobility:**

Shoulder mobility was assessed in five different arm movements: Only one of five arm movements (flexion) was significantly different between randomised groups, with a significant difference in mean reduction of movement of 6.3 (95% CI 0.1 - 12.6) degrees favouring SLNB ( $p = 0.04$ ).

**Psychological morbidity:**

There was no significant difference between randomised groups in depressive symptoms or state anxiety during the one-year follow up period.

**BSI & GSI:**

The SLNB group consistently had lower mean global GSI score than the axillary clearance group, but this was significant only at the immediate postoperative assessment (i.e. SLNB: 49.7, axillary clearance: 52.9,  $p=0.01$ ) and ceased to be significant when adjusted for trait anxiety.

There were no significant differences between SLNB and axillary clearance groups in MAC scores at any point by ITT.

In the immediate postoperative period the SF-36 physical combined score ( $p=0.001$ ), physical functioning score ( $p=0.003$ ) and vitality score ( $p=0.004$ ) were significantly higher (reflecting better quality of life) in the SLNB group than the axillary clearance group.

**Visual analogue scale:**

In the immediate postoperative period, the QOL score was significantly higher (reflecting better quality of life) in the SLNB group than the axillary clearance. ( $p = 0.01$ ).

**General comments** RCT was undertaken at 3 centres.

Random allocation was well conducted. It is not feasible that patients or surgeons remained blinded thereafter.

The authors report that there were no significant differences between study groups for patient and disease characteristics. However, no details were provided of statistical

testing.

57 patients in the SLNB group underwent subsequent axillary clearance (48 due to positive SN status and 9 SLNB failures). Since only ITT analyses are cited, the effect is to attenuate the often-observed differences in favour of SLNB.

Although many analyses were performed, alpha values were reduced a priori in some instances to reduce the risk of type I errors.

Losses to follow up and non-analysed patients were fully reported.

'Baseline' measurements were made at 7-14 days post surgery as a surrogate for a true baseline; considered by the authors to be more ethical than a preoperative assessment. It is possible, based on this range, that patients were assessed for baseline with up to a whole week's difference in time since surgery. It is not possible to tell to what extent the randomisation process was able to overcome this imprecision.

Veronesi, Paganelli, Viale, Luini, Zurrada, Galimberti, Intra, Veronesi, Robertson, Maisonneuve, Renne, De, De & Gennari . A randomized comparison of sentinel-node biopsy with routine axillary dissection in breast cancer. N Engl J Med 349[6]. 2003.

Design: Randomized controlled trial (diagnosis, screening), evidence level: 1+  
Country: Italy, setting: Secondary care

**Inclusion criteria** Women patients with primary, unifocal breast cancer tumours  $\leq$  2cm in diameter.

Eligible age range 40 to 75 years

**Exclusion criteria** Male patients and those scheduled to undergo mastectomy.

**Population** number of patients = 516.

### **Interventions**

Aim: To evaluate the staging performance, side effects and disease-related events in patients staged by SLNB, compared to axillary clearance.

Intervention group: SLNB followed by axillary clearance if SN positive (n=259).

Control group: SLNB plus axillary clearance (n=257).

SLNB technique

L, R.

Histology

FS.

### **Outcomes**

Diagnostic test parameters.

Overall survival (using Kaplan-Meier method and log rank test) and incidence of breast cancer-related events.

Surgical side effects:

Axillary pain;

Numbness ;

Arm mobility;

Arm swelling (by difference in circumference from that of untreated arm).

**Follow up** 24 months

### **Results STAGING**

Data from entire study:

Sentinel node localisation rate (based on 532 randomised patients) =  $527/532 = 99.1\%$  (95% CI 97.8% to 99.6%): the 5 cases of SLNB failure were among 16 cases not analysed for outcomes.

However in 649 patients considered for this RCT, the SN localisation rate was  $638/649 = 98.3\%$  (95% CI 97.0% to 99.1%).

Number of SNs removed per patient: mean 1.7 (no range available).

Data from control group only:

Prevalence of axillary disease =  $91/257 = 35.4\%$  (95% CI 29.8% to 41.4%).

Accuracy =  $249/257 = 96.9\%$  (95% CI 94.0% to 98.4%).

FNR =  $8/91 = 8.8\%$  (95% CI 4.5% to 16.4%).

**MORBIDITY** (non ITT analysis)

Assessment of outcome was made at 24 months after surgery.

The 259 patients who underwent axillary clearance stayed in hospital for an average (presumably mean) of 4.3 days, compared to 2.1 days for 167 patients who underwent SLNB only.

A sample of 100 patients who underwent SLNB only had less pain, numbness and arm swelling and better arm mobility at 2 years' follow up than a sample of 100 patients who underwent SLNB plus axillary clearance:

Respective percentages that were pain free were 92% and 61% (difference 31%, 95% CI 19.6% to 41.5%).

Respective percentages reporting numbness were 1% and 68% (difference 67%, 95% CI 56.4% to 75.4%).

Respective percentages with arm mobility =80% were 100% and 79% (difference 21%, 95% CI 13.2% to 30.0%).

Respective percentages with a difference in arm circumference =1cm compared to the other arm were 7% and 37% (difference 30%, 95% CI 18.9% to 40.4%).

**RECURRENCE** (ITT analysis)

Median follow up (of 516 patients) = 46 months.

15 breast cancer-related events occurred in the control group versus 10 in the intervention group, with no significant difference between groups in cumulative incidence of breast cancer related events ( $p=0.26$ , log rank test)

Recurrence of tumour in the treated breast occurred in 1 (0.4%) patient in the intervention group and 1 (0.4%) patient in the control group;

A primary tumour in the contralateral breast occurred in 2 (0.8%) patients in the intervention group and 3 (1.2%) patients in the control group;

Axillary recurrence occurred in 2 (0.8%) patients in the intervention group and 0 (0%) patients in the control group;

Distant metastases occurred in 10 (3.9%) patients in the intervention group and 6 (2.3%) patients in the control group.

**SURVIVAL** (ITT analysis)

There was no statistically significant difference in overall survival between the two groups. Overall, 8 patients died: 6 in the control group (2 (0.8%) from breast cancer) and 2 in the intervention group (1 (0.4%) from breast cancer,  $p=0.15$ , log rank test).

### **General comments**

Subjects who were not eligible for the trial, who refused randomisation or who were not evaluable were fully reported. No subjects are reported as dropping out of the study.

Randomisation was well reported but blinding of patients or investigators was unlikely thereafter.

Informed consent and ethical approval were evident.

No significant differences were found between the intervention and control groups in terms of demography, tumour characteristics or prognostic factors.

Morbidity outcomes were not statistically tested, nor were confidence intervals provided.

Surgical side effects were compared between 100 consecutive patients from the control group (who underwent SLNB plus axillary clearance) with a sample of 100 patients from the intervention group who underwent SLNB only, using an interview at 6 months follow-up and a questionnaire at 24 months follow-up.

This non-ITT analysis was presumably restricted to 200 patients due to the large amount of effort required to interview patients and issue and collate questionnaires. 95% CIs were not constructed for these proportions reported in the paper since the proportions are of convenience samples and are of limited value.

There is little suggestion of bias in this study. The main limitation is that follow up period was relatively short such that survival and recurrence information was incomplete.

Fleissig, Fallowfield, Langridge, Johnson, Newcombe, Dixon, Kissin & Mansel . Post-operative arm morbidity and quality of life. Results of the ALMANAC randomised trial comparing sentinel node biopsy with standard axillary treatment in the management of patients with early breast cancer. Breast Cancer Research & Treatment 95[3]. 2006.

Design: Randomized controlled trial (diagnosis, screening), evidence level: 1++  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** Patients with primary, invasive breast cancer of age <80 years and scheduled for mastectomy or breast conserving surgery.

Patients had to be clinically node negative but with any tumour size.

**Exclusion criteria** Multicentric cancer, previous ipsilateral breast or axillary surgery other than benign excision biopsy, previous ipsilateral radiotherapy to axilla or breast, pre-existing limb disease causing swelling, known allergy to patent blue dye/human albumin, pregnancy/breast feeding, inability to complete quality of life questionnaire in English.

**Population** number of patients = 829, age range 28 to 80 years, mean age = 57 years.

### **Interventions**

Aim: to report fully on quality of life data from the ALMANAC RCT which compared standard axillary surgery (axillary clearance or FNS) with SLNB, and to report on the role of axillary node status, age, type of breast surgery and right/left handedness.

Intervention group (n=515) underwent SLNB. Patients with disease positive SN underwent axillary clearance or radiotherapy and patients staged as N0 had no further treatment.

Control group (n=516) underwent standard axillary management (axillary clearance or node sampling).

SLNB technique

L, R, D.

Histology

S.

### **Outcomes**

Quality of life using:

Trial Outcome Index (TOI) = sum of FACT-B physical and well-being subscales NB: Maximum score 108 reflecting high quality of life, with a change in 5 points regarded as a meaningful difference.

Arm functioning subscale score (range 0-20) and FACT-B+4 score (range 0-160), reflecting global quality of life.

Spielberger State/Trait Anxiety Inventory (STAI), where higher scores indicate greater anxiety.

**Follow up** Follow up in this paper is longer than that reported by Mansel et al. (2006) i.e. to 18 months from surgery.

Outcomes were assessed at 1, 3, 6, 12 and 18 months, by questionnaire.

## **Results**

Paper provides further information to that of Mansel et al. (2006) as follows:

TOI:

Two-way ANOVA examined the change in TOI from baseline to each study time point between randomised groups and in different age groups. This revealed a significant effect of treatment group (1 month  $p < 0.001$ , 3 months  $p = 0.027$ , 6 months  $p = 0.017$ , 12 months  $p = 0.011$ , 18 months  $p = 0.006$ ) in favour of the SLNB group and a significant effect of age ( $p < 0.001$ ) in favour of older patients for the first 6 months after surgery.

There was no significant interaction between treatment group and age.

Two-way ANOVA examined the mean change in TOI from baseline to each of the study time points between randomised groups and whether the patient had WLE or mastectomy. This

revealed a significant effect of treatment group in change of TOI from baseline to 1 month ( $p = 0.021$ ). There were no other significant effects.

## **ARM MORBIDITY**

Arm functioning subscale:

Two-way ANOVA examined the change in arm functioning subscale score from baseline to each of the study time points between randomised groups and in each age group. This revealed a significant effect of treatment group ( $p < 0.001$ ) in favour of the SLNB group and a significant effect of age (1, 12 months  $p = 0.001$ , 3 months  $p = 0.003$ , 6, 18 months  $p = 0.002$ ) in favour of older patients. There was no significant interaction between randomised group and age.

Effect of surgery on the dominant arm:

Patients, who had surgery on the same side as their dominant arm, had similar arm functioning scores as patients, who had surgery on the contralateral side.

Two-way ANOVA examined the change in arm functioning in each randomised group and whether the operation was on the same or the opposite side to the dominant hand. There was a significant effect in the change of arm functioning by treatment group at each follow up ( $p < 0.001$ ), but no significant effects related to handedness and no significant interaction effects.

## **PATIENT REPORTED ARM PROBLEMS**

(All proportions tested by Chi square)

Swollen/tender arm:

At each postal follow-up the proportion of patients reporting the problem (somewhat/quite a bit/very much) of a swollen or tender arm was significantly higher in the standard treatment group than in the SLNB group ( $p < 0.001$  at 1, 3, 6 months and  $p = 0.002$  at 12 and 18 months).

Numbness:

The proportion of patients reporting numbness in their arm on the operated side was also significantly higher in the standard treatment group than in the SLNB group ( $p < 0.001$  at 1, 3, 6, 12, and 18 months).

#### Pain:

The proportion of patients reporting painful movement of the arm on the operated side was higher in the standard treatment group than in the SLNB group at 1, 3 months ( $p < 0.001$ ) and 12 months ( $p = 0.005$ ) after surgery, but not significantly different at 6 months ( $p = 0.694$ ) or 18 months ( $p = 0.159$ ) after surgery.

#### Poor range of movement:

The proportion of patients reporting poor range of movement on the operated side was significantly higher in the standard treatment group than in the SLNB group at the 1 month ( $p < 0.001$ ) and 3 months ( $p = 0.035$ ) postal follow-ups but differences between groups were no longer significantly different at later follow-ups (6 months  $p = 0.167$ , 12 months  $p = 0.142$  and 18 months  $p = 0.266$ ).

#### Stiffness:

At each postal follow-up the proportion of patients reporting stiffness of the arm on the operated side (somewhat/quite a bit/very much) was higher in the standard treatment group than in the SLNB group, but the difference between groups was not always statistically significant ( $p < 0.001$  at 1 month,  $p = 0.031$  at 3 months,  $p = 0.089$  at 6 months,  $p = 0.038$  at 12 months,  $p = 0.051$  at 18 months).

### QUALITY OF LIFE

#### FACT-B+4 score:

Two-way ANOVA examined change in FACT-B+4 from baseline to each of the study time points between randomised groups and in each age group (under 50, 50-64, 65 and older). This revealed a significant effect of treatment group (1 month  $p < 0.001$ , 3 months  $p = 0.04$ , 12 months  $p = 0.024$ , 18 months  $p = 0.019$ ) except at 6 months ( $p = 0.059$ ), in favour of the SLNB group and a significant effect of age ( $p < 0.001$ ) in favour of older patients for the first 6 months after surgery. There was no significant interaction between treatment group and age.

Two-way ANOVA examined the mean change in FACT-B+4 from baseline to each of the study time points between randomised groups and in patients having WLE or mastectomy. This revealed a significant effect of treatment group on change in FACT-B+4 from baseline to 1 month ( $p = 0.014$ ). There were no other significant effects.

#### Anxiety:

State anxiety scores at baseline and during the trial did not vary by randomised group. There were also no significant differences between the anxiety levels of patients in the SLNB group, with positive nodes, who went on to have axillary clearance at a second operation, compared with patients in the control (standard treatment) group who were node positive.

Two-way ANCOVA examining the effects of randomised group and age group on state anxiety demonstrated a significant effect of age on anxiety for the first 6 months after surgery (1 month  $p < 0.001$ , 3 months  $p = 0.01$ , 6 months  $p = 0.007$ , 12 months  $p = 0.138$ , 18 months  $p = 0.302$ ) in favour of older patients. There were no significant effects of treatment

group and no significant interaction effects.

**General comments**

NB Same RCT as Mansel et al. (2006).

829 patients returned questionnaires: 424 in the SLNB group and 405 in the standard treatment group. 80% (662/829) of patients returned all 6 questionnaires. 32 questionnaires were invalid and were excluded from the analysis.

All analyses were by intention to treat unless otherwise stated.

Three age groups were analysed: under 50, 50-64, 65 and older.

The three age groups analysed differed with regard to tumour grade, proportion of screen detected cancers, proportion of breast conserving surgery operations and likelihood of receiving adjuvant therapy.

Mansel, Fallowfield, Kissin, Goyal, Newcombe, Dixon, Yiangou, Horgan, Bundred, Monypenny, England, Sibbering, Abdullah, Barr, Chetty, Sinnott, Fleissig, Clarke & Ell . Randomized multicenter trial of sentinel node biopsy versus standard axillary treatment in operable breast cancer: the ALMANAC Trial.[see comment]. J Natl Cancer Inst 98[9]. 2006.

Design: Randomized controlled trial (harm), evidence level: 1++  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** Patients with primary, invasive breast cancer of age <80 years and scheduled for mastectomy or breast conserving surgery.

Patients had to be clinically node negative but with any tumour size.

**Exclusion criteria** Multicentric cancer, previous ipsilateral breast or axillary surgery other than benign excision biopsy, previous ipsilateral radiotherapy to axilla or breast, preexisting limb disease causing swelling, known allergy to patent blue dye/human albumin, pregnancy/breast feeding, inability to complete quality of life questionnaire in English.

**Population** number of patients = 991.

**Interventions** ALMANAC RCT

Aim: to compare morbidity following standard axillary surgery (axillary clearance or FNS) with SLNB.

Intervention group (n=515) underwent SLNB. Patients with disease positive SN underwent axillary clearance or radiotherapy and patients staged as N0 had no further treatment.

Control group (n=516) underwent standard axillary management (axillary clearance or node sampling).

SLNB technique

L, R, D.

Histology

S.

**Outcomes** Arm morbidity (including subjective and objective assessment of lymphoedema, the latter based upon % volume changes from baseline calculated from numerous circumference measurements, using the contralateral arm as a control)

Quality of life using:

An enhanced Functional Assessment of Cancer Therapy - Breast questionnaire, plus 4 additional arm morbidity items (FACT-B+4);

Trial Outcome Index (TOI) = sum of FACT-B physical and well-being subscales NB: Maximum score 108 reflecting high quality of life, with a change in 5 points regarded as a meaningful difference.

Spielberger State/Trait Anxiety Inventory (STAI).

Axillary recurrence rate

**Follow up** Patients were reviewed at 1, 3, 6, 12 and 18 months after surgery.

This paper reports data up to 12 months from surgery.

## Results

### STAGING

SN localisation rate was 504/515 = 97.9% (95% CI 96.2% to 98.8%).

44/468=9.4% of patients who underwent lymphoscintigraphy had SNs in the internal mammary chain. A further seven SNs in the internal mammary chain were revealed only with a gamma probe.

Number of SNs removed per patient: median 2, range 1-11.

In the control group 123 patients underwent FNS with a median of 5 ANs removed (range 2-25). 373 patients underwent axillary clearance;

Number of ANs removed per patient in axillary clearance: median 15, range 1-42).

Prevalence of axillary disease was similar between randomised groups: 26% in the intervention group and 23% in the control group (difference = 2.4%, 95% CI -3.0% to 7.7%).

### MORBIDITY

Patient reported lymphoedema:

The proportion of patients reporting moderate or severe arm swelling was significantly greater in the standard treatment arm compared to the SLNB arm at 1, 3, 6 and 12 months follow up (e.g. 13% and 5% respectively at 12 months,  $p < 0.001$ , Chi square test).

RR of any lymphoedema in SLNB group compared to standard treatment group = 0.37 (95% CI 0.23-0.60)

Objectively assessed lymphoedema:

Patients in the standard treatment group had statistically significantly more arm swelling at 1, 3 and 6 months after surgery than patients in the SLNB group ( $p < 0.001$ ,  $p = 0.001$  and  $p = 0.003$  respectively, t test; e.g. ratio of arm volume at 6 months to arm volume at baseline: 1.02 in the SLNB group and 1.06 in the standard treatment group). This difference ceased to be statistically significant at 12 months.

Sensory deficit:

At all time points a greater proportion of patients in the standard treatment group had physician assessed sensory loss than in the SLNB group ( $p < 0.01$  for all, Chi square) e.g. at 12 months follow up, 31% of patients in the standard treatment arm had physician assessed sensory loss compared with 11% in the SLNB arm.

RR of sensory deficit at 12 months was 0.37 (95% CI 0.27-0.50) in favour of the SLNB group.

Patients in the standard treatment group had more extensive physician-assessed intercostal brachial nerve damage (based on mild, moderate, severe,  $p < 0.001$  for all, Chi square); e.g. 9% of patients in the SLNB group had moderate or severe nerve damage compared with 31% in the standard treatment group.

Shoulder function:

Patients in the standard treatment group experienced statistically significantly more impairment of shoulder

flexion and abduction on the ipsilateral side at 1 month after surgery ( $p = 0.004$  and  $p = 0.001$ , respectively, t test). However, shoulder flexion and abduction improved rapidly at

the subsequent time points in both groups, and differences between the groups were no longer statistically significant. There was no statistically significant difference in shoulder internal or external rotation between the two groups at any time point.

Other efficacy assessments:

A significantly greater proportion of patients in the standard treatment arm (79%) required surgical drains compared to the SLNB arm (17%) ( $p < 0.0001$ , Chi square test).

11% of patients in the SLNB group experienced an infection in hospital compared with 15% in the standard treatment group ( $p = 0.051$ , Chi square).

Patients in the SLNB arm returned to normal activities statistically significantly more quickly compared to the standard treatment arm ( $p = 0.001$ , Mann Whitney test); e.g. at 3 months the proportions, respectively in each group that had resumed their normal activities were 94% and 91%. There was no statistically significant difference between randomised groups in the time taken to return to paid work.

#### MEASURES OF QUALITY OF LIFE

The proportion of patients for whom the TOI score decreased from baseline by at least five points was statistically significantly higher in the standard treatment group than in the SLNB group at all time points ( $p < 0.001$ , at 1 and 3 months after surgery;  $p = 0.002$ , 6 months after surgery;  $p = 0.001$ , 12 months after surgery).

Arm functioning subscale:

Compared with baseline, arm functioning subscale score at 1, 3, 6, and 12 months after surgery was worse in both groups, but the impairment was greater in the standard group than in the sentinel lymph node biopsy group ( $p < 0.0001$ , t test).

FACT-B+4:

The change in scores from baseline was statistically significantly less favourable for the standard treatment group than for the SLNB group at 1 month ( $p < 0.001$ , t test), 3 months ( $p = 0.001$ ), 6 months ( $p = 0.003$ ), and 12 months ( $p = 0.002$ ) after surgery e.g. at 12 months scores in each respective group were 130.5 (95% CI 128.4-132.6) and 132.7 (95% CI 130.9-134.6).

STAI:

There was no difference between randomised groups at any time point in the mean trait anxiety score or the mean state anxiety score.

#### RECURRENCE

At 12 months from surgery 4 patients in the standard treatment group and 1 patient in the SLNB group experienced axillary recurrence (difference = 2.7%, 95% CI -1.5%-7.8%).

#### SURVIVAL

There were 7 deaths in each group; 2 due to metastatic breast cancer in the standard treatment group and 2 due to metastatic breast cancer in the SLNB group.

-

**General comments** Data on local recurrence and survival will be published at a later date with data from the ongoing NSABP-32 and ACOSOG trials.

After SLNB 92% of patients in each study arm received breast conserving surgery and 8% of patients in each study arm received mastectomy.

Power calculation performed. All analyses reported are by ITT.

Patients were randomised on a 1:1 basis to each group.

At baseline, the two groups were similar in terms of quality of life scores and patient and tumour characteristics.

The study benefited from a standardised validation phase across all 15 participating centres with the aim of standardising surgical competence (see Clarke, Newcombe and Mansel, 2004).

1031 patients were randomised. Due to patient ineligibility, refusal of initial management, 495 patients underwent SLNB and 496 patients underwent standard axillary surgery. Trial accrual stopped early due to concern with loss of equipoise in terms of morbidity.

17% of patients in the SLNB group underwent axillary clearance and 25% of the patients in the standard treatment group underwent FNS: this serves to attenuate the morbidity benefit of SLNB in the ITT analysis.

The finding of less surgical drain use in the SLNB group than in the standard treatment group is not surprising since the authors report that drain use is routine only following axillary clearance procedures.

Ung . Australasian experience and trials in sentinel lymph node biopsy: The. Asian Journal of Surgery 27[4]. 2004.

Design: Randomized controlled trial (diagnosis, screening), evidence level: 3  
Country: New Zealand/Australia, setting: Secondary care

**Inclusion criteria** Women with invasive breast cancer and tumour size < 3.0 cm.  
68% of patients were aged between 50 and 69 years.

**Exclusion criteria** -

**Population** number of patients = 150.

**Interventions** SNAC trial; in progress in 32 centres.

Aim: to compare SLNB with axillary clearance with regard to morbidity, recurrence and survival.

This paper reports on the staging performance based upon an interim analysis of the first 150 randomised patients.

Experimental group (n=75):

SLNB with subsequent axillary clearance if the SN is positive and no further surgery if the SN is negative.

Control group (n=75):

SLNB plus immediate axillary clearance.

SLNB technique

Varied by centre: combinations of L, R and D were employed.

Histology

S, IHC.

**Outcomes** Staging performance of SLNB reported here.

**Follow up** -

**Results** STAGING

Sentinel node localisation rate (in both groups combined) = 146/150 = 97.3% (95% CI 93.3% to 99.0%).

Number of SNs removed per patient: mean = 239/150 = 1.6.

Data from control group only:

Prevalence of axillary disease (based upon control group only) = 21/73 = 28.8% (95% CI 19.7% to 40.0%).

Accuracy = 70/71 = 98.6% (95% CI 92.4% to 99.8%).

FNR = 1/21 = 4.8% (95% CI 0.9% to 22.7%).

**General comments** Randomisation was undertaken centrally, with stratification for age (<50 versus =50 years), tumour palpability (palpable versus non-palpable), combinations of lymphatic mapping, gamma probe and blue dye to locate the SN and institution.

These data are not truly based upon RCT design, since staging information is largely derived from the control group alone. Study is graded accordingly here.

A validation phase preceded randomisation of patients: surgeons were required to demonstrate satisfactory performance in SLNB plus axillary clearance in 20 procedures with localisation rate =90%. Therefore, this study provides staging data using mature techniques, accepting some variability in precise method between centres.

Hung, Chan, Ying, Chong, Mak & Yip . Randomized clinical trial comparing blue dye with combined dye and isotope for sentinel lymph node biopsy in breast cancer. The British journal of surgery 92[12]. 2005.

**Design**

Randomized controlled trial (diagnosis, screening), evidence level: 1+  
Country: Hong Kong, setting: Secondary care

**Inclusion criteria**

123 women with early breast cancer.

**Exclusion criteria**

Age over 70 years, tumour greater than 3cm in size, multicentric tumour, previous breast/axillary surgery, pregnancy.

**Population**

Mean age = 52 years.

**Interventions**

Aim: to compare the staging performance of SLNB when performed with radiocolloid plus dye versus SLNB when performed with dye alone.

Combined technique group (n=61): underwent SLNB with radiocolloid and dye (including lymphoscintigraphy) and immediate axillary clearance to level I/II.

Blue dye group (n=57): underwent SLNB with dye alone and immediate axillary clearance to level I/II.

**Outcomes**

Staging performance of SLNB.

**Follow up**

Not reported.

**Results**

Staging performance; blue dye technique:

SN localisation rate = 49/57 = 86%

Mean no. SNs removed per patient = 1.8

Prevalence of axillary disease = 25/57 = 44%

FNR = 1/22 = 4.5%

Accuracy = 48/49 = 98%

Staging performance; combined technique:

SN localisation rate = 61/61 = 100%

Mean no. SNs removed per patient = 2.1

Prevalence of axillary disease = 33/61 = 54%

FNR = 0/33 = 0%

Accuracy = 61/61 = 100%

The SN localisation rate was significantly higher with combined technique (100%) compared to blue dye technique (86%), p=0.002, Chi square. Accuracy and FNR were not statistically significantly different between the two techniques.

**General comments**

A power calculation performed indicated a target size of 70 subjects in each group.

Each group was comparable for patient/tumour factors that could be expected to affect the SLNB procedure (statistically tested).

FNR reported here (based on 2:2 table) is  $c/(a+c)$  whereas authors reported FNR as  $c/(\text{total patients with identified SNs})$  which is the complement of accuracy.

Prevalence for the dye only group is based on whole group including patients in whom SLNB failed.

Of 123 patients randomised, 5 were excluded due to definitive diagnosis of DCIS and two due to inappropriate administration of blue dye .

## Case control study

Leidenius, Krogerus, Tukiainen & Von . Accuracy of axillary staging using sentinel node biopsy of diagnostic axillary lymph node dissection - A case-control study. APMIS 112[4-5]. 2004.

Design: Case control study (diagnosis, screening), evidence level: 2-  
Country: Finland, setting: Secondary care

**Inclusion criteria** Patients with histologically unifocal, invasive breast cancer with tumour size  $\leq$  30mm.

**Exclusion criteria** -

**Population** number of patients = 332.

**Interventions** Aim = to examine whether higher prevalence is detected by SLNB than axillary clearance based on a more exhaustive histology technique employed in SLNB. 166 patients staged by SLNB were matched 1:1 with 166 patients staged by axillary clearance.

Matching factors included age, tumour size, histological type and grade.

SLNB technique

L, R, D.

Histology

SLNB: FS, S, IHC.

axillary clearance: S.

**Outcomes** Difference in attributed axillary disease prevalence between groups, by analysis of discordant pairs i.e. proportion of patients staged as axillary positive by SLNB, compared to axillary clearance.

**Follow up** -

**Results** STAGING

Number of SNs removed per patient: mean 2.6 (range 1 to 9)

Number of ANs removed per patient: mean 13.8 (range 6 to 27).

Axillary metastases were detected in 62 (37.4%) of SLNB patients and 51 (30.7%) of axillary clearance patients i.e. an apparent upstaging effect of 6.7% (difference 6.7%, 95% CI -3.6% to 16.6%) arising in SLNB patients.

57 pairs were discordant in relation to detection of axillary metastases. In 34 discordant pairs the SLNB patient had axillary metastasis detected and in 23 discordant pairs the axillary clearance patient had axillary metastasis detected ( $p=0.19$ , Chi square McNemar). Therefore, no group emerged as significantly more likely to be staged as axillary positive.

In the 57 discordant pairs, mean tumour size was 15.1mm (range 6 to 30 mm) in axillary node positive patients and 15.4 (range 7 to 28) mm in axillary node negative patients ( $p = 0.81$ , Mann-Whitney U).

Mean age was 59.9 (range 42 to 86) years in axillary node positive patients and 59.4 (range 36 to 83) years in axillary node negative patients ( $p = 0.98$ , Mann-Whitney U). Therefore, neither tumour size nor age appeared to explain positive axillary status.

-

**General comments** No SN localisation rate reported since only patients with successful SLNB procedures were eligible for inclusion.

Case control study design crucially assumed that groups had equal true prevalence: patients in each group were satisfactorily matched for many prognostic factors (statistically tested).

There was no apparent risk of 'over matching' for the procedure performed, assuming that no disease factor determined performance of SLNB or axillary clearance. The two groups arose from standard practice at the centre at different times.

All SLNB patients from original series of 191 were accounted for; no matching pairs were found for 25 SLNB patients (excluded from analysis).

Prospective case series

Agarwal, Kakkos, Cunningham, Darzi, Lee, Rajan & Hadjiminias . Sentinel node biopsy can replace four-node-sampling in staging early breast cancer. Eur J Surg Oncol 31[2]. 2005.

Design: Prospective case series (other), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** Patients with primary, unifocal, invasive breast cancer.  
Tumour size = 25mm.  
Disease grade I-III.  
Disease stage T1-3.

**Exclusion criteria** -

**Population** number of patients = 234.

**Interventions** Single centre case series study

Aim: to compare the staging information provided by SLNB, with FNS as gold standard.

All patients underwent SLNB plus FNS (validation period).

Patients with metastatic disease in the axillary node field identified by either method underwent axillary clearance.

SLNB technique

R, D

Histology

FS, S

**Outcomes** Diagnostic test parameters.

**Follow up** -

**Results** STAGING

Sentinel node localisation rate = 221/234 = 94.4% (95% CI 90.7% to 96.7%)

Number of sentinel nodes removed per patient: mean = 1.4 (range, 1-4).

Prevalence of axillary disease in patients with localised SN = 77/221 = 34.8% (95% CI 28.8 to 41.3%).

Accuracy = 221/221 = 100% (95% CI 98.3% to 100%).

FNR = 0/77 = 0% (95% CI 0% to 0.02%).

Authors concluded that SLNB could replace FNS to stage the axilla for patients with early stage breast cancers.

-

**General comments** The 'gold standard' of FNS may not have been applied in its usual situation since the presence of blue dye and/or radioactive tracer from SLNB may have influenced which subsequent nodes were sampled.

Carlo, Grant, Knox, Jones, Hamilton, Livingston & Kuhn . Survival analysis following sentinel lymph node biopsy: a validation trial demonstrating its accuracy in staging early breast cancer. Baylor University Medical Center Proceedings 18[2]. 2005.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients with primary, unifocal, invasive breast cancer.  
Primary tumour size <5cm (mean 1.42cm. range 0 to 4.05cm).

**Exclusion criteria -**

**Population** number of patients = 345, age range 29 to 85 years, mean age = 567 years.

**Interventions** Aim: to evaluate the performance of SLNB in an operational setting by measuring 5-year disease free survival.

All patients underwent SLNB. Patients with positive SN underwent axillary clearance (cohort 1) and patients staged as N0 by SLNB underwent no further surgery (cohort 2).

SLNB Technique

R, D.

Histology

FS, S, IHC.

**Outcomes** Disease free survival estimated at 5 years, by Kaplan-Meier method with log rank test.

**Follow up -**

**Results** STAGING

Sentinel node localisation rate = 315/345 = 91.3% (95% CI 87.9% to 93.8%).

A mean of 2.4 sentinel nodes were removed from each patient.

RECURRENCE

Median follow up was 60 months.

Axillary recurrence occurred in 0/222 =0% of patients staged as N0 by SLNB (cohort 2).

SURVIVAL

Estimated 5-year disease free survival in 315 patients who successfully underwent SLNB was 94% (95% CI 91% to 97%).

Estimated 5 year disease free survival was significantly longer in the 222 patients with negative SNs (cohort 2, 96%), compared to the 93 patients with positive SNs (cohort 1, 89%), (p = 0.02).

Estimated 5 year disease free survival by disease stage based upon SLNB differed significantly:

Stage I: 97%

Stage IIa: 90%

Stage IIb: 85%

Stage IIIa: 78% (p < 0.001, percentages read from graph).

-

**General comments** The analysis excluded patients who underwent SLNB, but in whom the SLNB was a technical failure.

SNs were considered positive if any malignant cells were present by the highly sensitive IHC histology.

The median follow up period after surgery was 60 months, with no patients lost to follow up.

The Kaplan Meier analysis and log rank test used in the analysis were appropriate to the setting. The study made one minor numerical error and did not consistently report confidence intervals with proportions.

Patient and disease characteristics were reported for the whole study group together.

The survival analysis by disease stage took account of the important tumour size prognostic variable.

Clarke, Newcombe & Mansel . The learning curve in sentinel node biopsy: The ALMANAC experience. Ann Surg Oncol 11[3]. 2004.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** Patients with primary, invasive breast cancer.

Patients were eligible for this study with no upper limit on tumour size specified, provided tumours were of stage T3 or less.

**Exclusion criteria** -

**Population** number of patients = 520, age range 27 to 82 years, mean age = 57.6 years.

**Interventions** Study represents the ALMANAC RCT validation phase, undertaken in 14 centres in the UK.

**Aim:** to evaluate the competence of surgeons in performing SLNB prior to embarking on a RCT.

All patients underwent SLNB plus either FNS or axillary clearance as 'gold standard'.

The standard for surgeons to proceed to RCT phase was a SN localisation rate of =90% and a false negative rate of <5% in 40 procedures.

SLNB technique

L, R, D.

Histology

S.

**Outcomes** Sentinel node localisation rate.

False negative rate (against standard surgery as 'gold standard').

**Follow up** -

**Results** STAGING

Sentinel node localisation rate = 96.3% (95% CI 94.4% to 97.7%).

Mean number of sentinel nodes sampled per patient = 2.1 (range 1 to 9).

Prevalence of axillary disease in the entire study group = 169/520 = 32.5% (95% CI 28.6% to 36.6%).

Accuracy = 510/520 = 98.1% (95% CI 96.5% to 99.0%).

FNR = 10/169 = 5.9% (95% CI 3.2% to 10.5%).

Higher rates of failed SN localisations and a higher FNR were observed in surgeons' first procedures than in subsequent procedures.

-

**General comments** Study sets a standard for the calculation of valid staging outcome measures, considering case mix in the series. MORE HERE

Cody, Hill, Tran, Brennan & Borgen . Credentialing for breast lymphatic mapping: how many cases are enough? Ann Surg 229[5]. 1999.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients with biopsy proven, invasive breast cancer.

8 patients with DCIS were excluded from analysis.

**Exclusion criteria -**

**Population** number of patients = 500, age range 21 to 87 years, mean age = 56 years.

**Interventions** Prospective, single-centre, case series study.

Aim: To examine the staging performance of SLNB, according to the experience of the surgeon.

Most data are of 104 patients who underwent SLNB with immediate axillary clearance.

SLNB technique

R, D.

Histology

Not reported.

**Outcomes** Staging performance of SLNB using axillary clearance as gold standard.  
SLNB failure rate and FNR, examined by the experience of surgeons.

**Follow up -**

**Results** STAGING

Sentinel node localisation rate in larger series =  $458/492 = 93.1\%$  (95% CI 90.5% to 95.0%).

Number of SNs removed per patient: no data available.

Data for 104 patients (who underwent SLNB plus axillary clearance):

Prevalence of axillary disease =  $47/104 = 45.2\%$  (95% CI 36.0% to 54.8%).

Accuracy =  $99/104 = 95.2\%$  (95% CI 89.2% to 97.9%).

FNR =  $5/47 = 10.6\%$  (95% CI 4.6% to 22.6%).

Effect of surgeons' experience:

A higher SN localisation rate was seen in more experienced surgeons (94%) than in less experienced surgeons (86%,  $p=0.012$ , Fisher's exact test).

In the larger case series, the SLNB failure rate fell as the series of procedures were completed: there were 10 failures in the first 100 patients and 8, 6, 6 and 4 failures in each subsequent 100 patients.

Most SLNB false negative cases occurred early in the surgeons' experience.

-

**General comments** In the whole series of 500 patients, 423 procedures were performed by 3 surgeons with experience of SLNB (mean of 140 procedures per surgeon).

The remaining 5 surgeons (with less experience) performed a mean of 16 procedures each.

Therefore, two 'experience' groups emerged, although not clearly defined. An analysis was performed between these groups for SN localisation rate, but FNR was assessed between groups by narrative alone.

It is unclear why axillary clearance was performed in 104 patients, but possibly represents a validation period.

However, it cannot be ruled out that patients with poorer prognoses based upon tumour characteristics, were more likely to undergo axillary clearance, with the effect of raising the prevalence of axillary disease in these 104 patients.

The reported SN localisation rate is for the larger series of patients (n=492) representing greater surgical experience than for the 104 patients described above.

Although data were presented for FNR in each surgeon according to surgical experience, no analysis was performed.

Haid, Kuehn, Konstantiniuk, Kobere-Wuhrer, Knauer, Kreienberg & Zimmermann . Shoulder-arm morbidity following axillary dissection and sentinel node only biopsy for breast cancer. Eur J Surg Oncol 28[7]. 2002.

Design: Prospective case series (harm), evidence level: 3  
Country: Germany, setting: Secondary care

**Inclusion criteria** Patients with invasive breast cancer.

SLNB group: patients staged as N0.

Mean tumour diameter 17.4mm.

axillary clearance group: no stage stipulated.

Mean tumour diameter 23.3mm.

**Exclusion criteria** Patients who received axillary radiotherapy were excluded.

**Population** number of patients = 151, mean age = 57 years.

**Interventions** Aim: to examine morbidity following SLNB only, compared to that following axillary clearance.

Compares two groups:

SLNB group: patients who underwent SLNB only (n=66)

axillary clearance group: randomly selected patients who underwent routine axillary clearance only (n=85).

Groups were defined retrospectively but assessment of outcome was prospective.

SLNB technique

Not reported.

Histology

S, IHC.

**Outcomes** Morbidity, using a summation score (range 0 to 100), which was 60% based upon patient reported information and 40% upon clinically assessed information and considered pain, lymphoedema, loss of strength, range of motion and sensitivity to touch.

**Follow up -**

**Results** STAGING

Sentinel node localisation rate (based on larger series) = 219/237 = 92.4% (95% CI 88.3% to 95.1%).

Mean number of SNs removed per patient in SLNB group= 1.8.

A mean of 13 nodes were removed in the axillary clearance group.

**MORBIDITY**

Follow-up ranged from a minimum of 2 months to a maximum of 48 months from surgery (no median reported).

The total summation score was significantly higher (representing better functioning) in the SLNB group (92.8) compared to the axillary clearance group (80.6,  $p < 0.001$ ). All individual measures were statistically significant (with  $p < 0.05$ ) except for abduction ( $p = 0.8$ ).

Patients in the SLNB group had significantly higher score for subjective outcomes (54.1) compared to patients in the axillary clearance group (45.5,  $p < 0.001$ ).

Patients in the SLNB group had significantly higher score for objective outcomes (38.6)

compared to patients in the axillary clearance group (34.7,  $p < 0.001$ ).

With the analysis stratified by primary surgical procedure, these differences remained statistically significant in patients who underwent breast conserving surgery but statistical significance was lost for the majority of measures in patients who underwent mastectomy.

-

**General comments** No clear criteria were set to identify the two study groups from the larger series. It was not reported whether the axillary clearance group patients had nodal disease. Patients with knowledge of more extensive disease may have over-reported their morbidity.

The axillary clearance group had generally more advanced disease at the outset including significantly larger tumours ( $p = 0.019$ ) greater likelihood of receiving adjuvant chemotherapy ( $p < 0.001$ ) and mastectomy (no  $p$  value) compared to the SLNB group.

One cannot be certain that the two groups compared were similar at the beginning of the study.

The number of patients lost to follow up and the median follow-up period were not reported.

All patients were evaluated in the spring of 2001, and hence at different times in their recovery from surgery.

Many  $p$  values were reported, with increasing likelihood of a type I error. No multivariate analysis was performed which may have adjusted for the effects of different variables.

Krag, Harlow, Weaver & Ashikaga . Radiolabeled sentinel node biopsy: collaborative trial with the National Cancer Institute. World J Surg 25[6]. 2001.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients with operable, invasive breast cancer.

**Exclusion criteria** -

**Population** number of patients = 145, mean age = 53 years.

**Interventions** Aim = to test the staging performance of SLNB.  
All patients underwent SLNB plus immediate axillary clearance.  
SLNB technique  
R.  
Histology  
S.

**Outcomes** Staging performance of SLNB compared to axillary clearance as gold standard.

**Follow up** -

**Results** STAGING

Sentinel node localisation rate =  $127/145 = 87.6\%$  (95% CI 81.2% to 92.0%).

Number of SNs removed per patient: mean 2.8, SD 1.8.

Number of ANs removed per patient in axillary clearance: mean 15.6, SD 6.5.

Prevalence of axillary disease =  $45/127 = 35.4\%$  (95% CI 27.7% to 44.1%).

Accuracy =  $125/127 = 98.4\%$  (95% CI 94.4% to 99.6%).

FNR =  $2/45 = 4.4\%$  (95% CI 1.2% to 14.8%).

In 8.6% of patients, internal mammary SNs were identified and removed.

-

**General comments** Patient characteristics were analysed between successful SLNB localisations and failures: no patient or disease factor was found to be significantly associated with SN localisation.

This study represents a series of patients treated at a centre, which had already performed studies of radioactive tracers and adopted the use of a single tracer for this study. However, no formalised training period for the two participating surgeons had been implemented.

Langer, Marti, Guller, Moch, Harder, Oertli & Zuber . Axillary recurrence rate in breast cancer patients with negative sentinel lymph node (SLN) or SLN micrometastases: Prospective analysis of 150 patients after SLN biopsy. Ann Surg 241[1]. 2005.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Switzerland, setting: Secondary care

**Inclusion criteria** Patients with palpable breast tumours.

Mean age was 59.9 (SD 11.7) years in patients who underwent axillary clearance and 63.5 (SD 12.0) years in patients who underwent only SLNB.

**Exclusion criteria** -

**Population** -

**Interventions** Aim: to evaluate axillary recurrence in patients staged as N0 by SLNB without axillary clearance.

All patients underwent SLNB. Two study groups were defined:

1. Patients with no detectable SN metastases or SN micrometastases of size  $\leq 2$ mm by SLNB, were staged as N0 and did not undergo axillary clearance (cohort 2, n=150).
2. Patients with SN metastases of size  $> 2$ mm by SLNB, were considered SN positive and underwent axillary clearance (cohort 1, n=74).

SLNB technique

L, R, D.

Histology

FS, S, IHC.

**Outcomes** Morbidity

Local recurrence

Axillary recurrence

Distant metastasis

Disease-related deaths

**Follow up** -

**Results** STAGING

SN identification rate was  $224/236 = 94.9\%$  (95% CI 91.3% to 97.1%).

A mean of 2.1 (SD1.4) SNs were removed per patient.

MORBIDITY

15/74 (20.3%) patients who underwent axillary clearance developed axillary complications: seroma (n=8), wound infection (n=2), chronic lymphoedema (n=5).

1/150 (0.7%) of patients who underwent SLNB alone experienced complications: haematoma (n=1).

The difference in the proportion of patients in each group with complications was 19.6% (95% CI for difference 11.4% to 30.1%).

## RECURRENCE

Median follow-up was 42 months (range 12 to 64 months) overall. 2 patients were lost to follow up.

Local recurrence (breast)

6/149 = 4.0% of patients who underwent SLNB alone (cohort 2) had local recurrence in the breast compared with 4/73 = 5.5% of patients who underwent axillary clearance (cohort 1).

Axillary recurrence

The axillary recurrence rate in patients treated with SLNB alone (cohort 2) was 1/149 = 0.7% compared to 1/73 = 1.4% in patients who underwent axillary clearance (cohort 1).

Distant metastasis

3/149 (2.0%) of patients staged as N0 by SLNB (cohort 2) developed distant metastases compared with 7/73 (9.6%) of patients who underwent axillary clearance (cohort 1).

## SURVIVAL

11 patients died; 5/11 deaths were related to metastatic breast cancer (not reported by group).

-

**General comments** Data represent 236 procedures in 234 patients.

Reporting of absolute numbers of patients was rigorous throughout.

The study used highly sensitive IHC histology.

This study considered patients with small metastases ( $\leq 2\text{mm}$ ) in the SN to have stage N0, with omission of axillary clearance with the use of adjuvant therapy.

Only 2 patients were lost to follow up (one in each analysis group). These were excluded from the analyses.

In the 'SLNB only' group, subgroup analysis of N0 stage patients with small SN metastases of size 0 to 0.2mm versus 0.2 to 2mm revealed no significant differences in disease related events. This may be because so few events were observed in the follow-up period, or may be due to the protective role of adjuvant therapy.

The authors consider their rate of axillary recurrence in cohort 2 of 0.7%, with rates from other published studies, which have range 0.1% to 1.5%.

Reitsamer, Peintinger, Prokop, Rettenbacher & Menzel . 200 Sentinel lymph node biopsies without axillary lymph node dissection - No axillary recurrences after a 3-year follow-up. Br J Cancer 90[8]. 2004.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Austria, setting: Secondary care

**Inclusion criteria** Patients with invasive breast cancer.

Mean tumour size was 16.5 (range, 1 to 50) mm in patients who underwent SLNB only and 20.5 (range, 5 to 55) mm in patients who underwent SLNB plus axillary clearance.

**Exclusion criteria** -

**Population** number of patients = 333.

**Interventions** Aim: to measure the rate of axillary recurrence in patients staged as N0 by SLNB, without axillary clearance.

Two groups were defined:

Cohort 1: patients with disease positive SLNB result who underwent subsequent axillary clearance (n=128);

Cohort 2: patients staged as N0 by SLNB (n=200).

SLNB technique

L, R, D.

Histology

FS, S, IHC

**Outcomes** Axillary recurrence rate

Also provides information on upstaging by FS, S and IHC histology

**Follow up** -

**Results** STAGING

SN localisation rate =  $328/333 = 98.5\%$  (95% CI 96.5% to 99.4%).

Mean number of SNs removed per patient in cohort 2= 2.1.

Mean number of ANs removed per patient in cohort 1= 20.8.

The SN was the only positive node in  $77/128 = 60.2\%$  (95% CI 51.5% to 68.2%) of patients with positive SLNB result.

$15/215 = 7.0\%$  (95% CI 4.2% to 11.2) of patients staged as N0 by standard histology were upstaged by the use of IHC histology.

$104/128 = 81.3\%$  (95% CI 73.6% to 87.1%) of patients with positive SNs who underwent axillary clearance did so in the same operation as SLNB due to intraoperative histology by FS.

RECURRENCE

Median follow-up was 36 (range 22 to 56) months.

There were no local or axillary recurrences in either group (cohorts 1 and 2) at a median follow-up of 36 months.

-

**General comments** All patients from the original series were accounted for; 5 cases of SLNB failure underwent immediate axillary clearance (excluded from follow-up data). Patient characteristics, exclusion criteria and follow-up practice thoroughly reported. Patients were attributed positive SN status using the highly sensitive IHC technique.

Rietman, Dijkstra, Geertzen, Baas, de, Dolsma, Groothoff, Eisma & Hoekstra . Short-term morbidity of the upper limb after sentinel lymph node biopsy or axillary lymph node dissection for Stage I or II breast carcinoma.[see comment][erratum appears in Cancer. Cancer. 2004 May 1;100(9):1991]. Cancer 98[4]. 2003.

Design: Prospective case series (harm), evidence level: 3  
Country: Netherlands, the, setting: Secondary care

**Inclusion criteria** Patients with invasive breast cancer.

**Exclusion criteria** -

**Population** number of patients = 204, mean age = 56 years.

**Interventions** Aim: to prospectively compare short-term morbidity between SLNB and axillary clearance.

Two groups of patients were defined:

1. Patients who underwent SLNB alone (n=66).
2. Patients who underwent axillary clearance alone or SLNB and subsequent axillary clearance (n=138). axillary clearance was performed to level I-II.

SLNB technique

R, D.

Histology

Not reported.

**Outcomes** Surgical complications.

Patient-reported pain (visual analogue scale [VAS] with range 0 to 10cm).

Numbness (yes/no).

Upper limb mobility and strength (using instruments).

Arm circumference.

Activities of daily living (ADL) using the Shoulder disability questionnaire (SDQ) and the Groningen activity restriction scale (GARS).

**Follow up** -

**Results** MORBIDITY

Surgical complications:

Seroma lasting 4 weeks or more occurred in 3/60 = 5.0% of SLNB patients and in 18/119 = 15.1% of axillary clearance patients (difference 10.1%, 95% CI -0.08% to 18.3%) (p=0.051).

Wound infection necessitating antibiotic treatment occurred in 6/63 = 9.5% of SLNB patients and 20/121 = 16.5% of axillary clearance patients (difference, 7.0%, 95% CI -4.2% to 16.2%) (p=0.265).

Outcomes measured at follow-up point (6 weeks after surgery):

In the study group as a whole, patient-assessed pain increased from a score of mean 0.5 (SD 1.2) preoperatively to mean 1.3 (SD 1.3) at follow-up (p<0.001). 67.6% of all patients

experienced numbness at follow-up.

In the study group as a whole, upper limb morbidity was significantly reduced at follow-up compared to preoperative levels in terms of forward flexion, abduction and external rotation, with  $p < 0.05$  for these parameters. Neither external rotation nor grip strength was significantly reduced.

In the study group as a whole, arm circumference was not significantly increased at follow-up.

In the study group as a whole, the mean SDQ score and the mean GARS score significantly increased (worsened) at follow-up compared to the preoperative scores ( $p < 0.001$ ).

There were no significant differences between the SLNB group and the axillary clearance group for any outcome measure at follow-up. However, the sizes of changes were generally larger in the axillary clearance group compared to the SLNB group.

-

**General comments** The study reported exclusion of 1 patient; otherwise, all patients treated at the 2 centres appear to be included. Only three patients were lost to follow up.

Unusually, this study prospectively included patients with clinically suspicious nodes.

The axillary clearance group includes patients who underwent axillary clearance up to two weeks after SLNB, which introduces variability with regard to the targeted 6-week follow-up point.

Statistical methods were partially described, although no statistical test was described for the proportion outcomes, where Chi square may have been suitable.

The outcome measures provided meaningful objective and subjective information on the effect of surgery on patients' everyday activities.

The use of a preoperative baseline meant that patients were in the same state at the study outset.

No patient had started adjuvant therapy prior to the follow-up assessment at 6 weeks post surgery.

Morbidity in the axillary clearance group may have been accentuated by a greater proportion ( $68/138 = 49.3\%$ ) of patients receiving mastectomy, than in the SNB group ( $17/66 = 25.8\%$ ; difference 23.5%, 95% CI 9.3% to 35.7%).

Torrença, Fabry, Van, Van Diest, Pijpers, Meijer & Nieweg . Omitting axillary lymph node dissection in sentinel node negative breast cancer patients is safe: A long term follow-up analysis. J Surg Oncol 88[1]. 2004.

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Netherlands, the, setting: Secondary care

**Inclusion criteria** Patients with breast cancer.

Mean tumour size 1.5 (range 0.4 to 5.0) cm.

**Exclusion criteria** -

**Population** number of patients = 104, age range 32 to 81 years, mean age = 55 years.

**Interventions** Prospective, single-centre, case series study

Aim: to measure axillary recurrence and survival in patients staged as N0 by SLNB without axillary clearance (Cohort 2).

SLNB technique

L, R, D.

Histology

S, IHC.

**Outcomes** Disease free survival and overall survival.

**Follow up** -

**Results** STAGING

A mean of 1.3 SNs (range, 1 to 3) were excised per patient.

RECURRENCE

Median follow-up was 57 (range 48 to 83) months.

Axillary recurrence occurred in 1/104 = 0.96% of patients.

Distant metastases occurred in 3/104 = 2.9% of patients.

SURVIVAL

Proportion of patients alive at 4 years from point of surgery = 102/104 = 98.1%.

Proportion of patients alive and disease free at 4 years from point of surgery = 101/104 = 97.1%, including the 1 patient with treated recurrence in the denominator.

-

**General comments** The study includes all patients representing cohort 2, treated at the centre.

The SN localisation rate was not reported in this follow up study, but use of the triple technique (L, R, D) gives confidence of a high rate of 'true SN' detection, assuming that surgeons were adequately trained.

A mean of 1.25 SNs were excised per patient. Interestingly 82 of the total 104 SN negative patients were staged based on 1 SN.

In all patents N0 stage was attributed detection of no cancer cells by IHC histology; a

highly sensitive technique.

Retrospective case series

Blanchard, Donohue, Reynolds & Grant . Relapse and morbidity in patients undergoing sentinel lymph node biopsy alone or with axillary dissection for breast cancer. Arch Surg 138[5]. 2003.

Design: Retrospective case series (harm), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients with primary, invasive breast cancer; staged as N0.

**Exclusion criteria** -

**Population** -

**Interventions** Retrospective, single centre case series study with prospective survey of a subgroup.

Aim: to measure axillary recurrence rates and physical morbidity in patients staged by SLNB, with or without axillary clearance.

(n=776)

Of 1253 patients treated by SLNB, 894 patients staged as N0 were contacted by questionnaire. 776 patients responded, representing two retrospectively defined groups:

axillary clearance group: (cohort 4) patients treated by SLNB plus axillary clearance (validation period, n=91)

SLNB group: (cohort 2) patients treated by SLNB only (after validation period, n= 685).

SLNB Technique

Variable: initially D; thereafter L, R, D.

Histology

FS, S, IHC.

**Outcomes** Patient-reported rates of lymphoedema, seroma, pain and infection.

Axillary recurrence.

**Follow up** -

**Results** STAGING

A mean of 2.3 (SD 1.3) SNs were removed in patients in the SLNB group and a mean of 1.8 (SD 1.0) SNs were removed in patients in the axillary clearance group.

Questionnaire results

Mean follow up was 2.4 years (SD 0.9 years).

**MORBIDITY**

Lymphoedema was reported by 39/683 = 6% of SLNB group patients, compared to 31/91 = 34% of axillary clearance group patients (difference 28.3%, 95% CI 19.2% to 38.7%).

Lymphoedema was reported as severe (necessitating use of a support sleeve) in 4/683 =

0.6% of SLNB group patients compared with 8/91 = 9% of axillary clearance group patients (difference 8.2%, 95% CI 3.8% to 15.8%) ( $p < 0.001$ ).

Pain was reported by 95/681 = 14% of SLNB group patients, compared to 35/91 = 38% of axillary clearance group patients (difference 24.5%, 95% CI 14.8% to 35.1%). Pain was reported as severe (necessitating use of analgesia for more than one month after surgery) in 6/681 = 0.9% of SLNB group patients compared with 4/91 = 4% of axillary clearance group patients (difference 3.5%, 95% CI 0.7% to 9.9%) ( $p < 0.001$ ).

Seroma necessitating aspiration was reported by 50/681 = 7% of SLNB group patients, compared to 21/89 = 24% of SLNB plus axillary clearance patients (difference 16.3%, 95% CI 8.3% to 26.2%) ( $p < 0.001$ ).

Infection requiring treatment with antibiotics was reported by 20/681 = 3% of SLNB only patients, compared to 8/88 = 9% of axillary clearance group patients (difference 6.2%, 95% CI 1.5% to 14.1%) ( $p = 0.006$ ).

52/505 = 10% patients reporting lymphoedema 10% (52) reported receiving radiotherapy, which was not significantly different to 18/247 = 7% who reported lymphoedema with no radiotherapy (difference 3%, 95% CI -1.6% to 7.0%),  $p = 0.18$ ). A similar, non-significant result was obtained for pain, by radiotherapy. However, the authors did not differentiate between radiotherapy to the breast from the axilla.

#### RECURRENCE

1/685 = 0.15% of SLNB group patients (cohort 2) experienced axillary recurrence.

-

**General comments** The two analysis groups were similar in terms of many disease and treatment characteristics. However patients in the SLNB group were older than those in the axillary clearance group (mean 61.6 years versus 58.3 years respectively,  $p = 0.03$ ), had less advanced disease stage ( $p = 0.01$ ).

This study does not report exactly which data originated from a retrospective review of medical notes, rather than the questionnaire.

Histology was highly sensitive.

The SLNB method changed over time, but is poorly reported. Non-standardised SLNB may have affected the reported outcomes.

No survival data are cited since the reporting was inadequate.

The axillary clearance group included some patients with clinically palpable, suspicious nodes.

The questionnaire was not included in the paper.

The study did not consistently report multivariate analyses, raising suspicion that only significant findings were reported.

Cserni, Rajtar, Boross, Sinko, Svebis & Baltas . Comparison of vital dye-guided lymphatic mapping and dye plus gamma probe-guided sentinel node biopsy in breast cancer. World J Surg 26[5]. 2002.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Hungary, setting: Secondary care

**Inclusion criteria** Patients with invasive breast cancer.

**Exclusion criteria** -

**Population** number of patients = 184, mean age = 59 years, median age = 60 years.

**Interventions** Retrospective, single-centre case series.

Aim = to evaluate the staging performance of SLNB during a validation period.

All patients underwent SLNB plus axillary clearance.

Different patient groups were defined according to practice at the centre over time (from 201 procedures in 199 patients).

SLNB technique

Initially D, later R, D.

Histology

S, IHC.

**Outcomes** Staging performance of SLNB based upon axillary clearance as gold standard.

**Follow up** -

**Results** STAGING

Data from whole series (including learning phase and period where SLNB was performed with blue dye alone):

Sentinel node localisation rate =  $184/201 = 91.5\%$  (95% CI 86.9% to 94.7%).

Number of SNs removed per patient: mean 1.4, median 1.

Prevalence of axillary disease =  $106/184 = 57.6\%$  (95% CI 50.4% to 64.5%).

Accuracy =  $176/184 = 95.7\%$  (95% CI 91.7% to 97.8%).

FNR =  $8/106 = 7.5\%$  (95% CI 3.9% to 14.2%).

Data for subgroup of 72 patients staged by SLNB using blue dye plus radioactive tracer (excludes surgical training phase):

Sentinel node localisation rate =  $72/72 = 100\%$  (95% CI 94.9% to 100%).

Number of SNs removed per patient: mean 1.4, median 1.

Prevalence of axillary disease =  $30/72 = 41.7\%$  (95% CI 31.0% to 53.2%).

Accuracy =  $71/72 = 98.6\%$  (95% CI 92.5% to 99.8%).

FNR =  $1/30 = 3.3\%$  (95% CI 0.6% to 16.7%).

Learning curve:

The SN identification rate for the first six groups of ten procedures was 50%, 80%, 90%, 80%, 90% and 100%, respectively. The accepted standard of 90% localisation rate was achieved for the previous 30 procedures at the 53rd procedure.

-

**General comments** The study group was poorly defined: an undisclosed number of

patients with in situ disease were included.

Also, during the study period, the centre was performing SLNB alone in some patients, staged as N0. Hence, this group did not undergo axillary clearance and could not occur in the series reported, possibly contributing to the high prevalence reported.

In all sentinel nodes, any malignant cells detected by highly sensitive IHC warranted a positive status, which may also serve to raise the prevalence.

The subgroup of 72 patients represented those treated by surgeons who had completed training in SLNB. By this time, the centre used both radioactive tracer plus blue dye. This provides data for a centre, which has reached maturity in performing SLNB.

This Hungarian centre did not appear to draw a clear distinction between a validation period and an operational period: it is not possible to clearly define the effect of surgical competence, technical method for SLNB and practice setting.

Giuliano, Jones, Brennan & Statman . Sentinel lymphadenectomy in breast cancer. J Clin Oncol 15[6]. 1997.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients with invasive breast cancer.  
Mean tumour size was 2.11 (SD 1.38) cm.

**Exclusion criteria** -

**Population** number of patients = 107.

**Interventions** Aim: to report on the staging performance of SLNB during a validation period.

All patients underwent SLNB plus axillary clearance.

SLNB technique

D.

Histology

S, IHC.

**Outcomes** Staging performance of SLNB based on axillary clearance as 'gold standard'.

**Follow up** -

**Results** STAGING

Sentinel node localisation rate =  $100/107 = 93.5\%$  (95% CI 87.1% to 96.8%).

Number of SNs removed per patient: mean 1.8 (range 1 to 8), SD 1.8.

Number of ANs removed per patient: 20.3 (range 7 to 60), SD 7.8.

Prevalence of axillary disease =  $42/100 = 42\%$  (95% CI % 32.8% to 51.8%).

Accuracy =  $100/100 = 100\%$  (95% CI 96.3% to 100%).

FNR =  $0/42 = 0\%$  (95% CI 0% to 8.4%).

-

**General comments** Results represent performance attained at a centre of excellence, which developed the technique.

Based on these results the centre omitted axillary clearance in all cases of SLNB.

All patients accounted for in original series, to illustrate how 107 patients were identified.

8 patients with clinically suspicious nodes were included; introducing a bias towards better performance based upon prior knowledge, and also through raising the prevalence (see discussion).

Imoto, Wada, Murakami, Hasebe, Ochiai & Ebihara . Prognosis of breast cancer patients treated with sentinel node biopsy in Japan. Jpn.J Clin Oncol 34[8]. 2004.

Design: Retrospective case series (prognosis), evidence level: 3  
Country: Japan, setting: Secondary care

**Inclusion criteria** Patients with unilateral, invasive breast cancer staged as N0.

**Exclusion criteria** -

**Population** number of patients = 209.

**Interventions** Aim: to measure recurrence and survival in patients who were surgically staged as N0 by SLNB compared to axillary clearance.

Study compares two groups treated at a single centre:

SLNB group: Patients staged as N0 by SLNB (cohort 2, n=112).

axillary clearance group: Patients staged as N0 by SLNB plus axillary clearance (cohort 4, validation period, n=97).

SLNB technique

L, R, D.

Histology

FS, S.

**Outcomes** Disease-related events.

Relapse-free survival, by Kaplan Meier survival analysis and log rank test.

**Follow up** -

**Results** STAGING

SLNB localisation rate was 79/97=81.4% (95% CI 72.6% to 88.0%) in the validation phase and 111/112= 99.1% (95% CI 95.1% to 99.8%) thereafter.

RECURRENCE

Median follow-up in all patients was 52 months.

In all patients, 18 (9%) experienced disease relapse.

Loco-regional recurrence was seen in 5/97 = 5.2% of patients in the axillary clearance group (cohort 4) and 5/112 = 4.5% patients in the SLNB group (cohort 2).

Distant metastases were seen in 5/97 = 5.2% of patients in the axillary clearance group (cohort 4) and 3/112 = 2.7% of patients in the SLNB group.

3 (3.1%) deaths due to breast cancer occurred in the axillary clearance group (cohort 4) compared to 1 (0.9%) in the SLNB group (cohort 2).

SURVIVAL

The relapse-free survival rates in the axillary clearance (cohort 4) and SLNB (cohort 2) groups were 94% and 93% respectively (p=0.78, log rank test).

-

**General comments** The study provided details of how the two groups were derived from a

series of 391 patients; criteria for exclusion from the analysis were clearly defined. Differences in prognostic variables were statistically tested between groups: the axillary clearance group had significantly larger tumour size ( $p=0.008$ ), greater likelihood of mastectomy ( $p=0.01$ ) and more advanced disease stage ( $p=0.015$ ) than the SLNB group. However, the groups were clearly defined by the change in practice from validation period to operational period. The reported loco-regional recurrence rate of 4.5% for cohort 2 presumably includes axillary recurrence plus local recurrence in the breast.

Katz, Niemierko, Gage, Evans, Shaffer, Fleury, Smith, Petrucci, Flax, Drogula & Magnant . Can axillary dissection be avoided in patients with sentinel lymph node metastasis?[see comment]. [Review] [46 refs]. J Surg Oncol 93[7]. 2006.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients treated with SLNB between 1998 and 2003.

110 patients had DCIS  
1034 patients had invasive disease

307 patients underwent mastectomy and 833 breast conserving surgery. In 8 patients the type of definitive surgery was unknown.

**Exclusion criteria** Retrospective study: none reported.

**Population** number of patients = 1133, age range 30 to 96 years, median age = 57 years.

**Interventions** Retrospective analysis of 1148 SLNB procedures in 1133 patients treated at a single centre and recorded on a pathology database.

SLNB technique: R, D  
Histology: FS, S, IHC

**Outcomes** Risk factors for the presence of SN metastases.

Risk factors for the presence of further axillary node metastases in patients who undergo axillary clearance for positive SLNB result.

**Follow up** No follow-up reported, study assesses predictive factors for SN and non SN axillary nodal involvement.

**Results** 246 patients had involved SNs and underwent axillary clearance.  
121 patients had involved SNs and did not undergo axillary clearance.

Prevalence of axillary disease =  $367/1148 = 32\%$

A median of 2 SNs were identified per procedure (range 1-15)

#### RISK FACTORS FOR SN INVOLVEMENT

By Pearson Chi square the proportion of patients with positive SNs varied significantly by subgroup for the following variables (as categorical variables):

Age (higher rates of SN involvement in younger patients,  $p < 0.001$ );  
Type of surgery (higher rates of SN involvement after mastectomy,  $p < 0.008$ );  
Tumour size (higher rates of SN involvement with larger tumours,  $p < 0.001$ );  
Histology (higher rates of SN involvement for invasive histology,  $p < 0.001$ );  
Invasion of lymphovascular space (higher rates of SN involvement when present,  $p < 0.001$ ).

By Pearson Chi square the proportion of patients with positive SNs did not vary significantly by subgroup for the following variables (as categorical variables):

Number of SNs identified;  
ER receptor status;  
PR receptor status.

The statistical significance observed was the same whether SN positivity was determined by H&E histology or by any technique (including more sensitive techniques).

On multiple logistic regression analysis age, histology, type of surgery, primary tumour size and lymphovascular invasion were statistically significantly associated with SN involvement (no further details reported).

#### RISK FACTORS FOR INVOLVEMENT OF ADDITIONAL NON-SENTINEL NODES

By Pearson Chi square the proportion of patients with positive further nodes varied significantly by subgroup for the following variables (as categorical variables):

Presence of lymphovascular invasion ( $p=0.001$ );

Number of SNs examined (higher rates of further nodal involvement where fewer SNs were examined,  $p=0.03$ );

Histological method to detect SN metastasis (higher rates of further nodal involvement for H&E,  $p=0.03$ );

Number of involved SNs (higher rates of further nodal involvement where  $\geq 3$  SNs involved,  $p=0.002$  for H&E histology and  $P=0.05$  for any histological technique);

Number of uninvolved SNs (higher rates of further nodal involvement where fewer SNs uninvolved,  $p<0.001$ );

Size of the largest SN metastasis (higher rates of further nodal involvement for larger SN metastases,  $p<0.001$ ).

By Pearson Chi square the proportion of patients with further involved axillary nodes did not vary significantly by subgroup for the following variables (as categorical variables):

Age;

Type of definitive surgery;

Tumour size;

Histology.

On multiple logistic regression analysis the presence of lymphovascular invasion, increasing number of positive SNs, increasing size of the largest SN metastasis and decreasing number of negative SNs were statistically significantly associated with further axillary node involvement (no further details reported).

-

**General comments** It is not reported, but this series of patients appear to have been treated in an operational phase for SLNB i.e. without planned axillary clearance for any patients irrespective of SN status.

Kokke, Jannink, Barneveld, van der Linden, Gelderman, Wissing & Bosscha . Incidence of axillary recurrence in 113 sentinel node negative breast cancer patients: A 3-year follow-up study. Eur J Surg Oncol 31[3]. 2005.

Design: Retrospective case series (therapy), evidence level: 3  
Country: Netherlands, the, setting: Secondary care

**Inclusion criteria** Women with invasive breast cancer, stage N0 by SLNB.  
Mean tumour size 14.0 (range 2 to 35) mm.

**Exclusion criteria** -

**Population** number of patients = 113.

**Interventions** Aim: To measure the axillary recurrence rate in patients staged as N0 by SLNB (cohort 2).  
SLNB technique  
L, R, D.  
Histology  
S.

**Outcomes** Disease-related events; primarily, axillary recurrence.

**Follow up** -

**Results** RECURRENCE

Mean follow-up was 37.5 (range 24.1 to 53.6) months.

1 patient developed an axillary recurrence:  $1/113 = 0.9\%$ . Review of the original pathology slides showed metastasis in the SN.

1 patient developed supraclavicular lymph node metastasis (outside the axilla):  $1/113 = 0.9\%$ .

2 patients developed a further primary tumour in the contralateral breast  $2/113 = 1.8\%$ .

-

**General comments** 113 patients were drawn from an original series of 197 treated by SLNB at a single centre. The 84 patients excluded were accounted for with suitable reasons e.g. history of cancer in the bilateral breast.

Study implies 1 case of false negative result from the pathology laboratory.

Follow-up examination was by clinical examination exam only: no use of ultrasound imaging was reported, which is a more sensitive technique. The frequency of follow-up examinations was 3 monthly in the first year and 6 monthly thereafter.

Langer, Guenther, Haigh & DiFronzo . Lymphatic mapping improves staging and reduces morbidity in women undergoing total mastectomy for breast carcinoma. Am Surg 70[10]. 2004.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients with biopsy proven breast cancer, who had mastectomy as primary surgery.

Mean tumour size 2.5 (range 0.3 to 8.0) cm.

**Exclusion criteria** -

**Population** number of patients = 99, age range 34 to 87 years, mean age = 59 years.

**Interventions** Aim: to compare morbidity between SLNB and axillary clearance.

Patients who underwent mastectomy were identified from a larger series and two groups were defined:

1. Patients who underwent SLNB plus axillary clearance
2. Patients who underwent SLNB only.

SLNB technique

D.

Histology

FS, S, IHC.

**Outcomes** Staging performance of SLNB compared to axillary clearance as gold standard in subset of 56 patients.

Post operative morbidity, including:

Paresthesia;

Restricted arm movement;

Lymphoedema;

Infection;

Seroma.

**Follow up** -

**Results** STAGING

Sentinel node localisation rate (based upon whole series of 100 procedures) = 96/100 = 96% (95% CI 90.1% to 98.4%).

Number of SNs removed per patient: mean 1.7, range 1 to 5.

Data from 56 patients who underwent SLNB plus axillary clearance:

Prevalence of axillary disease = 28/56 = 50% (95% CI 37.3% to 62.7%).

Accuracy = 53/56 = 94.6% (95% CI 85.4% to 98.2%).

FNR = 3/28 = 10.7% (95% CI 3.7% to 27.2%).

**MORBIDITY**

Mean follow up was 51 months (range 6 to 107) months.

A smaller proportion of patients who underwent SLNB alone experienced adverse events, compared to patients who underwent SLNB plus axillary clearance.

These differences were statistically significant for paresthesia (25% versus 78% respectively,  $p < 0.0001$ ), restricted arm movement (0% versus 16% respectively,  $p < 0.0054$ ) and lymphoedema (0% versus 13% respectively,  $p < 0.0202$ ) but not for infection (0% versus 3% respectively,  $p < 0.5152$ ) or seroma (0% versus 5% respectively,  $p < 0.0813$ , Fisher's exact test).

-

**General comments** Data represent 100 procedures in 99 patients.

Patients who provide staging outcomes ( $n=56$ ) underwent axillary clearance either in the validation phase ( $n=34$ ) or based on a positive SN by intraoperative histology. The latter case introduced further patients with positive axillary status, thus raising the prevalence.

Since this series underwent mastectomy, and included patients with tumours that were large (8cm) or of advanced stage (T4). This may also increase the prevalence of axillary disease.

Assessment of morbidity outcomes was based upon clinical follow-up.

Some numerical errors were evident and no confidence intervals were reported. Statistical methods were otherwise adequately reported.

100 SLNB procedures were performed in 99 patients: therefore, one patient with two SLNB procedures yielded a greater influence than the 98 others with regard to morbidity outcomes.

Patient and tumour characteristics were reported for the whole series.

Naik, Fey, Gemignani, Heerdt, Montgomery, Petrek, Port, Sacchini, Sclafani, VanZee, Wagman, Borgen, Cody III, Bland, Ross, Leong, Morrow & Strasberg . The risk of axillary relapse after sentinel lymph node biopsy for breast cancer is comparable with that of axillary lymph node dissection: A follow-up study of 4008 procedures. Ann Surg 240[3]. 2004.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients with invasive, unilateral breast cancer, of tumour size T3 or less.

**Exclusion criteria** -

**Population** -

**Interventions** Aim: to measure the rate of axillary recurrence in different cohorts of patients staged by SLNB with or without axillary clearance.

(n=4008, selected from a total series of 6278 patients).

Patients were analysed in four groups:

Cohort 1: patients with positive SN result who underwent axillary clearance (n=1132)

Cohort 2: patients with negative SN result who did not undergo axillary clearance (n=2340)

Cohort 3: patients with positive SN result who, unconventionally, did not undergo axillary clearance (n=210). This decision was based upon clinical judgment and/or patient preference.

Cohort 4: patients with negative SN result who underwent axillary clearance (n=326) in the validation period.

SLNB technique

R, D.

Histology

FS, S, IHC.

**Outcomes** Rate of axillary local recurrence

**Follow up** -

**Results** STAGING

SN localisation rate reported as 97.3 %.

RECURRENCE

Median follow-up was 31 months (minimum 12 months).

There was axillary recurrence in 10 patients overall, out of 4008 patients (0.25%). In 3 patients (0.07%), the axillary recurrence was the sole initial site of treatment failure.

Axillary recurrence occurred in 4/1132 = 0.35% of patients cohort 1.

Axillary recurrence occurred in 3/2340 = 0.13% of patients cohort 2.

Axillary recurrence occurred in 3/210 = 1.4% of patients cohort 3.

Axillary recurrence occurred in 0/326 = 0% of patients cohort 4.

The axillary recurrence rate was 0.18% in the three conventionally treated cohorts (1, 2 and 4) compared to 1.4% in the unconventionally treated cohort 3 (p=0.013).

Of the 210 patients in cohort 3, 53 (25.2%) received adjuvant radiotherapy. Of these 23/53

(43%) underwent radiotherapy to the breast only and 30/53 (57%) underwent radiotherapy extended to the axilla: there was no recurrence in this sub group of 30 patients.

-

**General comments** The study had the advantage of a large sample size with the aim of recording a rare occurrence.

Given that as many as 23 SNs were removed in SLNB, the researchers set a threshold value of 10 nodes removed, above which patients were analysed as receiving axillary clearance, and below which patients were analysed as not receiving axillary clearance irrespective of whether the surgeon recorded axillary clearance as a procedure.

The Fisher exact test was used for the categorical variable of whether axillary recurrence occurred. No confidence intervals were reported.

The length of follow-up period was acknowledged by the authors as inadequate to detect all recurrence that may arise, since breast cancer has a long natural history.

Veronesi, Galimberti, Mariani, Gatti, Paganelli, Viale, Zurrada, Veronesi, Intra, Gennari, Rita, Luini, Tullii, Bassani & Rotmensz . Sentinel node biopsy in breast cancer: early results in 953 patients with negative sentinel node biopsy and no axillary dissection.[see comment]. Eur J Cancer 41[2]. 2005.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Italy, setting: Secondary care

**Inclusion criteria** Women with invasive breast cancer; mean tumour size 1.2 cm.

**Exclusion criteria** -

**Population** number of patients = 953, age range 24 to 86 years, mean age = 55 years.

**Interventions** Aim: to measure disease related events in a series of patients staged as N0 by SLNB, without axillary clearance (Cohort 2).

SLNB technique

L, R.

Histology

FS.

**Outcomes** Disease-related events, particularly axillary recurrence rate. Survival, estimated by Kaplan-Meier method.

**Follow up** Median follow-up was 38 months.

**Results** 55 unfavourable events occurred:

Axillary recurrence occurred in 3/953 = 0.3% of patients;

Local recurrence occurred in 12/953 = 1.3% of patients;

Contralateral breast cancer occurred in 5/953 = 0.5% of patients;

Distant metastases occurred in 20/953 = 2.1% of patients;

New primary tumours occurred in 13/953 = 1.4% of patients.

There were 6 deaths (5 due to breast cancer); 5-year mortality was estimated at 1.4% (standard error of mean: 0.6%).

-

**General comments** No exclusions from the analysis are reported, so the 953 patients reported appear to represent the entire cohort 2 for the centre.

198 women had already undergone an excisional breast biopsy prior to sentinel node biopsy, which would warrant exclusion from some SLNB studies.

Zavagno, Carcoforo, Franchini, Renier, Barutta, De Salvo, Maravegias, Capitanio, Nitti & Lise . Axillary recurrence after negative sentinel lymph node biopsy without axillary dissection: a study on 479 breast cancer patients. Eur J Surg Oncol 31[7]. 2005a.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Italy, setting: Secondary care

**Inclusion criteria** Patients with primary tumour size  $\leq$  3cm.

**Exclusion criteria** -

**Population** number of patients = 479, age range 31 to 86 years, median age = 61 years.

**Interventions** Aim: To measure the rate of axillary recurrence in cohort 2: patients staged as N0 by SLNB without axillary clearance.

SLNB technique

L, R.

Histology

FS, S, IHC.

**Outcomes** Rate of axillary recurrence.

**Follow up** -

**Results** Median follow up was 35.8 months (range 12 to 68 months).

No axillary recurrences were observed (rate = zero).

Authors conclude that patients with negative SLNB result are not exposed to increased risk of evident axillary recurrence in the short term.

-

**General comments** The study excluded 70/549 (12.8%) patients staged as N0 by SLNB who either underwent axillary clearance as a precaution or were lost to follow up. Only patients with 'successful' SLNB were eligible to be analysed so the study provided no estimate of the failure rate of SLNB. Therefore, the selection of cases appears to be justifiable.

Prognostic and demographic variables were well reported for the whole study group.

Systematic review of diagnostic studies

Kim, Giuliano & Lyman . Lymphatic mapping and sentinel lymph node biopsy in early-stage breast carcinoma: A metaanalysis. Cancer 106[1]. 2006.

Design: Systematic review of diagnostic studies (diagnosis, screening), evidence level: 2++

Country: United States, setting: Secondary care

**Inclusion criteria** Studies reporting original series of patients who underwent both SLNB plus axillary clearance as planned procedures, regardless of the result of SLNB.

**Exclusion criteria** -

**Population** number of patients = 8059, mean age = 57 years.

**Interventions** SLNB with planned axillary clearance (representing 'validation phase' for SLNB).

Of 69 included studies, SLNB technique was as follows:

R (16 studies)

D (18 studies)

Combined (34 studies)

**Outcomes** False negative rate (FNR)

Post-test probability negative (PTPN)

Diagnostic odds ratio (OR)

SN localisation rate

**Follow up** No follow-up reported; study assesses staging outcomes for SLNB.

**Results** 69 studies were included. Study quality, on a scale of 0-5 was  $\leq 2$  in 50% of studies and varied inversely with FNR ( $p=0.002$ ): FNR was 14% in the studies with the poorest quality score of zero.

Identification of SN:

SN localisation rate =  $7765/8059 = 96.35\%$

Mean number of SNs reported = 1.92 (median 2, mode 2)

Mean proportion of patients with positive SNs = 42% (median 40%, mode 50%, range 17%-74%)

FNR:

Reported FNR had mean 8.4%, median 7%, range 0%-29.4%

The observed FNR decreased with increasing study size ( $p=0.046$ ) and there was a statistically significant inverse correlation between FNR and SN localisation rate ( $p=0.001$ ).

Pooled estimate of FNR = 7.0% [95% CI 5.2%-8.8%,  $p<0.0001$ ]

PTPN:

There was a statistically significant inverse correlation between PTPN and SN localisation rate ( $p=0.0001$ ).

Pooled estimate of PTPN = 4.6% [95% CI 3.8%-5.4%,  $p < 0.0001$ ]

SLNB technique:

SN localisation rate varied by SLNB technique: 83.1% for dye alone, 89.2% for radiocolloid and 91.9% for combined technique ( $p = 0.007$ ).

FNR varied by SLNB technique: 10.9% for dye alone, 8.8% for radiocolloid and 7.0% for combined technique ( $p = 0.047$ ).

Multivariate analysis:

Statistically significant, independent predictors of the FNR in linear regression analysis (adjusted for study size) included:

Reporting of measures of test performance ( $p = 0.009$ );

SN localisation rate ( $p = 0.011$ )

Proportion of positive lymph nodes ( $p = 0.013$ ).

Statistically significant predictors of a FNR  $< 10\%$  included:

Reporting of patient characteristics (OR=5.8);

Description of reasons for study withdrawal (OR=6.6);

SN localisation rate  $> 90\%$  (OR= 3.5).

Statistically significant, independent predictors of the PTPN in linear regression analysis (adjusted for study size) included:

Proportion of positive lymph nodes ( $p = 0.003$ );

Reporting of measures of test performance ( $p = 0.010$ );

SN localisation rate ( $p = 0.013$ ).

Statistically significant predictors of a PTPN  $< 10\%$  included:

$< 50\%$  positive lymph nodes (OR=17.3);

SN localisation rate  $> 90\%$  (OR=17.5);

Reporting of patient characteristics (OR=9.7).

-

**General comments** Included studies represent 'validation phase' of SLNB i.e. with immediate axillary clearance as gold standard.

Review does not comment on the threshold used in each study to determine positive nodal status, particularly SN; i.e. related to histology technique.

Quality assessment of included studies considered:

Description of patient characteristics;

Reasons for study withdrawal;

Measures of test performance;

Measures of variability;

Description of the technique used (R, D or both).

Study quality assessment and data extraction was performed by two independent reviewers.

Rigorous assessment of study heterogeneity performed and appropriate methods used accordingly, for meta-analysis.

Cox, Bass, McCann, Ku, Berman, Durand, Bolano, Wang, Peltz, Cox, Salud, Reintgen & Lyman . Lymphatic mapping and sentinel lymph node biopsy in patients with breast cancer. Annu.Rev Med 51[pp 525-542]. 2000.

Design: Systematic review of diagnostic studies, evidence level: 2-  
Country: US/various, setting: Secondary care

**Inclusion criteria** Case series: 1147 women, mean age 58.5 years, median 57 years, SD 13.2 years

Systematic review: Studies with original study populations, axillary clearance performed as well as SLNB, with description of surgical/statistical methodology.

Total number of patients: 1842 in 12 series.

**Exclusion criteria** Case series: Pregnancy

**Population** -

**Interventions** Case series:

SLNB technique: R, D

Histology : FS (rarely), S, IHC

Systematic review:

SLNB technique: combined (4 studies), R (4 studies), D (4 studies)

**Outcomes** Staging performance of SLNB including:

Pre-test probability ( = prevalence of axillary disease by gold standard, axillary clearance)

Post-test probability negative (PTPN) (= probability of an axillary lymph node involvement in patients with a negative SN result).

PTPN = pre-test odds/[1 + post-test odds] where:

Post-test odds = pre-test odds x likelihood ratio (LR)

LR = [1 - sensitivity]/specificity

Pre-test odds = prevalence/[1 - prevalence]

**Follow up** Not reported: Study reports staging outcomes

**Results** Case series:

SN localisation rate = 1098/1147 = 95.7%

Number of SNs per patient = 2395/1098 = 2.2

Pre-test probability = 54/173 = 31.2%

FNR = 1/54 = 1.85%

Accuracy = 172/173 = 99.4%

PTPN = 0.83%

Systematic review:

SN localisation rate = 1534/1717 = 91.5%

Pre-test probability = 37.6% [95% CI 35.3% to 39.9%]

PTPN = 4.17% [95% CI 2.99% to 5.35%]

-

**General comments** Systematic review: Chi square test revealed low heterogeneity between 12 included studies therefore meta-analysis appears justified.

## Update of 6A – SLNB invasive BC

<p>Veronesi, U., Paganelli, G., Viale, G., Luini, A., Zurrada, S., Galimberti, V., Intra, M., Veronesi, P., Maisonneuve, P., Gatti, G., Mazzarol, G., De, C. C., Manfredi, G. &amp; Fernández, J. R. (2006) Sentinel-lymph-node biopsy as a staging procedure in breast cancer: update of a randomised controlled study. <i>The lancet oncology</i>, 7: 983-990.</p>
<p><b>Design:</b> RCT (extended follow-up from original Veronesi 2003 study), 1+</p>
<p><b>Country:</b> Italy</p>
<p><b>Aim:</b> to update the original Veronesi 2003 with results from longer follow-up, .</p>
<p><b>Inclusion criteria</b></p> <ul style="list-style-type: none"><li>• Women with breast tumours of diameter 2 cm or less were randomly assigned after breast-conserving surgery either to SLNB and total ALND (ALND group), or to SLNB followed by ALND only if the SLN was involved (SLN group).</li><li>• Analysis was restricted to patients whose tumour characteristics met eligibility criteria after treatment.</li></ul>
<p><b>Exclusion criteria</b> Multicentric cancer or previous excisional biopsy</p>
<p><b>Population</b> Women with breast tumours of diameter 2 cm or less. Women aged 40–75 years with invasive breast carcinoma and no history of any other cancer, except skin cancer, were eligible for inclusion.</p>
<p><b>Interventions</b> Women were randomly assigned after breast-conserving surgery either to SLNB and total ALND (ALND group), or to SLNB followed by ALND only if the SLN was involved (SLN group). 257 patients in the ALND group 259 patients in the SLN group</p>
<p><b>Outcomes</b> The main outcomes were: the number of axillary metastases in women in the SLN group with negative SLNs, staging power of SLNB, disease-free and overall survival (defined as time from surgery until the date of death (from any cause) or until the date of last follow-up.)</p> <p>Secondary outcomes: the development of any breast cancer- related event (reappearance of tumour within the breast; axillary, supraclavicular, or distant metastases)</p> <p>Associations between the status of the axillary nodes and the characteristics of the primary tumour were assessed by Fisher's exact test. Logistic regression was used to assess the association between various clinico-pathological characteristics (age, tumour size, location, grade, presence of peritumoral lymphatic and vascular invasion, oestrogen-receptor status, and proliferative rate) and SLN metastases.</p> <p>Mean follow-up of 78 months (median 79, range 15–97)</p>
<p><b>Results</b></p>

n=516 evaluable patients

Of the 257 patients in the ALND group, 83 (32%) had a positive SLN and 174 (68%) had a negative SLN;

8 (5%) of those with negative SLNs were found to have false-negative SLNs.

Of the 259 patients in the SLN group, 92 (36%) had a positive SLN, and 167 (65%) had a negative SLN;

1 case of overt clinical axillary metastasis was seen in the follow-up of the 167 women in the SLN group who did not receive ALND (ie, one false-negative).

After a median follow-up of 79 months (range 15–97), 34 events associated with breast cancer occurred: 18 in the ALND group, and 16 in the SLN group (log-rank  $p=0.6$ ).

The overall 5-year survival of all patients was 96.4% (95% CI 94.1–98.7) in the ALND group and 98.4% (96.9–100) in the SLN group (log-rank  $p=0.1$ ).

Characteristics predictive of SLN status:

- peritumoral vascular invasion (linked to a very high rate of SLN metastases (61 of 87 patients; 70%))
- size of primary carcinoma (the prevalence of SLN metastases varied from 22% (28 of 130 patients) in tumours less than 1.0 cm in diameter to 38% (55 of 143 patients) in tumours larger than 1.5 cm.
- Age, site of primary carcinoma, oestrogen-receptor status, grade, and proliferative fraction did not show any significant relation with involvement of SLNs.

### **General comments**

SLNB can allow total ALND to be avoided in patients with negative SLNs, while reducing postoperative morbidity and the costs of hospital stay. The finding that only one overt axillary metastasis occurred during follow-up of patients who did not receive ALND (whereas eight cases were expected) could be explained by various hypotheses, including those from cancer-stem-cell research.

Krag, D. N., Anderson, S. J., Julian, T. B., Brown, A. M., Harlow, S. P., Ashikaga, T., Weaver, D. L., Miller, B. J., Jalovec, L. M., Frazier, T. G., Noyes, R. D., Robidoux, A., Scarth, H. M., Mammolito, D. M., McCready, D. R., Mamounas, E. P., Costantino, J. P., Wolmark, N. & National Surgical Adjuvant Breast and Bowel Project (2007) Technical outcomes of sentinel-lymph-node resection and conventional axillary-lymph-node dissection in patients with clinically node-negative breast cancer: results from the NSABP B-32 randomised phase III trial. *The lancet oncology*, 8: 881-888.

**Design:** RCT, 1+

**Country:** US

**Aim:** To evaluate the efficacy and safety of SLN biopsy compared to ALND.

**Inclusion criteria**

Women with operable invasive primary breast cancer and clinically negative nodes.

The randomisation was stratified according to age at entry ( $\leq 49$  years or  $\geq 50$  years); surgical treatment plan (lumpectomy or mastectomy); and clinical tumour size ( $\leq 2.0$  cm, 2.1–4.0 cm, or  $> 4.0$  cm).

**Exclusion criteria**

**Population**

5611 women with invasive breast cancer were randomly assigned to receive either SLN resection followed by immediate conventional ALND (n=2807; group 1) or SLN resection without ALND if SLNs were negative on intraoperative cytology and histological examination (n=2804; group 2)

Patients in group 2 underwent ALND if no SLNs were identified or if one or more SLNs were positive on intraoperative cytology or subsequent histological examination.

**Interventions**

Women were randomised into SLN biopsy associated with ALND (ALND group) or SLN biopsy followed by ALND only if the SLN was metastatic (SLN group)

**Outcomes**

- Accuracy and technical success of SLN resection plus ALND versus SLN resection alone
- Side effects

**Results**

Technical success (defined as the ability to identify and remove at least one SLN)

- 97.3% (2672 of 2746) in group 1: 74 patients in group 1 did not have SLNs identified
- 97% (2707 of 2790) in group 2: 83 patients in group 2 did not have SLNs identified.

Overall nodal status was established from the histological status of all examined lymph nodes:

- For 766 patients (29.2%) overall nodal status was positive; for the remaining 1853 patients it was negative (70.8%).
- **Of the 1928 SLN negative patients, 1853 (96.1%) were confirmed to be node negative by ALND (negative predictive value).**
- **75 patients classified as node negative by SLN biopsy were node positive on subsequent**

**ALND:**

- false-negative rate = 9.8% (75 of 766; 95% CI 7.8–12.2)
- sensitivity = 90.2% (691 of 766; 87.8–92.2).

- Overall accuracy of SLN resection in this group of patients was 97.1% (2544 of 2619; 96.4–97.7).

**Assessment for possible association with false-negative rates:**

- Differences in tumour location when assessed by region, type of previous diagnostic biopsy, and number of SLNs removed statistically affected false-negative rates.
- Data on the relation between intraoperative cytology and subsequent histological examination were available for 2697 patients in group 2.
- Overall accuracy of intraoperative cytology = 89.7% (2418 of 2697; 95% CI 88.4–90.8%).
- The negative predictive value of intraoperative cytology = 88.1% (86.7–89.4).
- The positive predictive value = 97.5% (95.4–98.7).
- The false-negative rate for intraoperative cytology = 38.6% (268 of 694; 35.0–42.4).
- Sensitivity of intraoperative cytology = 61.4% (426 of 694; 57.6–65.0).
- Only 11 of the 2003 patients deemed to have negative nodes on histological examination were classified as having positive nodes on intraoperative cytology (0.5%; 0.3–1.0).

Of the 5379 patients who had at least one SLN removed, similarities in those who were SLN positive, across groups, were observed: (26.0% [694 of 2672] in group 1 and 25.7% [696 of 2707] in group 2;  $p=0.85$ ).

Of the 5536 patients who had an SLN procedure done (with or without technical success):

- 28.5% (783 of 2746) in group 1 were identified as node positive,
- 25.6% (715 of 2790) of patients in group 2,
- a difference of 2.9% ( $p=0.02$ )

Author claim: Because this was a randomised trial, it maybe assumed that about 2.9% of positive-node patients in group 2 were misclassified as node negative because their positive nodes were not removed by ALND.

- In 61.4% (426 of 694) of SLN-positive patients in group 1, positive SLNs were the only positive nodes identified. Although the nodal status of the remaining SLN-positive patients was correctly established by doing an ALND, 38.6% (268 of 694) of the SLN-positive patients would have had at least one unresected positive node if completion ALND had not been done.
- In the patients with pathologically positive SLNs, the pathologically positive SLN specimens were located exclusively outside axillary levels I and II in 1.4% of cases. Because conventional ALND would not have identified these patients as node positive, they would have been incorrectly classified as node negative if only ALND had been done.

**Adverse Events:**

- Allergic reactions were associated with blue dye injections: Out of 5588 patients with data on toxic effects: 0.4 % ( $n=25$ ) had grade 1 or 2 allergic reactions and 0.2% ( $n=12$ ) had grade 3 or 4 allergic reactions.
- No deaths due to allergic reactions were reported.

**General comments**

Summary from Abstract:

**Findings**

Data for technical success were available for 5536 of 5611 patients; 75 declined protocol treatment, had no SLNs removed, or had no SLN resection done. SLNs were successfully removed in 97.2% of patients (5379 of 5536) in both groups combined. Identification of a

preincision hot spot was associated with greater SLN removal (98·9% [5072 of 5128]). Only 1·4% (189 of 13171) of SLN specimens were outside of axillary levels I and II. 65·1% (8571 of 13171) of SLN specimens were both radioactive and blue; a small percentage was identified by palpation only (3·9% [515 of 13171]). The overall accuracy of SLN resection in patients in group 1 was 97·1% (2544 of 2619; 95% CI 96·4–97·7), with a false-negative rate of 9·8% (75 of 766; 95% CI 7·8–12·2). Differences in tumour location, type of biopsy, and number of SLNs removed significantly affected the false-negative rate. Allergic reactions related to blue dye occurred in 0·7% (37 of 5588) of patients with data on toxic effects.

### **Interpretation**

The findings reported here indicate excellent balance in clinical patient characteristics between the two randomised groups and that the success of SLN resection was high. These findings are important because the B-32 trial is the only trial of sufficient size to provide definitive information related to the primary outcome measures of survival and regional control. Removal of more than one SLN and avoidance of excisional biopsy are important variables in reducing the false-negative rate.

Zavagno, G., De Salvo, G. L., Scalco, G., Bozza, F., Barutta, L., Del, B. P., Renier, M., Racano, C., Carraro, P., Nitti, D. & GIVOM, T. (2008) A Randomized clinical trial on sentinel lymph node biopsy versus axillary lymph node dissection in breast cancer: results of the Sentinella/GIVOM trial. *Annals of Surgery*, 247: 207-213.

**Design:** RCT 1+

**Country:** Italy

**Aim:** To evaluate the effectiveness of SLN biopsy followed by standard ALND with SLN biopsy followed by ALND (only if the SLN was found to be positive at histology)

**Inclusion criteria**

Patients with invasive breast cancer  $\leq 3$  cm and clinically negative axilla.

**Exclusion criteria**

Nonpalpable tumors, multiple tumors, ductal carcinoma in situ, tumors  $\geq 3$  cm, clinically positive axilla, distant metastases, previous neoadjuvant therapy, pregnancy, age  $>80$  years

**Population**

697 patients available for the analysis.

**Interventions**

1. Patients in the first arm (ALND group) underwent SLN biopsy immediately followed by standard ALND.
2. Patients in the second arm (SLN group) underwent SLN biopsy with frozen section examination and ALND was performed only in patients with metastatic SLN. In cases with negative SLN frozen section examination but positive definitive histology, a delayed ALND was performed.

**Outcomes**

disease-free survival (DFS), overall survival (OS), physical morbidity, and quality of life.

**Results**

**Identification and Removal of the SLNs:**

SLNs were identified in 662 cases (95.0%).

The rate of identification was similar in the 2 arms (94.9% in the ALND arm and 95.1% in the SLN arm).

**SLN Status and False Negative Rate:**

Of the 334 patients with identified SLNs in the ALND group, 90 had a positive SLN at definitive histology (26.9%, 95% CI 22.3–32.0)

Among the 328 patients with identified SLNs in the SLN group, 99 had a positive SLN at definitive histology (30.2%, 95% CI 25.3–35.5)

Among the 323 patients who underwent ALND in this group, 90 had a positive SLN and 233 had a negative SLN at the definitive histology.

- 18 of 233 patients with negative SLNs were found to have other nodal metastases in the ALND specimen: negative predictive value = 92.3% (215 of 233 patients, 95% CI 88.1–95.4),
- overall accuracy of the SLN status = 94.4% (305 of 323 patients, 95% CI 91.3–96.7)
- sensitivity was 83.3% (90 of 108 patients, 95% CI 74.9–89.8)
- specificity was 100% (by definition)
- The false negative rate was 16.7% (18 of 108 patients, 95% CI 10.2–25.1).

**Side Effects and Quality of Life Evaluation**

Women in the SLN group had significantly less lymphoedema ( $P = 0.01$ ), restrictions of shoulder mobility ( $P = 0.016$ ), and numbness ( $P < 0.0001$ ) compared with those in the ALND group.

No differences were found between the 2 groups in all HRQOL domains of the SF-36.

The analysis of the Psychological General Well Being Index questionnaire showed a more positive outcome in the anxiety domain and in the general index for the SLN group ( $P = 0.013$  and  $P = 0.015$ , respectively).

### **Unfavorable Events (Disease recurrence and Survival)**

Median follow up = 55.6 months.

At the time of analysis, there were 51 events, 22 in the ALND group and 29 in the SLN group

- Locoregional recurrences have occurred in 3 patients in the ALND group and in 16 patients in the SLN group (Local recurrences in the SLN group: 8 ipsilateral breast and 4 thoracic wall recurrences compared with 2 ipsilateral breast and 1 thoracic wall recurrences in the ALND arm).
- 5 cases of contralateral breast cancer (3 in the ALND group and 2 in the SLN group)
- Distant metastases in 16 patients in the ALND group and in 11 patients in the SLN group
- Other primary tumors were detected in 1 patient in the ALND group and 3 patients in the SLN group.
  
- 35 patients died, 18 from metastatic breast cancer (8 in the ALND group and 10 in the SLN group) and 17 from other causes (6 in the ALND group and 11 in the SLN group).

At 5 years, the Kaplan-Meier estimates of DFS:

- ALND 89.9% (95% CI 85.3–93.1)
- SLN group 87.6% (95% CI 83.3–90.9)

The difference was 2.3% ( $P = 0.7692$ ) with a 95% CI ranging from -3.1% to 7.6%.

(Because the upper bound is more than the acceptable difference of 6%, it can not exclude the possibility of a worse DFS in the SLN arm.)

The 5 years Kaplan-Meier estimates of OS:

- 95.5% (95% CI 92.2–97.5) in the ALND group
- 94.8% (95% CI 91.6 –96.8) in the SLN group

### **General comments**

The high false negative rate was explained as an consequence of inexperienced and untrained surgeons conducting the procedure. The authors claim that this would probably reflect standard practice and that the levels reported in other studies was probably higher than the reality.

Lucci, A., Mccall, L. M., Beitsch, P. D., Whitworth, P. W., Reintgen, D. S., Blumencranz, P. W., Leitch, A. M., Saha, S., Hunt, K. K., Giuliano, A. E. & American College of Surgeons Oncology Group (2007) Surgical complications associated with sentinel lymph node dissection (SLND) plus axillary lymph node dissection compared with SLND alone in the American College of Surgeons Oncology Group Trial Z0011. *Journal of clinical oncology : official journal of the American Society of Clinical Oncology*, 25: 3657-3663.

**Design:** RCT, 1

**Country:** US

**Aim:** To compare the complications associated with SLN dissection (SLND) plus ALND, versus SLND alone.

**Inclusion criteria**

All participants were women at least 18 years old undergoing breast conservation therapy who had clinical T1 or T2, N0, M0 breast cancer; one or two positive SLNs; and an Eastern Cooperative Oncology Group/Zubrod functional status  $\leq 2$

**Exclusion criteria**

Patient withdrawal before surgery; nodes not positive on examination of HE-stained samples; too many positive SLNs; distant metastatic disease; unclear margins; presence of gross extra capsular invasion; and various other reasons.

**Population**

group 1 (SLND+ALND; n=445)

group 2 (SLND alone; n=446)

**Interventions**

- SLN dissection (SLND) plus ALND, versus SLND alone.
- SLNDs were performed with isosulfan blue, a radiopharmaceutical, or both.
- Patients with a medial hemisphere lesion had preoperative lymphoscintigraphy to confirm axillary drainage. After the blue and/or hot nodes were removed, any remaining axillary nodes were palpated; if suggestive of disease, they were considered SLNs and removed.
- ALND was defined as the removal of all anatomic level I and II nodes on the affected side, with at least 10 identified nodes per axillary specimen.

**Outcomes**

- Adverse effects for all operative procedures were recorded at 30 days, every 6 months until year 3, and then annually.
- Surgical effects assessed at day 30 included wound infections, axillary seroma, axillary paresthesia, and brachial plexus injury (BPI).
- Surgical effects documented every 6 months included axillary paresthesia, Lymphoedemas and BPI.

**Results**

**Adverse surgical effects:**

- 70% (278 of 399) of patients after SLND+ ALND
- 25% (103 of 411) after SLND alone ( $P \leq 0.001$ )

**Wound Infection:**

On multivariate analysis, both greater BMI ( $P=0.0113$ ) and having had an ALND ( $P=0.0026$ ) were significant predictors for developing a wound infection, but age and number of nodes removed were not significant predictors.

**Axillary Seromas at 30 Days:**

- Having had an ALND was a significant predictor ( $P \leq 0.0001$ ) for axillary seroma at 30 days
- Older age was a significant predictor of seroma formation ( $P= 0.028$ ) in the SLND+ALND arm but not in the SLND-alone arm.
- When age, BMI, and linked age and study group were included in a model to evaluate association; the age and age/study group linkage were significant predictors of seroma.
- BMI and number of nodes removed were not significant in any of the models.

**Axillary Paresthesias**

- At day 30 : Axillary paresthesias were the most common surgical effect
- Having had an ALND was the only factor that predicted axillary paresthesias at any time point ( $P<0.0001$ )
- The number of nodes removed was a significant predictor of paresthesia 30 days after an ALND but not after SLND alone
- There was no significant decline in reported axillary paresthesias at 6 or 12 months compared with rates at 30 days.
- Younger age remained a significant predictor for paresthesia 1 year after ALND ( $P=0.0131$ ), but the number of nodes removed did not remain a significant predictor (from multivariate analysis).

**Lymphoedema**

- From multivariate analysis, having ALND was not a significant predictor of lymphoedema at 6 months, but it was significant at 1 year ( $P< 0.0001$ ) and after 12 months ( $P,0.0001$ )
- When subjective data from all follow-ups were combined, having had an ALND was also a significant predictor of lymphoedema ( $P \leq 0.0001$ ).
- Based on proximal arm measurement data, no clinical factors (including number of nodes removed) reliably predicted lymphoedema at 30 days, 6 months, or 1 year. (arm measurements were not always recorded at these follow-up times and the number of patients for whom data were available was much lower than the number of assessable patients).

**BPI**

- True overall BPI incidence = 8 of 821 (0.97%)
- 18 BPIs were reported originally, but when re-evaluated, 10 should have been more accurately classified as axillary paresthesias.
- 88% of all BPIs were resolved at last follow-up

**General comments**

Authors' conclusion:

In this trial Z0011, the use of SLND + ALND resulted in more wound infections, axillary seromas, and paresthesias than SLND alone. Lymphoedema was more common after SLND + ALND but was significantly different only by subjective report. The use of SLND alone resulted in fewer complications.

**Evidence Tables**  
**Axillary sampling**

**Randomized controlled trials**

Chetty, Jack, Prescott, Tyler & Rodger . Management of the axilla in operable breast cancer treated by breast conservation: a randomized clinical trial. Edinburgh Breast Unit.[see comment]. Br J Surg 87[2]. 2000.

**Design**

Randomized controlled trial (therapy), evidence level: 1+  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria**

Patients of age <70 years with unilateral invasive breast cancer of clinical size <=4cm and no evidence of metastatic disease.

**Exclusion criteria**

Patients with clinically multicentric or inoperable tumours or those with fixed nodes or history of previous malignancy except skin basal cell carcinoma.

**Population**

Number of patients = 466, median age = 54 years.

**Interventions**

Axillary sample group (n=234): underwent breast conserving surgery plus removal of a minimum of four nodes by incision and palpation [without any localisation aid].

Axillary clearance group (n=232): underwent breast conserving surgery plus level III axillary clearance.

**Outcomes**

Overall survival  
Disease free survival  
Axillary recurrence free survival

Arm volume and circumference  
Shoulder mobility and muscle power

**Follow up**

Median follow-up was 4.1 years

**Results**

There was no statistically significant difference between randomised groups for overall survival [p=0.2, log rank test] or disease free survival [p=0.68, log rank test].

Survival:

The estimated 5 year survival rate was 88.6% (SD 2.5%) in the axillary sample group and 82.1% (SD 3.1%) in the axillary clearance group. 5 year estimated disease free survival rates were 79.1% (3.1%) and 76.0% (3.5%) respectively.

**Axillary recurrence:**

There was no significant difference between randomised groups in axillary recurrence ( $p=0.94$ , log rank test).

**Morbidity:**

At 6 months from surgery, arm flexion was statistically significantly lower in the axillary clearance group ( $p=0.003$  ANCOVA) and in the axillary sample plus RT group ( $p=0.004$ ) compared to the axillary sample group.

There were no differences between groups in power to flex the shoulder at any time point, nor in abduction.

There was little difference in the upper arm circumference between the three groups. At three years from surgery the forearm circumference was significantly greater after axillary clearance than after node sample ( $p=0.005$ ) or node sample plus RT ( $p=0.04$ ).

**General comments**

For axillary sample, nodes were identified starting at the axillary tail and working upwards.

Patients received/did not receive radiotherapy (RT) on an individual basis according to clinical judgement/standard practice at the time, and not by random allocation:

All but 48 patients received breast RT

5/232 patients in the axillary clearance group received axillary RT.

91/234 patients in the axillary sample group received RT.

29 patients did not receive their randomised treatment. 12 patients were found to have benign or non-invasive disease.

Survival analyses are by ITT.

Morbidity analyses are by treatment received [3 groups]:

Axillary clearance;

Axillary sample plus axillary RT;

Axillary sample.

Study does not appear to provide compelling evidence on morbidity due to non-ITT analysis, numerous assessment points, 3 analysis groups and incomplete reporting.

A median of 15 nodes were removed in the axillary clearance group (range 4-36) and a median of 5 (range 2-12) in the axillary sample group.

Forrest, Everington, McDonald, Steele, Chetty & Stewart . The Edinburgh randomized trial of axillary sampling or clearance after mastectomy. Br J Surg 82[11]. 1995.

**Design**

Randomized controlled trial (diagnosis, screening), evidence level: 1+  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria**

Patients with clinically operable invasive breast cancer (T1-2 or operable T3, N0-1, M0).

Median ages in randomised groups were 58.7 and 57.

**Exclusion criteria**

Patients unlikely to participate in continuous follow up, those with Paget's disease of the nipple, insitu disease or multifocal or contralateral breast cancer.

**Population**

number of patients = 417.

**Interventions**

Intervention group (n=203): Total mastectomy plus removal of a target of four nodes by incision and palpation [without any localisation aid].

Control group (n=203): Total mastectomy plus axillary clearance.

**Outcomes**

Survival  
Recurrence

**Follow up**

Median 11 years (range 2-13 years)

**Results**

Disease specific survival

There was no significant difference between groups for disease specific survival at a median of 11 years follow up: 57/203 patients died due to breast cancer in the axillary sample group compared to 54/203 in the axillary clearance group, HR 1.11 [95% CI 0.80-1.53].

Distant recurrence

There was no significant difference between groups for distant recurrence at a median of 11 years follow up: HR as above 1.05 [95% CI 0.74-1.5].

Locoregional recurrence

There was no significant difference between groups in terms of locoregional recurrence: 29 patients had locoregional recurrence in the axillary sample group compared with 38 in the axillary clearance group (HR 1.35 in favour of axillary sample group [95% CI 0.83-2.19]).

General comments The last 135 randomised patients all underwent axillary sample prior to randomisation in theatre, with axillary clearance performed

immediately where allocated.

Analysis of reported outcomes was by ITT. 11 patients were ineligible and excluded and 23 patients had protocol violations but were analysed as per ITT.

Time to event analysis was by Kaplan-Meier curves and Cox survival models.

A mean of 6 nodes (median 4) were removed in the axillary sample group and a mean of 20 (median 20) were removed in the axillary clearance group.

82/86 patients with involved nodes in the axillary sample group received RT to the chest wall and axilla; no patients in the axillary clearance group received RT.

## Retrospective comparative studies

Cserni . The reliability of sampling three to six nodes for staging breast cancer. J Clin Pathol 52[9]. 1999.

### Design

Retrospective comparative study (diagnosis, screening), evidence level: 3  
Country: Hungary, setting: Secondary care

### Inclusion criteria

499 patients with pathological nodal stage pN0-1, identified from a consecutively treated series.

### Exclusion criteria

None stated.

### Population

Number of patients = 499.

### Interventions

Aim: to assess the optimal number of axillary nodes that are required to stage the axilla.

A retrospective review of pathology reports was performed. Patients underwent axillary clearance with nodes numbered consecutively in order of their size, based on the blue staining area on haematoxylin and eosin histology.

### Outcomes

Rate of concordance of sampling 3, 4, 5 and 6 nodes, based on size order, with axillary clearance.

### Follow up

Not reported.

### Results

Mean no. of lymph nodes per axillary specimen was 10.7 (range 1-45).

The rates of concordance (%) of the information provided by limited sampling of nodes with that of axillary clearance were as follows:

Based on definitively positive axillae:

3 nodes: 89-93%

4 nodes: 94-97%

5 nodes: 95-98%

6 nodes: 97-98%

Based on all axillae:

3 nodes: 94-96%

4 nodes: 97-98%

5 nodes: 98-99%

6 nodes: 99%

### General comments

Ranges in results arise from cases where nodes were of similar size such that they were allocated size rank jointly e.g. 3 nodes of similar size, each labelled, '2-4'.

It appears that patients did not undergo limited sampling, but axillary clearance: the analysis considered information provided by a limited number of nodes compared to that provided by axillary clearance.

Kingsmore, Ssemwogerere, Hole, Gillis & George . Increased mortality from breast cancer and inadequate axillary treatment. Breast 12[1]. 2003.

**Design**

Retrospective comparative study (therapy), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria**

4637 patients who received axillary staging with number of nodes examined stated, out of a consecutive series of 7144 patients with invasive breast cancer, identified from a cancer registry.

**Exclusion criteria**

364 patients who underwent staging surgery but with no report of the number of nodes examined.

**Population**

Number of patients = 4637.

**Interventions**

Aim: to derive the minimum number of nodes required to safely stage the axilla in patients with breast cancer.

Survival and pathological data were retrospectively reviewed in a large series of patients with breast cancer and also in a reference group of patients in whom 10 or more lymph nodes were removed for staging (considered to be adequate staging based on previous literature).

**Outcomes**

Survival (based on breast cancer specific mortality)

**Follow up**

Mean 9.5 years, range 3-18 years

**Results**

Compared to the reference group, node negative patients had significantly greater survival at 5 and 10 years where 4 or more nodes were examined, compared to where 1-3 nodes were examined (hazard ratio [HR] 1.31 [95% CI 1.07-1.60],  $p < 0.01$ ).

Compared to the reference group, node positive patients had significantly greater survival at 5 and 10 years where 4 or more nodes were examined, compared to where 1-3 nodes were examined (HR 1.85 [95% CI 1.54-2.21],  $p < 0.01$ ).

Application of 4 node threshold to series of 4637 patients:

In node-negative patients, those who had examination of four or more axillary nodes had statistically significantly increased survival compared to patients who had 3 or less nodes examined (87% and 81% respectively, at 5 years; 76% and 70% respectively, at 10 years, HR 1.34 [95% CI 1.09-1.65]).

In node-positive patients, those who had examination of four or more axillary

nodes had statistically significantly increased survival compared to patients who had 3 or less nodes examined 59% and 53% respectively, at 5 years; 42% and 35% respectively, at 10 years, HR 1.20 [95% CI 1.02-1.41]).

**General comments**

No information on tumour grade was analysed.

The effects of adjuvant RT, chemotherapy and hormone therapy were not accounted for.

Variation in pathology technique was not accounted for.

No details are provided about intended surgical staging techniques e.g. whether axillary clearance, unguided sample or blue dye guided sample. Patients were treated prior to 1994; hence no patients underwent SLNB.

The reference group was verified by demonstrating that node positivity varied by tumour size, and that these factors were associated with survival. Size of reference group not reported.

## Prospective case series

Hadjiminas & Burke . Intraoperative Assessment of Nodal Status in the Selection of Patients with Breast-Cancer for Axillary Clearance. Br J Surg 81[11]. 1994.

### Design

Prospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

### Inclusion criteria

114 patients with operable breast cancer of stage I-II.

### Exclusion criteria

None stated.

### Population

Number of patients = 114.

Interventions Aim: to report on a centre's experience with axillary sample as an alternative procedure to automatic axillary clearance.

All patients underwent an unguided axillary sample of four nodes. Patients with disease revealed by intra-operative contact cytology underwent axillary clearance. Patients with negative contact cytology underwent no further surgery.

### Outcomes

Objective arm lymphoedema, defined as: difference between the sum of the circumferences of the normal and affected arm, measured at 2 points, was 4cm or more.

Objective shoulder stiffness, defined as: maximum abduction of 160 degrees or less.

### Follow up

Mean 18.7 months, median 20 months.

### Results

43 patients underwent axillary clearance in addition to axillary sample due to positive cytology and 71 patients axillary sample only due to negative cytology.

Rate of lymphoedema:

After axillary clearance: 6/43 = 14.0%

After axillary sample alone: 0/71 = 0% ( $p < 0.02$ , Fishers exact test).

### General comments

No patients received axillary RT.

Paper does not state that 5 patients with apparent falsely negative contact

cytology result underwent axillary clearance.

The result may be confounded by the effect of having two surgical procedures rather than one.

Very little data reported on shoulder stiffness: no statistical test reported.

Hoar & Stonelake . A prospective study of the value of axillary node sampling in addition to sentinel lymph node biopsy in patients with breast cancer. Eur J Surg Oncol 29[6]. 2003.

**Design**

Prospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria**

66 consecutive patients with primary, operable, invasive breast cancer.  
1 patient had bilateral breast cancer and so 67 axillae represent the cases.

**Exclusion criteria**

No exclusions were made on the basis of tumour size or patient age.

**Population**

Number of patients = 66, age range 27 to 86 years, mean age = 55 years.

**Interventions**

Aim: to assess the staging performance of SLNB plus axillary sample as a staging procedure, compared to axillary clearance as gold standard.

All patients underwent SLNB, extended where necessary such that all patients had a minimum of 4 nodes removed as the 'SLNB plus axillary sample' procedure. If 4 or more SNs were removed, then only suspicious further nodes were removed as the 'SLNB plus axillary sample' procedure.

All patients then underwent a level II axillary clearance.

SLNB technique: radiocolloid, dye, lymphoscintigraphy.  
Histology technique: all nodes were examined by a single, standard section.

**Outcomes**

Staging performance (against axillary clearance as gold standard) of:  
SLNB alone;  
SLNB extended to axillary sample (reported by whether additional sampled nodes were palpably suspicious during surgery).

**Follow up**

Not reported

**Results**

Median no. of SNs removed per case in SLNB= 2 (range 1-8).  
Median no. of nodes removed in SLNB plus axillary sample = 5 (range 2-14).  
Median total no. of nodes removed (SLNB plus axillary sample plus axillary clearance) = 16 (range 7-35).

Staging performance of SLNB alone:  
SN identification rate = 65/67 = 97%  
No. SNs removed per patient = median 2 (range 1-8)  
Prevalence of axillary disease = 29/67 = 43.3%, or amongst patients with localised SNs, 28/65 = 43.1%.  
FNR = 4/28 = 14.3%

Accuracy =  $[24+37]/65 = 93.8\%$

Staging performance of SLNB extended to axillary sample of a minimum of 4 nodes where further sampled nodes included palpably suspicious nodes:

FNR =  $1/28 = 3.6\%$

Accuracy =  $[27+37]/65 = 98.5\%$

Staging performance of SLNB extended to axillary sample of a minimum of 4 nodes where further sampled nodes did not include any palpably suspicious nodes:

FNR =  $1/28 = 3.6\%$

Accuracy =  $[27+37]/65 = 98.5\%$

i.e. staging performance of SLNB plus axillary sample did not vary by whether the further sampled nodes were palpably suspicious.

### **General comments**

8 patients had undergone excision biopsy or wide local excision prior to SLNB, for presumed DCIS and one patient had received neoadjuvant chemotherapy.

The 'SLNB plus axillary sample' procedure may not be independent of the SLNB procedure and the research setting is not as rigorous as one where axillary sample is the first procedure performed.

In some cases a procedure was classified as both a SLNB and a 'SLNB plus axillary sample'; hence the sample was a guided sample by radiocolloid, lymphoscintigraphy and dye.

SLNB did not use serial sectioning, but all nodes received the same histological technique.

High FNR may be related to the patients in the series: 27.7% of patients had tumours >30mm in size.

Ishikawa, Momiyama, Hamaguchi, Tanabe, Tomita, Ichikawa, Nakatani, Sasaki, Nozawa, Inayama, Inui & Shimada . Blue-dye technique complements four-node sampling for early breast cancer. Eur J Surg Oncol 31[10]. 2005.

**Design**

Prospective case series (diagnosis, screening), evidence level: 3  
Country: Japan, setting: Secondary care

**Inclusion criteria**

33 consecutive patients with breast cancer of clinical stage N0-1

**Exclusion criteria**

None stated.

**Population**

Number of patients = 33, age range 26 to 75 years, mean age = 53 years.

**Interventions**

Aim: to evaluate the staging performance of dye assisted axillary sample compared to axillary clearance as gold standard.

All patients underwent a dye-assisted axillary sample of a target of four nodes, including non-blue-staining, palpable nodes, followed by a level II axillary clearance.

**Outcomes**

Staging performance of dye-assisted axillary sample.

**Follow up**

Not reported.

**Results**

Mean no. of blue stained nodes per patient (range) = 1.7 (0-4).

Mean no. of nodes sampled per patient (range) = 3.4 (0-7).

Total no. of nodes removed, including axillary clearance (range) = 18 (0-32).

Prevalence of axillary disease = 11/32 = 34.4%

FNR = 0/11 = 0%

Accuracy = 32/32 = 100%

**General comments**

Study is hampered by small series size.

Study represents a validation period for dye-assisted axillary sample.

13 patients underwent preoperative excisional biopsy, which may hamper the identification rate of nodes by blue dye.

Inclusion of clinically N1 patients may act to increase prevalence of axillary disease by gold standard assessment.

32/33 patients underwent axillary clearance as gold standard: 1 patient with non-invasive DCIS did not undergo axillary clearance. Therefore staging

results are based on 32 patients.

Results shown are for a dye-assisted axillary sample, with palpation to include a target of four nodes, even if non-blue nodes are included.

A larger observational study was also initiated of axillary sample with axillary clearance only in cases of positive sample: only minimal results available with unspecified follow-up; not reported here.

Macmillan, Barbera, Hadjiminias, Rampaul, Lee & Pinder . Sentinel node biopsy for breast cancer may have little to offer four-node-samplers: Results of a prospective comparison study. Eur J Cancer 37[9]. 2001.

### **Design**

Prospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

### **Inclusion criteria**

200 consecutive patients with biopsy-proven primary invasive breast cancer of clinical stage T1-2, N0, M0.

### **Exclusion criteria**

Not reported.

### **Population**

Number of patients = 200.

### **Interventions**

Aim: to compare the staging performance of SLNB with axillary sample.

All patients received preoperative injection of radiocolloid.

During surgery all patients underwent axillary sample of a minimum of four nodes, based on palpation.

SNs were identified ex vivo using a gamma probe and the operated axilla was also probed for potentially remaining SNs. Any such SNs found in vivo were also removed.

SN identification technique: radiocolloid

Histology technique: 3-5mm intervals with standard (haematoxylin and eosin) assessment.

### **Outcomes**

Explores relationship between SNs and nodes examined by axillary sample.

### **Follow up**

Not reported.

### **Results**

A mean of 1.5 SNs were identified in total (ex vivo plus in vivo) per patient (range 1-3).

In 153/191 = 80.1% of patients with one or more SNs identified, all of the SNs were removed within the axillary sample.

In 38/191 = 19.9% of patients with one or more SNs identified, SNs were identified in the axilla after performing axillary sample.

Prevalence of axillary disease = 60/200 = 30%.

In 1 patient the axillary sample did not include a SN that was histologically positive for disease.

Other staging performance outcomes not reported since study does not evaluate true SLNB.

**General comments**

Study does not evaluate true performance of SLNB, but an artificial alternative.

The first SN was classed as the 'hottest' node ex vivo. Further SNs were defined by demonstrating 25% of the radioactivity of the first SN.

15 patients underwent preoperative scintigraphy.

Study design assumes:

that the preoperative scintigraphy did not influence which nodes were excised;  
that SN identification can be performed ex vivo to the same standard as in vivo;

that the axillary sample surgery does not affect the identification of further SNs in vivo.

Narreddy, Govindarajulu, Cawthorn & Sahu . Sentinel node biopsy in multifocal breast cancer: Accuracy of blue dye assisted four node sample. Ejc Supplements 4[2]. 2006.

**Design**

Prospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria**

17 patients with multifocal breast cancer, identified from a series of 74 patients who underwent axillary sample with blue dye and subsequent axillary dissection.

**Exclusion criteria**

None reported

**Population**

Number of patients = 17, mean age = 57 years.

**Interventions**

Aim: to report on the centre's validation period for axillary sample of four nodes with blue dye in patients with multifocal breast cancer.

All patients underwent axillary sample of four nodes with blue dye plus immediate axillary clearance.

**Outcomes**

Staging performance of axillary sample with axillary clearance as gold standard.

**Follow up**

Not reported.

**Results**

Authors report SN localisation rate as 17/17 patients in this subgroup and 97% for the larger series of 74 patients.

4 or more blue stained nodes were sampled in 13/17 cases.

Number of nodes removed per patient: not reported.

Prevalence of axillary disease = 13/17 = 76.5%

FNR=0/13=0%

Accuracy = 17/17=100%.

The axillary node sample included all the positive nodes in 7/13 cases, therefore 6/13 patients with positive axillary sample had further involved nodes revealed by axillary clearance.

**General comments**

Only abstract available. Small series represented.

Only patients with multifocal breast cancer are represented [higher risk group than other studies?].

Patients appear to have been treated in the centre's validation period.

Authors describe the four node axillary sample with blue dye procedure as 'SLNB'.

SN localisation rate reported should be interpreted with caution here since the procedure differs from SLNB as usually practiced in the UK.

Due to the very small series size, all staging outcomes should be interpreted with caution. Prevalence of axillary disease is much higher than in other series (usually of patients with unifocal disease).

Rampaul, Pinder, Mitchell, Morgan, Ellis, Blamey & MacMillan . Long-term regional recurrence and survival after axillary node sampling for breast cancer. Breast Cancer Res Treat 88. 2004.

**Design**

Prospective case series (diagnosis, screening), evidence level: 3

Country: United Kingdom, setting: Secondary care

**Inclusion criteria**

852 patients with primary operable breast cancer.

**Exclusion criteria**

None stated.

**Population**

Number of patients = 852.

**Interventions**

Aim: To report regional recurrence and survival in a series of patients who underwent axillary sample.

All patients underwent axillary sample.

Patients with no axillary disease (stage I) underwent no further axillary treatment.

Patients with axillary disease revealed by axillary sample (stage II: 1-3 nodes positive, stage III: 4 or more nodes positive) underwent axillary RT.

**Outcomes**

Axillary recurrence

Overall survival

**Follow up**

Median 7.5 years

**Results**

Axillary recurrence:

42 axillary recurrences occurred, at a rate of 0.66% per annum.

Stage III patients had a higher rate of axillary recurrence than than stage II or stage I patients ( $p < 0.001$ )

Overall survival:

At a median follow-up of 7.5 years, OS was as follows:

0 nodes positive: 89%

1 nodes positive: 84%

2 nodes positive: 75%

3 nodes positive: 65%

**General comments**

Abstract only. Abstract does not mention details of surgical technique e.g. whether blue dye is used.

No overall survival result is provided for the whole series combined.

Tanaka, Yamamoto, Kanematsu, Okugawa & Kamiyama . A four node axillary sampling trial on breast cancer patients. Breast 15[2]. 2006.

**Design**

Prospective case series (diagnosis, screening), evidence level: 3  
Country: Japan, setting: Secondary care

**Inclusion criteria**

237 patients with primary breast cancer of stage T1-2, N0-1: 23 patients had clinical stage N1 disease by preoperative assessment.

**Exclusion criteria**

None stated.

**Population**

Number of patients = 237, mean age = 57 years.

**Interventions**

Aim: to evaluate the staging performance of unguided axillary sample compared to axillary clearance as gold standard.

All patients underwent either mastectomy or breast conserving surgery followed by axillary sample of four palpable nodes and then axillary clearance.

Histology technique: study reports that 'all lymph nodes were examined by multiple sections'; exact technique not reported.

**Outcomes**

Staging performance of axillary sample compared to axillary clearance as gold standard.

**Follow up**

Not reported.

**Results**

A mean of 18.4 axillary nodes per patient were removed.

Prevalence of axillary disease =  $62/237 = 26.2\%$

FNR =  $4/62 = 6.5\%$

Accuracy =  $(58+175)/237 = 98.3\%$

**General comments**

204/237 = 86% of patients underwent axillary clearance to level I-II and 33/237 = 14% to level III.

Histopathological assessment appears to have been equal for all examined nodes.

The mean/median no. of nodes sampled per axillary sample procedure is not reported, but may be four exactly.

Thompson, Air, Jack, Kerr, Rodger & Chetty . Arm morbidity after breast conservation and axillary therapy. Breast 4[4]. 1995.

**Design**

Prospective case series (harm), evidence level: 3  
Country: UK/Australia, setting: Secondary care

**Inclusion criteria**

121 consecutive patients who opted for breast conserving surgery for unilateral breast cancer of clinical stage T1-T2, M0

**Exclusion criteria**

Patients who underwent mastectomy.

**Population**

Number of patients = 121.

**Interventions**

Aim: to measure upper limb morbidity in patients who received different surgical/RT treatment strategies to the axilla.

Morbidity outcomes were assessed in 4 groups:

1. Axillary sampling (n=28)
2. Axillary sampling plus axillary RT (n=61)
3. Axillary clearance of levels I, II and III (n=19)
4. Axillary clearance of levels I-II and axillary RT (n=13)

**Outcomes**

Upper limb volume, by water displacement:  
Change in arm volume on the treated side from preoperative volume, adjusting for changes in opposite arm;  
Upper limb circumference;

Shoulder mobility:  
abduction with external rotation;  
adduction with internal rotation;  
flexion;  
pure glenohumeral abduction.

**Follow up**

Outcomes were assessed preoperatively and 12 months post-operatively.

**Results**

Arm volume:  
At 12 months since surgery, arm volume had increased in all four groups of patients, with mean change in ipsilateral volume (cm<sup>3</sup>) as follows:  
Axillary sampling: +108 (t test, p=0.004)  
Axillary sampling plus axillary RT: +81 (t test, p=0.003)  
Axillary clearance of levels I-III: +75 (t test, p=0.39)  
Axillary clearance of levels I-II plus axillary RT: +216 (t test, p=0.064).

Number (%) of patients with an increase in arm volume >200ml:  
Axillary sampling: 6/28 = 21%

Axillary sampling plus axillary RT: 18/61 = 30%

Axillary clearance of levels I-III: 8/19 = 42%

Axillary clearance of levels I-II plus axillary RT: 7/13 = 54%

This proportion was significantly greater in patients who underwent axillary clearance than in patients who underwent axillary sample (unpaired difference between two proportions: axillary clearance minus axillary sampling = 42% - 21% = 19% [95% CI 1.0%-38.4%])

Arm circumference:

The mean increase in arm circumference was significantly greater in patients in the two axillary clearance groups (Group 3: 0.65cm; Group 4: 1.1cm) than patients in the two axillary sample groups ( Group 1: 0.35cm; Group 2: 0.25; ANOVA, F=7.94, df=1, p=0.006).

Upper limb mobility:

Patients who had RT after axillary node sample had statistically significantly reduced mean upper limb elevation (minus 6cm) compared with those who had no RT (minus 1cm t test, p=0.005).

There was no statistically significant difference in terms of flexion between the two axillary clearance groups.

Rotary movements at the shoulder were statistically significantly reduced by the addition of radiotherapy to either axillary sample or axillary clearance (Group 2: -1cm; Group4: -1.5cm versus Group 1: zero, Group 3: -0.4; ANOVA F=7.88, df=1, p=0.006 for abduction; Group 2: -2cm; Group4: -2.5cm versus Group 1: zero, Group 3: -0.4; ANOVA F=4.83, df=1, p=0.03 for adduction).

General comments Study is hampered by small numbers in comparison groups: has potential for wide variation in results due to limited sample size; neither mean arm volume increase in the two groups of patients treated by axillary clearance were statistically significant.

With regard to axillary clearance versus axillary sample comparisons, a greater proportion of patients received RT within the axillary sample groups than within the axillary clearance groups (this would work to attenuate the reported effect in favour of axillary sampling for arm circumference and % of patients with an increase in arm volume >200ml).

Authors regard an increase in arm volume of >200ml as a threshold for clinically important morbidity.

Study only assesses arm morbidity at the 12 month post-treatment stage and does not assess morbidity that may occur later.

95% CI for unpaired difference between two proportions calculated with spreadsheet available from Cardiff University (Newcombe, 2006), available online at:

[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls)

## Retrospective case series

Gui, Joubert, Reichert, Ward, Lakhani, Osin, Nerurkar, A'Hern, Benson & Underwood . Continued axillary sampling is unnecessary and provides no further information to sentinel node biopsy in staging breast cancer. Eur J Surg Oncol 31[7]. 2005.

### Design

Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

### Inclusion criteria

168 patients with primary breast cancer tumours of 3cm or less in size.

### Exclusion criteria

Neoadjuvant chemotherapy;  
Age >75 years at time of surgery;  
DCIS with no invasive component;  
Locally recurrent breast cancer;  
Metastatic disease.

### Population

Number of patients = 168, age range 27 to 75 years, mean age = 54 years.

### Interventions

Aim: to assess the staging performance of SLNB against axillary sample of a minimum of four nodes, and against axillary clearance.

82 patients underwent SLNB followed by axillary sample and, in cases with axillary disease revealed by either procedure, axillary clearance.

86 patients underwent SLNB followed by axillary clearance.

SLNB technique: Radiocolloid plus dye, or dye alone.

Histology technique: standard, with selective use of IHC in sentinel nodes.

### Outcomes

Staging performance of SLNB, with interest focused on additional information provided by axillary sample.

### Follow up

Not reported.

### Results

SN localisation rate =  $165/168 = 98.2\%$

Median (range) no. of SNs removed per patient:

Axillary sample group: 3 (1-5)

Axillary dissection group: 2 (1-8)

No. of axillary nodes removed by axillary clearance:

Axillary sample group: 12.5 (6-32) NB: represents only patients with positive axillae

Axillary clearance group: 8 (4-21)

Staging performance of SLNB [using either axillary clearance or sample as gold standard, n=165]:

Prevalence of axillary disease =  $44/165 = 26.7\%$

FNR =  $2/44 = 4.5\%$  [95% CI 0.6-15.5%]

Accuracy =  $(42+121)/165 = 98.8\%$

Staging performance of SLNB [using only axillary clearance as gold standard, n=84]:

Prevalence of axillary disease =  $26/84 = 31.0\%$

FNR =  $2/26 = 7.7\%$  [95% CI 0.9%-25.1%]

Accuracy =  $(24+58)/84 = 97.6\%$

Extending SLNB where necessary to sample a minimum of four nodes did not reveal any cases of further positive nodes.

**General comments**

SLNB method changed during this series, with the introduction of radiocolloid in addition to blue dye.

In all cases of axillary sample, presence of blue dye (or radiocolloid) is likely to have influenced choice of which nodes to remove and may enhance staging performance compared to unguided sampling.

The two FNRs reported are similar, noting their 95% CIs and limited series sizes.

Mathew, Barthelmes, Neminathan & Crawford . Comparative study of lymphoedema with axillary node dissection versus. Eur J Surg Oncol. 32[7]. 2006.

### **Design**

Retrospective case series (therapy), evidence level: 3  
Country: United Kingdom, setting: Secondary care

### **Inclusion criteria**

Group 1 was defined from a total of 770 patients who underwent surgery for invasive breast cancer between Jan 1994-Dec 1998 and group 2 from 546 patients who underwent surgery for invasive breast cancer between Jan 2000-Dec 2002.

Mean age was 59 in group 1 and 58 in group 2.

### **Exclusion criteria**

Previous breast cancer surgery;  
Neoadjuvant chemotherapy.

6 patients with incomplete records plus one patient lost to follow-up were excluded from analyses.

### **Interventions**

Aim: to compare the incidence of lymphoedema in node positive patients treated by breast conservation and axillary sample plus RT compared to breast conservation and axillary clearance.

Retrospective review of two series as follows:

Group 1 (n=312): underwent axillary sampling of a target of 6 nodes, with a stipulated minimum of 4 nodes. Patients with involved nodes underwent axillary RT.

Group 2 (n=194): underwent axillary clearance to level II or III without RT.

### **Outcomes**

Incidence of lymphoedema.

### **Follow up**

Minimum follow-up periods of two years were available for both groups.

### **Results**

Mean no. of nodes removed (range):

Group 1: 8 (3-17)

Group 2: 10 (4-27)

Prevalence of axillary disease at staging was 26% in group 1 and 20% in group 2. Therefore 26% of patients in group 1 would have received RT.

Incidence of lymphoedema (all patients):

Group 1: 7/312 = 2.2% [95% CI 1.1%-4.6%]

Group 2: 24/194 = 12.4% [95% CI 8.5%-17.8%]  
(p=0.001, Chi square)

Incidence of lymphoedema (node-negative patients; no RT in group 1):

Group 1: 2/231 = 0.87% [95% CI 0.24%-0.31%]

Group 2: 18/155 = 11.6% [95% CI 7.5%-17.6%]

(p=0.001, Chi square)

Incidence of lymphoedema (node-positive patients; RT given in group 1):

Group 1: 5/81 = 6.2% [95% CI 2.6%-13.7%]

Group 2: 6/39 = 15.4% [95% CI 7.3%-29.7%]

(p=0.17, Chi square)

### **General comments**

Criterion used for lymphoedema: difference of 2cm or more in arm circumference between affected and non affected limbs.

All patients received RT breast.

95% CI for single proportion calculated with spreadsheet from Cardiff University (Newcombe, 2006), available online at: [http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/CIPROPORTION.xls)

Sato, Tamaki, Takeuchi, Tsuda, Kosuda, Kusano, Hiraide & Mochizuki . Management of the axilla in breast cancer: a comparative study between sentinel lymph node biopsy and four-node sampling procedure. Jpn.J Clin Oncol 31[7]. 2001.

**Design**

Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Japan, setting: Secondary care

**Inclusion criteria**

206 patients with operable breast cancer with tumour size 5cm or less.

**Exclusion criteria**

Previous neoadjuvant chemotherapy, patients with large biopsy cavity or clinical evidence of axillary involvement.

**Population**

Number of patients = 206, age range 28 to 87 years, mean age = 54 years.

**Interventions**

Aim: to compare the efficacy of SLNB and axillary sample of a target of four nodes.

110 patients underwent SLNB and immediate axillary clearance to level I or II.

98 patients underwent axillary sample without localisation aid, with a target of 4 nodes sampled from the axillary tail upwards, and immediate axillary clearance.

SLNB technique: Radiocolloid plus dye.

Histology technique: not reported specifically for SLNB; standard methods for axillary nodes.

**Outcomes**

Staging performance of SLNB and axillary sample compared to axillary clearance as gold standard.

**Follow up**

Not reported

**Results**

Staging performance of SLNB:

SN localisation rate = 108/110 = 98.2%

Mean no. SNs removed per patient = 1.7 (range 1-7)

Prevalence of axillary disease = 41/108 = 38%

FNR = 1/41 = 2.4%

Accuracy = 107/108 = 99%

Staging performance of axillary sample:

Mean no. nodes removed per patient = 4 (range 2-7)

Prevalence of axillary disease = 48/98 = 49%

FNR = 2/48 = 4.2%

Accuracy = 96/98 = 98%

General comments The two retrospectively defined groups were similar for patient and tumour characteristics.

## Evidence Tables

### Predictive factors for axillary metastases

#### Retrospective case series studies

Anan, Mitsuyama, Tamae, Nishihara, Iwashita, Abe, Ihara & Toyoshima . Axillary lymph node metastases in patients with small carcinomas of the breast: is accurate prediction possible? Eur J Surg 166[8]. 2000.

Design: Retrospective case series (therapy), evidence level: 3  
Country: Japan, setting: Secondary care

#### **Inclusion criteria**

1003 patients with invasive breast cancer of tumour size 2cm or less on gross pathological examination.

#### **Exclusion criteria**

None stated.

#### **Population**

number of patients = 1003, age range 24 to 89 years, mean age = 53 years, median age = 51 years.

#### **Interventions**

Aim: to examine the value of 10 clinical and pathological factors in predicting metastatic involvement of the axilla.

All patients underwent axillary clearance.

Histology technique: standard

#### **Outcomes**

Association between variables and metastatic axillary nodes.

Factors examined were: age, palpability and size of tumour, macroscopic classification of tumour margin (well-defined, moderately defined or ill-defined), clinical axillary status, radiating spiculation on a mammogram, histological type, lymphatic invasion, oestrogen and progesterone receptor status.

#### **Follow up**

Not reported.

#### **Results**

255 patients had metastatic lymph nodes therefore prevalence of axillary disease =  $255/1003 = 25.4\%$ .

Univariate analysis showed that clinical axillary status, macroscopic classification of tumour margin, lymphatic invasion and age were significant predictors of metastatic axillae ( $p < 0.01$ , Chi square).

Multivariate analysis was performed for clinical axillary status, macroscopic classification of tumour margin, lymphatic invasion, age, radiating spiculation on mammography and tumour size, due to p values below 0.2. The same four

variables as above were independent predictors of axillary node metastases:

Proportion of patients with metastatic axillae by clinical node status:

N0: 32/159 = 20%

N1: 38/89 = 43%

N2: 7/7 = 100% ( $p < 0.0001$ )

Proportion of patients with metastatic axillae by tumour margin classification:

Well-defined: 34/50 = 17%

Moderately defined: 25/106 = 26%

Ill-defined: 33/99 = 33% ( $p < 0.0001$ )

Proportion of patients with metastatic axillae by tumour lymphatic invasion:

Present: 25/62 = 41%

Absent: 44/193 = 23% ( $p < 0.0001$ )

Proportion of patients with metastatic axillae by age:

$\leq 34$ : 7/16 = 41%

35-49: 26/104 = 25%

50-64: 32/106 = 30%

65+: 4/29 = 15% ( $p = 0.003$ ).

#### **General comments**

analysis was initially by univariate Chi square and then, for factors with a significant association ( $p < 0.2$ ), multiple logistic regression, with an alpha value of 0.05 for statistical significance.

Tumour margin classification is designed to be a measure of the extent of tumour invasion.

Barth, Craig & Silverstein . Predictors of axillary lymph node metastases in patients with T1 breast carcinoma. Cancer 79[10]. 1997.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria**

918 patients with T1 tumours who underwent treatment for breast cancer between 1979-1995.

**Exclusion criteria**

None stated.

**Population**

number of patients = 918.

**Interventions**

Aim: to determine the association between metastatic axillae and 11 clinical and pathologic factors.

All patients underwent axillary clearance.

Histology technique: standard.

**Outcomes**

Association between clinical and pathologic factors and metastatic axillae.

Factors examined were: tumour size, lympho-vascular invasion, nuclear grade, S-phase, ploidy, palpability, age, estrogen receptor status, progesterone receptor status, HER-2 status and histology.

**Follow up**

Not reported.

**Results**

Prevalence of axillary disease: 218/918 = 22.6%.

On univariate analysis, tumour size, tumour palpability, lympho-vascular invasion and nuclear grade were significantly associated with metastases in the axillary nodes (each with  $p < 0.0001$ ).

By multivariate analysis, the same four variables were independent predictors of axillary lymph node metastases:

Proportion of patients with metastatic axillary nodes by tumour lympho-vascular invasion:

Present: 53/116 = 46%

Absent: 143/74 = 19% ( $p = 0.0000001$ )

Proportion of patients with metastatic axillary nodes by tumour palpability:

Palpable: 183/656 = 28%

Non-palpable: 26/262 = 10% ( $p = 0.00004$ )

Proportion of patients with metastatic axillary nodes by nuclear grade:

1: 13/148 = 9%

2: 107/510 = 21%

3: 78/237 = 33% (p=0.0004)

Proportion of patients with metastatic axillary nodes by tumour size:

T1a: 4/92 = 4%

T1b: 42/245 = 17%

T1c: 163/581 = 28% (p=0.01)

Among 117 patients with nonpalpable, non high nuclear grade tumours  $\leq 1$ cm in size without lympho-vascular invasion, the incidence of axillary was 3%. Among 43 patients with T1c tumours and all three other risk factors, incidence was 49%.

#### **General comments**

Clinical assessment of the axilla was not always recorded; however the majority of patients were of clinical stage N0.

Statistical analysis was by univariate analysis (log rank test) and, for variables showing a statistically significant association with axillary involvement, multivariate analysis (Cox proportional hazards regression model).

Brenin, Manasseh, El-Tamer, Troxel, Schnabel, Ditkoff & Kinne . Factors correlating with lymph node metastases in patients with T1 breast cancer. Ann Surg Oncol 8[5]. 2001.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria**

1416 patients with breast cancers of stage T1 who were treated at a single centre between 1989 and 1998.

**Exclusion criteria**

Patients with multifocal tumours.

**Population**

number of patients = 1416, age range 23 to 88 years, mean age = 58 years.

**Interventions**

Aim: to examine the relationship between patient and tumour variables and incidence of axillary metastases.

All patients underwent axillary clearance.

Histology technique: standard, with immunohistochemistry only in equivocal cases.

**Outcomes**

Association between patient and tumour variables and axillary metastases. Variables examined were: age, race, height, weight, menopausal status, palpability, tumor size, positive margin on initial excision, histology, histological grade, lympho-vascular invasion (LVI), oestrogen receptor status (ER), progesterone receptor status, S-phase, and ploidy.

**Follow up**

Not reported.

**Results**

Prevalence of axillary disease: 326/1416 = 23%

On univariate analysis, the following variables were statistically significantly associated with the presence of axillary metastases: tumour palpability [palpable > non-palpable], T size [T1c > T1b > T1a], LVI [present > absent], histology [infiltrating ductal > lobular > other > tubular], histological grade [III > II > I], ER status, and positive margin on initial excision [positive > negative], all with  $p < 0.05$ , Chi square.

On multivariate analysis, the following variables were found to be independent predictors of axillary metastasis:

Larger Tumour size:

Proportion of patients with axillary metastases by tumour size:

T1a: 14/131 = 10.7%

T1b: 67/435 = 15.4%

T1c: 245/850 = 28.8%  
OR 2.9 [95% CI 1.9-4.3, p=0.0001].

Presence of LVI:

Proportion of patients with axillary metastases by presence of LVI:

Present: 94/219 = 43%

Absent: 143/792 = 18%

OR 2.6 [95% CI 1.8-3.64, p=0.0001].

Histological tumour grade:

Proportion of patients with axillary metastases by tumour grade:

III: 128/399 = 32%

II: 119/543 = 22%

I: 16/146 = 11%

OR (III>II>I) 1.6 [95% CI 1.2-2.1, p=0.0004].

Positive margin on initial biopsy:

Proportion of patients with axillary metastases by positive/negative margin on initial biopsy:

Positive: 140/538 = 26%

Negative: 181/862 = 21%

OR (present:absent) 23.8 [95% CI 5.6-101.2, p=0.0001].

Interaction variable for the negative interaction between positive margin and T stage:

OR 0.34 [95% CI 0.2-0.6, p=0.0001]

This indicates that patients with positive margins had risks largely unaffected by T stage, while increasing T stage conferred an increased risk for patients with negative margins.

Based on the multivariate analysis, risk of axillary metastases varied as follows:

LVI absent, margin negative, Grade I, T size T1a: 2% risk.

LVI present, margin positive, Grade III, T size T1c: 51% risk.

### **General comments**

Analysis was by Chi square for univariate analysis, and then by logistic regression using backward selection to eliminate statistically insignificant variables from the models.

Some data are missing for some variables since totals do not equal the total number of patients in the series (1416).

Re: positive margins, 'initial excision' and 'initial biopsy' appear to be interchangeable terms, which probably mean definitive treatment of the tumour.

NB grade = histological grade.

Cao, Paner & Rajan . Sentinel node status and tumor characteristics: A study of 234 invasive breast carcinomas. Archives of Pathology & Laboratory Medicine Vol 129(1)(pp 82-84), [1]. 2005.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: US/UK, setting: Secondary care

**Inclusion criteria**

234 patients with unifocal breast cancer with tumour size 25 mm or less treated between May 1998 and December 2002.

Age data not reported.

**Exclusion criteria**

None stated.

**Population**

number of patients = 234.

**Interventions**

Aim: to examine the relationship between the status of the sentinel node (SN) and tumour size, grade and presence or absence of lympho-vascular invasion (LVI).

All patients underwent SLNB. Patients with metastatic SNs underwent axillary clearance.

SLNB technique: not reported.

Histology technique: intra-operative, standard and selectively, immunohistochemistry.

**Outcomes**

Relationship between SN status and tumour size, grade and LVI.

**Follow up**

Not reported.

**Results**

**STAGING**

SN localisation rate: 221/234 = 94.4%

No. of SNs removed per patient: mean 1.38; range 1-4.

Rate of positive SNs = 77/221 = 34.8% [no gold standard reported].

**RISK FACTORS**

Univariate analysis:

LVI:

Proportion of patients with metastatic SNs by presence/absence of LVI:

Present: 30/46 = 76%

Absent: 42/175 = 24% (p<0.001)

Tumour grade:

Proportion of patients with metastatic SNs by tumour grade:

I: 13/78 = 16.7%

II: 49/108 = 45.4%

III: 14/31 = 45.2%

OR of positive SNs in grade II or III relative to grade I: 4.15 [95% CI 2.1-8.2].

**Tumour size:**

The median tumour size in cases of metastatic SNs was 20mm, compared to 15mm for negative SNs ( $p < 0.001$ ).

**Multivariate analysis:**

In logistic regression, increasing tumour size and presence of LVI were statistically significant independent predictors of SN metastasis:

LVI present: RR 9.8 [95% CI 5.46-17.86,  $p < 0.001$ ]

Increasing tumour size: RR (for an increment of 1mm) 1.065 [95% CI 1.038-1.092,  $p < 0.001$ ].

### **General comments**

Paper has exact same staging data as Agarwal et al. (2005) and may be the same series of patients.

Statistical analysis was by Mann-Whitney test for SN status and tumour size and Chi square for tumour grade and LVI. Binary logistic regression was performed to examine which factors were independent predictors of metastatic SNs.

The rate of positive SNs cannot be taken for true prevalence of axillary disease since no gold standard staging data are reported re: falsely negative SNs. However the RR values are prevalence dependent, i.e. upon the value of 34.8%.

Tumour grade data were available for 217 of 221 patients in whom SNs were identified.

NB grade = histological grade.

Chen, Palleschi, Khoynzhad, Gecelter, Marini & Simms . Role of primary breast cancer characteristics in predicting positive sentinel lymph node biopsy results - A multivariate analysis. Arch Surg 137[5]. 2002.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria**

257 patients who underwent SLNB. Eligibility for SLNB included patients with:  
no palpable axillary nodes;  
no previous history of axillary surgery;  
no contra-indications to radiocolloid.

**Exclusion criteria**

Stated above.

**Population**

number of patients = 257, age range 31 to 84 years, mean age = 62 years.

**Interventions**

Aim: to identify characteristics of primary breast tumours that are predictive of metastatic sentinel nodes.

Patients underwent SLNB and a medical database was retrospectively reviewed.

SLNB technique: radiocolloid, dye.

Histology technique: intra-operative, standard plus immuno-histochemistry.

**Outcomes**

Association between tumour variables and metastatic SNs.

Factors analysed were: age, tumour size, histological type, presence/absence of DCIS, architectural pattern of DCIS, extensive DCIS, presence/absence of LCIS, border of neoplasm, lympho-vascular invasion, host lymphoid reaction, grade, ER status and HER-2 status.

**Follow up**

Not reported.

**Results**

Prevalence of axillary disease =  $73/257 = 28.4\%$

In both univariate and multiple logistic regression, tumour size and lympho-vascular invasion were the only variables predictive of positive SNs:

Rate of SN involvement by tumour size:

T1a:  $5/37 = 13.5\%$

T1b:  $19/93 = 20.4\%$

T1c:  $37/103 = 35.9\%$

T2:  $12/24 = 50\%$

Rate of SN involvement by presence/absence of lympho-vascular invasion:

LVI present: 8/13 = 61.5%

LVI absent: 58/213 = 27.2% (p=0.02)

**General comments**

Analysis was univariate, then multivariate. Not all tests performed nor all p values are reported.

LVI data was available for only 226 patients.

Cutuli, Velten & Martin . Assessment of Axillary lymph node involvement in small breast cancer: Analysis of 893 cases. Clinical Breast Cancer 2[1]. 2001.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: France, setting: Secondary care

**Inclusion criteria**

893 women with breast cancer of clinical stage T0-2 (<3cm), N0-1, treated at a single centre between January 1980 and December 1991.

**Exclusion criteria**

None stated.

**Population**

number of patients = 893, median age = 52 years.

**Interventions**

Aim: to measure the risk of axillary metastasis in patients with small tumours, based upon clinical and histological parameters.

All patients underwent axillary clearance.

Histology technique: standard.

**Outcomes**

Association between the proportion of patients with axillary metastases according to subgroups based on: clinical tumour size (T0, T1, T2 <3cm), histological tumour size (0-9.9mm, 10-14.9mm, 15-19.9mm, 20-24.9mm, 25-29.9mm), histological subtype (infiltrating ductal carcinoma [IDC] grade I, II and III, infiltrating lobular carcinoma [ILC], other), age (<40 years, 40-60 years, >60 years), tumour location (inner, medial or outer quadrant), breast size (small, medium or large).

**Follow up**

Not reported.

**Results**

Prevalence of axillary disease was 25.3%

In multivariate analysis, clinical tumour size, histological subtype (including grade) and breast size were statistically significant independent predictors of axillary node metastasis:

Proportion of patients with axillary metastases by clinical tumour size:

T0: 21/152 = 13.8%

T1: 78/394 = 19.8%

T2 <3cm: 127/347 = 36.6% (p<0.0001)

Proportion of patients with axillary metastases by histological subtype:

IDC grade I: 32/175 = 18.3%

IDC grade II: 101/371 = 27.2%

IDC grade III: 65/172 = 37.8%

ILC: 17/75 = 22.7%

Other: 10/100 = 10% (p=0.0005)

Proportion of patients with axillary metastases by breast size:

Small (<10cm): 40/133 = 30.1%

Large (>10cm): 185/760 = 24.4% (p=0.004).

**General comments**

Statistical analysis was by Chi square test for each parameter in turn and then by multivariate analysis by logistic regression.

Breast size was based upon dosimetric size for RT.

Paper does not report any results of univariate analyses.

Giuliano, Barth, Spivack, Beitsch & Evans . Incidence and predictors of axillary metastasis in T1 carcinoma of the breast.[see comment]. J Am Coll.Surg 183[3]. 1996.

Design: Retrospective case series (harm), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria**

259 patients with T1 invasive breast cancer treated at a single centre between January 1988 and June 1994.

**Exclusion criteria**

Patients with incomplete data for any of the following parameters: tumour size, age, hormone receptor status, presence of DCIS and histology.

**Population**

number of patients = 259, age range 31 to 85 years, median age = 55 years.

**Interventions**

Aim: to examine the incidence and predictive variables of axillary lymph node metastasis in patients with breast cancer of stage T1.

All patients underwent axillary clearance.

Histology technique: standard.

**Outcomes**

Relationship between patient/tumour parameters and incidence of axillary node metastases. Parameters examined were: tumour size, age, hormone receptor status, presence of DCIS, histology, ploidy, and S-phase.

**Follow up**

Not reported.

**Results**

Presence of axillary disease was 69/259 = 27%.

In univariate analysis, only tumour size was statistically significantly associated with axillary node metastasis:

Proportion of patients with axillary metastases by tumour size:

T1a: 2/20 = 10%

T1b: 9/68 = 13%

T1c: 51/171 = 30% (p<0.002).

**General comments**

Statistical analysis was by Fisher's exact test.

Tumour ploidy and phase data were available in 64% of patients.

A subset of 114 patients underwent SLNB plus axillary clearance as part of a pilot study, with blue dye and immunohistochemistry. Staging data from the same centre have been reported by Giuliano et al. (1997) so are not cited here. Rates of metastatic axillary nodes reported here are by standard

histology techniques.

Grube, Hansen, Ye & Giuliano . Tumor characteristics predictive of sentinel node metastases in 105 consecutive patients with invasive lobular carcinoma. Am J Surg 184[4]. 2002.

Design: Retrospective case series (harm), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria**

103 cases of ILC in 102 patients (including 1 patient with metachronous, bilateral ILC) treated between October 1991 and May 2001. Patients were identified from a larger series of 121 patients with ILC.

Mean age was 60 in patients with positive SNs and 61 in patients with negative SNs.

**Exclusion criteria**

3 patients with failed SN localisation.  
16 patients enrolled in clinical trials: ACS Z0010 and Z0011.

**Population**

number of patients = 102, age range 42 to 87 years.

**Interventions**

Aim: to identify patient and tumour factors that are predictive of SN metastasis in patients with invasive lobular carcinoma (ILC).

All patients underwent SLNB.

SLNB technique: dye; radiocolloid only in some cases.  
Histology technique: standard; immunohistochemistry.

**Outcomes**

Compares prognostic factors between patients with SN metastases and patients without SN metastases. Factors examined were: tumour differentiation, grade, lympho-vascular invasion (LVI), ER status, PR status, HER-2 status, DNA index, S phase.

**Follow up**

Mean 39 months for patients with positive SNs.  
Mean 48 months for patients with negative SNs (follow up is not very relevant to cited outcomes).

**Results**

There were 51 cases (50%) with a positive SN and 52 cases (50%) with a negative SN.

Factors found by univariate analysis to vary statistically significantly by SN status were as follows:

Factors reported as 'demographic factors':

Proportion of patients with positive SNs by tumour palpability:  
Palpable: 40/68 = 59%

Not palpable: 11/35 = 31% ( $p=0.048$ , Chi square).

Proportion of patients with positive SNs by type of surgery:

Breast conservation: 36/81 = 44%

Mastectomy: 15/22 = 68% ( $p=0.048$ , Chi square).

Proportion of patients with positive SNs by pT size:

pT1: 11/45 = 24%

pT2: 23/39 = 59%

pT3: 16/18 = 89% ( $p=0.001$ , Chi square).

Mean tumour size by SN status:

SN positive: 3.9cm

SN negative: 1.9cm ( $p=0.0001$ , t test).

Factors investigated as prognostic factors:

Proportion of patients with positive SNs by presence/absence of LVI:

Present: 9/11 = 82%

Absent: 42/92 = 46% ( $p=0.023$ , Fisher's exact test).

LVI was the only prognostic factor defined a priori to be significantly associated with metastatic SNs, so no multivariate analysis was performed.

#### **General comments**

Study provides some narrative staging data for SLNB, but not cited here due to high likelihood of duplication with Giuliano et al. (1997).

Statistical analysis was univariate: by t test, Chi square or Fisher's exact test. Study therefore does not take account of the individual role of each variable by controlling for variation in other variables.

Authors decided not to investigate 'demographic' factors as prognostic factors per se e.g. pT stage, but variables found to be significantly associated with positive SNs are cited.

Houvenaeghel, Martino, Jacquemier, Moutardier, Tallet, Viens, Puig & Bardou . Risk of stage underestimation of breast cancer by sentinel lymph node biopsy method. Bull.Cancer (Paris) 90[5]. 2003.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: France, setting: Secondary care

**Inclusion criteria**

1,636 patients treated with axillary clearance for breast cancer of clinical stage T0, T1 or T2 <30 mm, N0 breast cancer between 1975 and 1999.

**Exclusion criteria**

Not known.

**Population**

number of patients = 1636.

**Interventions**

Aim: to measure the relationship between prognostic factors and the rate of metastatic axillary lymph nodes in patients with breast cancer.

All patients underwent axillary clearance.

**Outcomes**

Association between prognostic factors and axillary metastasis. Factors examined were: pathologic diameter, grading, lympho-vascular invasion (LVI), hormone receptor status, menopausal status and age.

**Follow up**

Not known.

**Results**

Prevalence of axillary disease: 444/1636 = 27%

Prevalence of axillary disease by T stage:

T0: 74/437 = 17%

T1: 202/766 = 26%

T2 <30mm: 168/433 = 39%

The following variables were statistically significantly associated with the rate of axillary metastases:

Proportion of patients with metastatic axillary nodes by presence/absence of LVI (univariate analysis):

LVI absent: 166/845 = 19.6%

LVI present: 208/506 = 41.1% (p<0.000001)

RR by multivariate analysis: 2.2 [95% CI 1.7-2.9], p<0.0001.

Proportion of patients with metastatic axillary nodes by tumour grade (univariate analysis):

I: 84/444 = 18.9%

II: 213/743 = 28.7%

III: 126/283 = 44.5% (p<0.00001)

RR by multivariate analysis, Grade III relative to grade I-II: 2.3 [95% CI 1.7-3.3],  $p < 0.0001$ .

Proportion of patients with metastatic axillary nodes by menopausal status (univariate analysis):

Post-menopausal: 247/1019 = 24.2%

Pre-menopausal: 197/617 = 31.9% ( $p = 0.0007$ )

RR by multivariate analysis: not provided.

Proportion of patients with metastatic axillary nodes by age group (univariate analysis):

$\leq 50$  years: 180/551 = 32.7%

$> 50$  years: 264/1085 = 24.3% ( $p = 0.0003$ )

RR by multivariate analysis: 1.4 [95% CI 1.0-1.8],  $p = 0.024$ .

Proportion of patients with metastatic axillary nodes by pathological tumour diameter (univariate analysis):

$\leq 30$ mm: 348/1295 = 26.9%

$> 30$ mm: 57/121 = 47.1%

RR by multivariate analysis: 2 [95% CI 1.3-3.1],  $p = 0.0014$ .

#### **General comments**

LVI data was available for 1351 patients; 285 patients had unclear LVI results and were excluded from the LVI analyses.

Grade data was available for 1470 patients; 166 patients had unclear grade results and were excluded from the grade analyses.

Pathological tumour size data was available for 1416 patients; 220 patients were excluded from the pathological tumour size analysis.

Grade is reported as 'grade'; therefore assumed to represent histological grade.

Katz, Niemierko, Gage, Evans, Shaffer, Fleury, Smith, Petrucci, Flax, Drogula & Magnant . Can axillary dissection be avoided in patients with sentinel lymph node metastasis?[see comment]. [Review] [46 refs]. J Surg Oncol 93[7]. 2006.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients treated with SLNB between 1998 and 2003.

110 patients had DCIS  
1034 patients had invasive disease

307 patients underwent mastectomy and 833 breast conserving surgery. In 8 patients the type of definitive surgery was unknown.

**Exclusion criteria** Retrospective study: none reported.

**Population** number of patients = 1133, age range 30 to 96 years, median age = 57 years.

**Interventions** Retrospective analysis of 1148 SLNB procedures in 1133 patients treated at a single centre and recorded on a pathology database.

SLNB technique: R, D  
Histology: FS, S, IHC

**Outcomes** Risk factors for the presence of SN metastases.

Risk factors for the presence of further axillary node metastases in patients who undergo axillary clearance for positive SLNB result.

**Follow up** No follow-up reported, study assesses predictive factors for SN and non SN axillary nodal involvement.

**Results** 246 patients had involved SNs and underwent axillary clearance.  
121 patients had involved SNs and did not undergo axillary clearance.

Prevalence of axillary disease =  $367/1148 = 32\%$

A median of 2 SNs were identified per procedure (range 1-15)

#### RISK FACTORS FOR SN INVOLVEMENT

By Pearson Chi square the proportion of patients with positive SNs varied significantly by subgroup for the following variables (as categorical variables):  
Age (higher rates of SN involvement in younger patients,  $p < 0.001$ );  
Type of surgery (higher rates of SN involvement after mastectomy,  $p < 0.008$ );  
Tumour size (higher rates of SN involvement with larger tumours,  $p < 0.001$ );  
Histology (no discernable pattern by histological subtype except for lowest rate in patients with DCIS,  $p = 0.001$ );  
Invasion of lymphovascular space (higher rates of SN involvement when present,  $p < 0.001$ ).

By Pearson Chi square the proportion of patients with positive SNs did not vary significantly by subgroup for the following variables (as categorical variables):

Number of SNs identified;  
ER receptor status;  
PR receptor status.

The statistical significance observed was the same whether SN positivity was determined by H&E histology or by any technique (including more sensitive techniques).

On multiple logistic regression analysis age, histology, primary tumour size and lymphovascular invasion were statistically significantly associated with SN involvement (no further details reported).

#### RISK FACTORS FOR INVOLVEMENT OF ADDITIONAL NON-SENTINEL NODES

By Pearson Chi square the proportion of patients with positive further nodes varied significantly by subgroup for the following variables (as categorical variables):

Presence of lymphovascular invasion ( $p=0.001$ );  
Number of SNs examined (higher rates of further nodal involvement where fewer SNs were examined,  $p=0.03$ );  
Histological method to detect SN metastasis (higher rates of further nodal involvement for H&E,  $p=0.03$ );  
Number of involved SNs (higher rates of further nodal involvement where  $\geq 3$  SNs involved,  $p=0.002$  for H&E histology and  $P=0.05$  for any histological technique);  
Number of uninvolved SNs (higher rates of further nodal involvement where fewer SNs uninvolved,  $p<0.001$ );  
Size of the largest SN metastasis (higher rates of further nodal involvement for larger SN metastases,  $p<0.001$ ).

By Pearson Chi square the proportion of patients with further involved axillary nodes did not vary significantly by subgroup for the following variables (as categorical variables):

Age;  
Type of definitive surgery;  
Tumour size;  
Histology.

On multiple logistic regression analysis the presence of lymphovascular invasion, increasing number of positive SNs, increasing size of the largest SN metastasis and decreasing number of negative SNs were statistically significantly associated with further axillary node involvement (no further details reported).

**General comments** It is not reported, but this series of patients appear to have been treated in an operational phase for SLNB i.e. without planned axillary clearance for any patients irrespective of SN status.

Peters-Engl, Konstantiniuk, Tausch, Haid, Hoffmann, Jagoutz-Herzlinger, Kugler, Redtenbacher, Roka, Schrenk & Steinmassl . The impact of preoperative breast biopsy on the risk of sentinel lymph node metastases: analysis of 2502 cases from the Austrian sentinel node biopsy study group. Br J Cancer 91[10]. 2004.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Austria, setting: Secondary care

**Inclusion criteria**

2328 patients with early, invasive breast cancer treated with SLNB in 12 contributing centres and identified from a larger series of 2500 patients.  
1890 patients yielded complete data for the analyses. Tumour size had range 0.5-80mm.

**Exclusion criteria**

Preoperative systemic treatment;  
Multifocal disease;  
In situ disease.

**Population**

number of patients = 1890, age range 23 to 96 years, median age = 60 years.

**Interventions**

Aim: to evaluate the impact of preoperative fine needle aspiration (FNA) or core biopsy of the primary tumour on the rate of metastasis to the SN of patients with early breast cancer.

All patients underwent SLNB.

SLNB technique: dye or radiocolloid or both.

Histology technique: intra-operative, standard, immunohistochemistry.

**Outcomes**

Proportion of patients with metastatic SNs by subgroup analysis for clinicopathologic factors:

Age, tumour size, histology, grade, location of tumour in breast, tumour palpability, performance of FNA/core biopsy, treatment within a validation period, contributing centre, SLNB technique, timing of SLNB (1st or 2nd procedure) and whether data on patients was collected prospectively or retrospectively.

**Follow up**

Not reported.

**Results**

**STAGING**

SN localisation rate: 2079/2328 = 89.3%

**RISK FACTORS**

230/1890 = 12.1% of patients underwent FNA.

818/1890 = 43.3% of patients underwent core biopsy.

842/1890 = 44.6% of patients underwent neither FNA nor core biopsy.

In univariate analysis, the following factors were statistically significantly associated with metastatic SNs:

Larger tumour size ( $p < 0.0001$ ), age ( $p = 0.002$ ), preoperative biopsy ( $p = 0.001$ ), histological type ( $p < 0.0001$ ), grade ( $p < 0.0001$ ), palpability ( $p < 0.0001$ ), timing of SLNB ( $p = 0.008$ ) and participating centre ( $p = 0.003$ ).

In multivariate analysis the following factors were statistically significantly associated with metastatic SNs:

Increasing tumour size:

OR 1.06 [95% CI 1.05-1.08],  $p < 0.0001$ .

Tumour grading:

Proportion of patients with metastatic SNs by tumour grade:

I: 53/293 = 18%

II: 360/1001 = 36%

III: 232/596 = 39%

OR, grade I relative to grade III: 0.55 [95%CI 0.32-0.81],  $p = 0.002$ .

Histological type:

Proportion of patients with metastatic SNs by histological type:

Ductal: 406/1230 = 33%

Ducto-lobular: 80/163 = 49%

Lobular: 92/235 = 39%

Other: 66/262 = 25%

OR, ducto-lobular relative to ductal histology: 2.16 [95% CI 1.48-3.16],  $p = 0.0001$ .

Age:

OR 0.98 [95% CI 0.97-0.99],  $p < 0.0001$ .

Palpability:

Proportion of patients with metastatic SNs by tumour palpability:

Palpable: 520/1270 = 41%

Not palpable: 124/620 = 20%

OR 1.77 [95% CI 1.37-2.29],  $p < 0.0001$ .

Participating centre (No data cited,  $p = 0.001$ ).

Notably, FNA/core biopsy was not found to have a statistically significant relationship with metastatic SNs.

### **General comments**

An unspecified number of patients underwent excisional biopsy of the breast tumour prior to SLNB, with immediate SLNB (as 1st procedure) if intra-operative histology revealed malignancy in the breast, or SLNB as 2nd procedure if standard histology revealed malignancy at a later date. SLNB as a 2nd procedure occurred in 140 (7.4%) patients overall, 32 (3.1%) in the biopsy group and 108 (12.8%) in the 'no biopsy' group. This implies that at least 140 patients underwent excisional breast biopsy. However excisional

breast biopsy was not analysed as a specific clinicopathologic factor, even though it may confound the effect of the factor of particular interest, FNA/core biopsy.

Analysis groups were compared for similarity:

Patients in the biopsy group had larger tumours than those in the 'no biopsy' group: mean 17.8mm versus 14.9mm respectively ( $p < 0.0001$ , t test).

There were more cases of ductal and lobular tumours and less ducto-lobular and other subtypes in the biopsy group compared to the 'no biopsy' group ( $p = 0.006$ , Chi square).

More patients in the 'no biopsy' group were treated during the SLNB validation phase compared to the biopsy group: 28% versus 17% respectively ( $p < 0.0001$ , Chi square).

More patients in the biopsy group had palpable tumours compared to the 'no biopsy' group: 74% versus 58% respectively ( $p < 0.0001$ , Chi square).

More patients in the biopsy group underwent SLNB with combined radiocolloid plus dye compared to the 'no biopsy' group: 69% versus 34% respectively ( $p < 0.0001$ , Chi square).

In all analyses, SN metastases were defined as metastases detected by either of standard histology/immunohistochemistry.

Grade reported as 'tumour grade': assumed to be histological grade.

Rivadeneira, Simmons, Christos, Hanna, Daly & Osborne . Predictive factors associated with axillary lymph node metastases in T1a and T1b breast carcinomas: analysis in more than 900 patients. J Am Coll.Surg 191[1]. 2000.

Design: Retrospective comparative study (diagnosis, screening), evidence level: 3

Country: United States, setting: Secondary care

**Inclusion criteria**

919 patients with invasive T1a-T1b breast cancer tumours (i.e.  $\leq 1$ cm in size), treated at a single institution between 1990 and 1996.

199 patients had T1a tumours.

720 patients had T1b tumours

**Exclusion criteria**

None stated.

**Population**

number of patients = 919, age range 24 to 90 years, mean age = 58 years, median age = 57 years.

**Interventions**

Aim: to determine clinical and pathologic factors predictive of axillary lymph node metastases in patients with invasive breast cancer and tumours  $\leq 1$ cm in size.

All patients underwent axillary clearance.

Histology technique: standard.

**Outcomes**

Relationship between clinical and pathological variables and the rate of axillary metastasis. Factors examined were: age, race, tumour size, tumour palpability, histologic type, histologic grade, oestrogen and progesterone receptor status, and lympho-vascular invasion (LVI).

**Follow up**

Not reported.

**Results**

Prevalence of axillary disease was  $165/919 = 18\%$

In the univariate analysis, the following factors were found to be statistically significantly associated with the presence of axillary metastases: age ( $p=0.01$ ), tumour diameter ( $p=0.01$ ), tumour grade ( $p=0.003$ ) and LVI ( $p=0.0001$ ).

Proportion of patients with metastatic axillary nodes by presence/absence of LVI (univariate analysis):

LVI present:  $14/28 = 50\%$

LVI absent:  $68/450 = 15\%$

OR 5.52 [95% CI 2.51-12.19], p=0.0001.

In the multivariate analysis the following variables were found to be independently statistically significantly associated with the presence of axillary metastases: age, tumour diameter and tumour grade:

Age:

OR (>=50 years relative to <50 years): 0.61 [95% CI 0.37-1.02], p=0.05\*

Tumour size:

OR (continuous variable, for each 1mm increase): 3.58 [95% CI 1.18-11.89], p=0.03

Tumour grade:

Proportion of patients with axillary metastases by tumour grade:

I: 27/205 = 13%

II: 38/240 = 16%

III: 22/76 = 29%

OR (grade III relative to grade I): 2.45 [95% CI 1.27-4.68], p=0.01

#### **General comments**

Analysis was by univariate analysis: Chi square and Chi square for a trend, and also by multivariate analysis: logistic regression.

In the multivariate analysis the LVI variable could not be modelled due to insufficient data (478 patients in total).

\*95% CI and p value appear to conflict.

Some analyses appear to be affected by missing data: i.e. between 398-566 patients.

NB Grade = histological grade.

Specht, Fey, Borgen & Cody . Is the clinically positive axilla in breast cancer really a contraindication to sentinel lymph node biopsy? J Am Coll.Surg 200[1]. 2005.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria**

106 patients with breast cancer and clinically palpable axillary nodes who underwent SLNB between September 1996 and August 2003, performed by two surgeons.

**Exclusion criteria**

Previous history of breast cancer;  
Earlier axillary surgery;  
Breast irradiation;  
Neoadjuvant chemotherapy;  
Cases not performed by two surgeons stated above.

**Population**

number of patients = 106, age range 26 to 88 years, median age = 51 years.

**Interventions**

Aim: to examine the role of SLNB in patients with clinically palpable axillary lymph nodes.

All patients underwent SLNB. Two groups were defined:

1. Patients with moderately suspicious nodes by palpation (n=62);
2. Patients with unequivocally suspicious nodes by palpation (n=44).

SLNB technique: dye, radiocolloid.

Histology technique:

**Outcomes**

Positive predictive value (PPV) of clinically palpable nodes, against axillary node status by definitive histology.

Patient/tumour factors compared between patients with falsely positive palpable axillae and those with truly positive palpable axillae. Factors compared were: age, previous surgical biopsy, body mass index, tumour size, histological grade.

**Follow up**

Not reported.

**Results**

Positive SNs were found in 63/106 = 59% of all patients with clinically palpable nodes.

In patients with moderately suspicious nodes by palpation, the rate of positive SNs was 29/62 = 48%.

In patients with unequivocally suspicious nodes by palpation, the rate of

positive SNs was 34/44 = 77%.

PPV (all patients) = 59%

PPV (patients with moderately suspicious nodes) = 47%

PPV (patients with unequivocally suspicious nodes) = 77%.

In patients with truly positive nodes by palpation, the following variables were statistically significantly different than in patients with falsely positive nodes by palpation:

Tumour size: mean 2.6cm and 1.6cm respectively, (p=0.002);

Proportion of patients with high histologic grade: 77% and 43% respectively (p=0.002).

#### **General comments**

'Moderately suspicious' nodes were defined as firm, shotty and more prominent than on the contralateral side.

Subgrouping of clinical suspicion of nodes based upon palpation appears to be vague and subjective, even assuming that two operating surgeons reported above, performed the examination.

Tan, Tan, Heng & Chan . Predictors of axillary lymph node metastases in women with early breast cancer in Singapore. Singapore Med J 46[12]. 2005.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Singapore, setting: Secondary care

**Inclusion criteria**

380 cases (in 373 patients) of early breast cancer of stage T1-2, N0-1, M0, treated between January 1999 and August 2002.

**Exclusion criteria**

Patients with missing data on factors examined.

**Population**

number of patients = 380, age range 24 to 87 years, median age = 52 years.

**Interventions**

Aim: to investigate the relationship between preoperative factors and the status of axillary lymph nodes.

All patients underwent axillary clearance

**Outcomes**

Relationship between preoperative/pathological factors and incidence of positive axillary nodes. Factors examined were: age, race, parity, menopausal status, family history of breast cancer, tumour stage/grade, histology, lympho-vascular invasion (LVI) and ER/PR status.

**Follow up**

Not reported.

**Results**

Prevalence of axillary disease =  $136/380 = 35.8\%$ .

In univariate analysis the following factors were significantly associated with axillary metastases: multiparity ( $p=0.03$ ), higher tumour stage ( $p<0.0001$ ), higher tumour grade ( $p=0.0003$ ), invasive ductal histology ( $p=0.0003$ ) and presence of LVI ( $p<0.0001$ ).

In multivariate analysis the following variables were independent predictors of axillary metastases: higher tumour stage, invasive ductal histology and presence of LVI. PR negative tumours were predictive of axillary metastases, but only with borderline statistical significance:

Proportion of patients with metastatic axillary nodes by tumour stage:

T1a:  $1/23 = 4.3\%$

T1b:  $7/37 = 18.9\%$

T1c:  $45/163 = 27.6\%$

T2:  $83/157 = 52.9\%$

OR (T1a relative to T2): 0.06 [95% CI 0.007-0.5]

OR (T1b relative to T2): 0.18 [95% CI 0.065-0.49]

OR (T1c relative to T2): 0.38 [95% CI 0.22-0.67],  $p=0.0001$ .

Proportion of patients with metastatic axillary nodes by tumour histology:

Invasive ductal: 128/322 = 39.6%

Invasive lobular: 4/13 = 30.8%

Other: 5/45 = 10.9%

OR (invasive lobular relative to invasive ductal): 0.9 [95% CI 0.24-3.4]

OR (others relative to invasive ductal): 0.26 [95% CI 0.09-0.72], p=0.04.

Proportion of patients with metastatic axillary nodes by LVI status:

LVI present: 43/57 = 75.4%

LVI absent: 91/317 = 28.7%

OR (present relative to absent): 7.7 [95% CI 3.5-17], p<0.0001.

Proportion of patients with metastatic axillary nodes by PR receptor status:

PR positive: 73/193 = 37.8%

PR negative: 58/154 = 37.7%

OR (positive relative to negative): 1.8 [95% CI 1.0-3.0], p=0.05.

**General comments**

Analysis was univariate (simple log regression) and multivariate for all factors (multiple log regression).

Tan, Wu, Fan, Hwang, Ewing, Lane, Esserman, Lu, Treseler, Morita & Leong . Primary tumor characteristics predict sentinel lymph node macrometastasis in breast cancer. Breast Journal 11[5]. 2005.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria**

**NB NODE POSITIVE POPULATION**

122 patients with primary invasive breast cancer who underwent SLNB between November 1997 and August 2003 and in whom one or more positive SNs were identified, out of a total of 644 patients.

Mean tumour size was 21.1mm (range 2-82mm)

**Exclusion criteria**

Palpable axillary nodes;  
Noninvasive tumours;  
Recurrent breast cancer;  
Failed preoperative lymphoscintigraphy.

**Population**

number of patients = 122, age range 25 to 83 years, median age = 53 years.

**Interventions**

Aim: to examine factors that may be predictive of sentinel node macrometastases in patients with breast cancer.

All patients underwent SLNB and had at least one positive SN identified.

SLNB technique: lymphoscintigraphy, radiocolloid (and sometimes dye)  
Histology technique: standard, immunohistochemistry (IHC).

**Outcomes**

Relationship between SN tumour burden (micrometastases or macrometastases) and tumour characteristics as follows: tumour size, tumour grade, nuclear grade, mitotic count, tubular formation, histology, lympho-vascular invasion (LVI), ER status, PR status, HER-2 status, number of positive SNs.

**Follow up**

Not reported.

**Results**

79/122 = 65% patients had macrometastases.  
43/122 = 35% patients had micrometastases.

In univariate analysis, the following factors were found to be statistically significantly associated with the finding of SN macrometastases: tumour size >15mm, tubular formation >=2, presence of LVI and no. positive SNs >=2:

Proportion of patients with macrometastatic SN by tumour size:

$\leq 15\text{mm}$ :  $22/42 = 52\%$

$>15\text{mm}$ :  $57/80 = 71\%$  ( $p=0.038$ ).

Proportion of patients with macrometastatic SN by tubular formation:

1:  $3/10 = 30\%$

$\geq 2$ :  $76/112 = 68\%$  ( $p=0.033$ ).

Proportion of patients with macrometastatic SN by LVI:

LVI present:  $29/36 = 81\%$

LVI absent:  $50/85 = 59\%$  ( $p=0.022$ ).

Proportion of patients with macrometastatic SN by no. of positive SNs:

1:  $48/87 = 55\%$

$\geq 2$ :  $31/35 = 89\%$  ( $p=0.00035$ ).

**General comments**

SN tumour burden was defined as follows:

Macrometastases:  $\geq 2\text{mm}$  on H&E

Micrometastases:  $< 2\text{mm}$  on H&E

Smaller metastatic deposits seen only on IHC were classed as negative.

Analysis was univariate; Chi square and Fisher's exact tests. Without multivariate analysis the effect of any one variable may depend on that of another.

Velanovich & Szymanski . Lymph node metastasis in breast cancer: common prognostic markers lack predictive value. Ann Surg Oncol 5[7]. 1998.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria**

851 patients with invasive breast cancer who underwent treatment with axillary clearance.

**Exclusion criteria**

None stated.

**Population**

number of patients = 851.

**Interventions**

Aim: to examine whether tumour factors are predictive of axillary metastases in patients with breast cancer.

All patients underwent axillary clearance.

**Outcomes**

Relationship between lymph node status and tumour factors. Results were reported by:

1. Presence of any lymph node metastasis;
2. Presence of 10 or more lymph node metastases.

Tumour factors examined were: histological type (infiltrating ductal or lobular carcinoma, medullary carcinoma), site of primary lesion in the breast (central, upper outer quadrant, upper inner quadrant, lower outer quadrant, lower inner quadrant), ER and PR status, DNA index, S-phase fraction, nuclear grade, and extensive intraductal component.

**Follow up**

Not reported.

**Results**

1. Presence of any lymph node metastasis:

Tumour size:

Univariate analysis:

Proportion of patients with axillary lymph node metastases by tumour size:

T1a: 8%

T1b: 15%

T1c: 30%

21-30mm: 53%

31-40 mm: 52%

41-50 mm: 67%

>51mm: 76% (p<0.0001)

Multivariate analysis: increasing tumour size had OR 1.5, p=0.04 (no increment reported).

Tumour location within the breast:

Univariate analysis:

There was a statistically significant difference in the proportion of patients with any axillary lymph node metastases by tumour location category ( $p=0.02$ ), but there was no discernable pattern.

Multivariate analysis did not reveal any tumour location as predictive of axillary metastasis.

Histological type:

Univariate analysis: there was no statistically significant association between axillary metastases and histological tumour type.

Multivariate analysis: Invasive lobular pathology was strongly independently predictive of axillary lymph node metastases: OR >400000,  $p=0.02$ , whereas tubular and medullary histology were strongly associated with lower odds of axillary metastasis: OR 0.000006,  $p=0.02$ .

ER and PR status:

In both univariate and multivariate analysis, there was no statistically significant association between any axillary metastases and ER/PR status.

Nuclear grade:

Univariate analysis:

Proportion of patients with one or more metastatic axillary nodes by nuclear grade:

I: 19%

II: 32%

III: 43% ( $p=0.0004$ )

Multivariate analysis: nuclear grade was not a statistically significant predictor of axillary lymph node metastasis.

## 2. Presence of 9 or more positive lymph nodes

Tumour size:

Univariate analysis:

Proportion of patients with 9 or more metastatic axillary lymph nodes by tumour size:

T1a: 0%

T1b: 1%

T1c: 4%

21-30mm: 6%

31-40 mm: 11%

41-50 mm: 16%

>51mm: 34% ( $p<0.0001$ )

Multivariate analysis: increasing tumour size had OR 14.8,  $p=0.026$  (no increment reported).

ER status:

Univariate analysis: ER status was not statistically significantly associated with the presence of 9 or more metastatic axillary nodes.

Multivariate analysis: Patients with ER negative tumours were statistically

significantly more likely to have 9 or more metastatic axillary nodes; OR 1.1,  $p=0.05$ .

**General comments**

Analysis was univariate (Chi square) and multivariate (logistic regression).

Summary statistics for the number of lymph nodes excised is not reported; regarding the outcome for 10 or more metastatic nodes, this is not possible if 9 nodes or fewer are examined.

On univariate analysis, tumour size, tumour location and nuclear grade were significantly associated with axillary node status.

The multivariate analysis for histological type doesn't seem plausible and is inconsistent with other studies; odds ratios do not state relative category, but appears to be ductal carcinoma.

Paper does not provide patient numbers for percentage proportions, nor 95% confidence intervals for odds ratios. Most percentages cited are read from graphs.

Authors report that in the multivariate analysis, the variables that are statistically significantly predictive of 1) one or more metastatic axillary lymph nodes; 2) 9 or more metastatic axillary lymph nodes; account for respectively 5.6% and 19.5% of the log likelihood of the regression in each case, implying that most of the metastases were unexplained by the factors analysed.

**Evidence table****Abbreviations:**

DCIS: ductal carcinoma in situ  
 DCISm: ductal carcinoma in situ with microinvasion  
 SLNB: sentinel lymph node biopsy  
 SN: sentinel node

**Retrospective case series studies (16)**

Camp, Feezor, Kasraeian, Cendan, Schell, Wilkinson, Copeland & Lind .  
 Sentinel lymph node biopsy for ductal carcinoma in situ: an evolving approach  
 at the University of Florida. Breast Journal 11[6]. 2005.

**Design:** Retrospective case series (diagnosis, screening), evidence level: 3  
**Country:** United States, **setting:** Secondary care

**Inclusion criteria** Patients with DCIS and DCISm

**Exclusion criteria** None stated: retrospective review

**Population** number of patients = 43.

**Interventions** Aim = to retrospectively review the experience of a single  
 centre of SLNB in patients with DCIS including DCISm.

All patients underwent SLNB.

SLNB technique: radiocolloid.

Histology technique: standard method, immunohistochemistry.

**Outcomes** Rates of SN positivity by final histological diagnosis.

**Follow up** None stated.

**Results** In total 7/43=16.3% of patients had positive SNs:

Final histology:

DCIS: 1/25=4% had positive SNs

DCISm: 5/17=29.4% had positive SNs

Invasive: 1/1=100% had positive SNs

SN positivity by tumour grade:

Of 13 patients with high nuclear grade, 1 [8%] was SN positive and 12 [92%]  
 were SN negative.

Upstaging to invasive disease:

1 patient with a biopsy diagnosis of DCIS was upstaged to invasive disease  
 after definitive surgery, representing:

1/25=4% of patients with DCIS;

1/43=2.3% of all patients in the series [DCIS+DCISm]

4 patients with positive SNs underwent axillary clearance and none had any  
 further positive axillary nodes.

**General comments**

Series represents patients with DCIS who underwent SLNB because they  
 were considered to be at high risk for invasive disease due to microinvasion,

comedo necrosis, multifocal, extensive or high grade DCIS, or the presence of a mass.  
Paper does not report rate of SN positivity by tumour size.  
Small series size.

Cox, Bass, Ku, Berman, Shons, Yeatman & Reintgen . Sentinel lymphadenectomy: a safe answer to less axillary surgery? Recent Results Cancer Res 152. 1998.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Series of patients with DCIS is a subset of 167 patients treated for breast cancer [mean age 58.5, SD 14.2 years].

17 patients had DCIS

**Exclusion criteria** None stated.

**Population** number of patients = 17.

**Interventions** Aim = to report on a centre's validation period for SLNB. All patients underwent SLNB plus axillary clearance.

SLNB technique: radiocolloid, dye.

Histology technique: intraoperative, standard method, immunohistochemistry.

**Outcomes** Rate of SN positivity by tumour size, reported for the whole patient series (n=167)

**Follow up** Not reported.

**Results** 1/17=5.9% of patients with DCIS had a positive SN

-

**General comments** Small number of patients with DCIS.  
Study does not report rate of SN positivity by tumour size or grade for patients with DCIS.

Cserni . Sentinel lymph node biopsy as a tool for the staging of ductal carcinoma in situ in patients with breast carcinoma. Surg Today 32[2]. 2002.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Hungary, setting: Secondary care

**Inclusion criteria** Patients with pure DCIS on final histology.

**Exclusion criteria** None stated: retrospective review, although patients with invasive disease are excluded from the analysis and no data are provided for patients with DCISm [it is possible that no cases occurred].

**Population** number of patients = 10.

**Interventions** To retrospectively review the experience of a single centre in SLNB in patients with DCIS.

SLNB technique: dye or radiocolloid plus dye.

Histology technique: standard method, immunohistochemistry.

**Outcomes** Rate of SN positivity by tumour grade and nodal pathological stage.

**Follow up** Not reported.

**Results** 1/10=10% of patients with pure DCIS had positive SNs:

SN positivity by tumour grade:

Low: 0/3=0%

Intermediate: 1/2=50%

High: 0/4=0%

Not reported: 0/1=0%

6 patients underwent axillary clearance including the patient with a positive SN. No patient had further positive axillary nodes.

-

**General comments** Small series of patients [10]

The one patient with no tumour grade reported had an intracystic papillary carcinoma.

Since 5 patients underwent axillary clearance following SLNB with negative result, these patients were apparently treated in the centre's validation period for SLNB.

Farkas, Stolier, Teng, Bolton & Fuhrman . An argument against routine sentinel node mapping for DCIS. Am Surg 70[1]. 2004.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients with pure DCIS.

**Exclusion criteria** Cases of DCIS diagnosed by biopsy at outside institutions

Cases of DCIS by biopsy that were revealed by definitive histology to be cases of invasive disease or DCISm.

**Population** number of patients = 44, age range 46 to 81 years, mean age = 63 years.

**Interventions** Aim: to determine the rate of positive SNs in patients with DCIS based on the experience of a single centre.

All patients underwent SLNB.

SLNB technique: mostly radiocolloid, dye.

Histology technique: standard method, immunohistochemistry.

**Outcomes** Rate of SN positivity.

**Follow up** Not reported.

**Results** 46 cases of DCIS were analysed in 44 patients.

The rate of SN positivity was zero.

The binomial probability of observing 0 positive SNs in 46 cases of SLNB, assuming a rate of SN positivity of 13% [see comment] was  $p < 0.01$ .

-

**General comments** Exclusion criteria are likely to produce a low rate of SN positivity compared to other series in the literature. Exclusion of cases of DCIS diagnosed by biopsy at outside institutions seeks to reduce the fallibility of diagnosis.

The rate of SN positivity of 13% was based upon that measured by Cox et al [2001]:

Cox CE; Nguyen K; Gray RJ; Salud C; Ku NN; Dupont E; Hutson L; Peltz E; Whitehead G; Reintgen D; Cantor A. Importance of lymphatic mapping in ductal carcinoma in situ (DCIS): why map DCIS? Am Surg 2001 Jun ;67(6):513-519.

This paper was not included since later follow up by Wilke et al. [2005] was included.

Design: Retrospective case series (diagnosis, screening), evidence level: 3

Country: Italy, setting: Secondary care

**Inclusion criteria** Patients with DCISm

**Exclusion criteria** Not specified: implied by inclusion criteria.

**Population** number of patients = 41, age range 29 to 67 years, mean age = 36 years.

**Interventions** Retrospective review of patients with DCISm treated with SLNB.

SLNB technique: preoperative lymphoscintigraphy, radiocolloid.

Histology technique: standard method, immunohistochemistry.

**Outcomes** Clinical presentation and pathological findings, including rate of SN positivity by tumour grade.

**Follow up** Not reported.

**Results** Rate of axillary positivity:

4/41 = 9.7% of patients with DCISm had positive SNs.

Rate of axillary positivity by tumour grade:

2/4=50% of patients with positive SNs had Grade I tumours compared to 5/37=13.9% of patients with negative SNs.

2/4=50% of patients with positive SNs had Grade II tumours compared to 12/37=33.3% of patients with negative SNs.

0/4=0% of patients with positive SNs had Grade III tumours compared to 19/37=52.8% of patients with negative SNs.

The SNs were the only affected node in 3 patients who underwent subsequent axillary clearance. In 1 patient axillary clearance revealed 4 further positive axillary nodes.

-

**General comments** Small series of patients with DCISm: higher risk group than pure DCIS.

Study appears to be retrospective in nature due to the definitive diagnosis of DCISm.

Small series size: no statistical testing performed and interpretation of small subgroups is difficult.

Study does not report rates of SN positivity by T size.

Katz, Gage, Evans, Shaffer, Fleury, Smith, Flax, Drogula, Petrucci & Magnant . Sentinel lymph node positivity of patients with ductal carcinoma in situ or microinvasive breast cancer. Am J Surg 191[6]. 2006.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** 109 patients had DCIS.  
21 patients had DCISm.

**Exclusion criteria** None specified.

**Population** number of patients = 130, age range 33 to 86 years, median age = 55 years.

**Interventions** Aim = to measure the rate of SN positivity in patients with DCIS, based on retrospective review of 131 SLNB procedures in 130 patients.

All patients underwent SLNB.

SLNB technique: dye initially, then radiocolloid, dye.  
Histology technique: standard method, immunohistochemistry.

**Outcomes** Rates of SN positivity.

Correlation of patient/tumour subgroups with SN positivity based upon standardised histological records.

**Follow up** Median follow-up 22 months, range 1 to 75 months.

**Results** ALL PATIENTS

Overall 10/131=7.6% of patients with DCIS including those with DCISm had positive SNs.

PURE DCIS

8/110=7.2% of patients with pure DCIS had positive SNs.

Of these, 2 patients underwent subsequent axillary clearance; no further positive axillary nodes were found.

Grade:

In patients with pure DCIS SN positivity by tumour grade was as follows:

Well differentiated: 2/8=25%

Moderately differentiated: 4/45=9%

Poorly differentiated: 2/55=4% p=ns [Chi square]

Tumour size:

In patients with pure DCIS SN positivity by tumour size was as follows:

<= 1.0 cm: 1/26=4%

1.1-2.0cm: 3/21=14%

2.1-5.0cm: 3/36=8%

>5.0cm: 1/21=5%

Unknown: 0/6=0% p=ns [Chi square]

In patients with pure DCIS, no patient, tumour or treatment related factor was predictive of SN involvement (including age, presentation, T size, grade, presence of necrosis, histological subtype, margin status, type of surgery, number of SNs identified).

#### PATIENTS WITH DCISm

2/21=9.5% of patients with DCISm had positive SNs.

Of these two patients one underwent axillary clearance and 1 further positive axillary node.

Grade:

In patients with DCISm SN positivity by tumour grade was as follows:

Well differentiated: 0/3=0%

Moderately differentiated: 1/9=11%

Poorly differentiated: 0/6=0%

Unknown: 1/3=33% p=ns [Chi square]

In patients with DCISm, no patient, tumour or treatment related factor was predictive of SN involvement (including age, presentation, T size, grade, presence of necrosis, histological subtype, hormone receptor status, margin status, type of surgery, number of SNs identified).

-

#### **General comments**

1 patient underwent bilateral SLNB for DCIS.

Pathology reported appears to be definitive, since a large pathology database was interrogated for the data.

Analysis used Chi square test.

DCIS grade was attributed using Van Nuys classification.

No tumour size subgroup data provided for patients with DCISm.

Kelly, Kim, Patrick, Grundfest & Crowe . Axillary lymph node metastases in patients with a final diagnosis of ductal carcinoma in situ. Am J Surg 186[4]. 2003.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** 134 patients with definitive diagnosis of pure DCIS underwent axillary surgery:

93 patients underwent axillary clearance only

14 patients underwent SLNB only

27 patients underwent SLNB plus axillary clearance

**Exclusion criteria** Patients with DCISm

**Population** number of patients = 134, mean age = 54 years.

**Interventions** Aim = to measure the incidence of axillary node metastases in patients with DCIS, prior to and after the introduction of SLNB and immunohistochemistry histology.

Patients underwent SLNB and/or ALND.

SLNB technique: dye or radiocolloid plus dye

Histology technique: immunohistochemistry for SNs. Standard method for axillary nodes from axillary clearance.

**Outcomes** Rate of detection of axillary disease, reported by axillary surgery procedure.

**Follow up** -

**Results** 3/134=2% of patients with pure DCIS had axillary disease.

In all 3 patients with pure DCIS and axillary disease, the tumour grade was grade II.

-

**General comments** 'Axillary clearance' in this study refers to removal of level I and II axillary nodes.

Study does not report axillary involvement by tumour size.

Klauber-DeMore, Tan, Liberman, Kaptain, Fey, Borgen, Heerdt, Montgomery, Paglia, Petrek, Cody III & Van Zee . Sentinel lymph node biopsy: Is it indicated in patients with high-risk ductal carcinoma-in-situ and ductal carcinoma-in-situ with microinvasion? *Ann Surg Oncol* 7[9]. 2000.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** 76 patients with DCIS [median age 56 years, range 38-81 years]

31 patients with DCISm [median age 51 years, range 31-80 years]

**Exclusion criteria** None specified.

**Population** number of patients = 107.

**Interventions** Aim: to retrospectively report the rate of axillary metastasis in patients with high risk DCIS and DCISm who underwent SLNB.

SLNB technique: radiocolloid, dye

Histology technique: standard method, immunohistochemistry.

**Outcomes** Rate of SN positivity

**Follow up** Not reported.

### Results

All patients:

12/107=11.2% of all patients with DCIS (including DCISm) had positive SNs.

Pure DCIS:

9/76=12% of patients with pure DCIS had positive SNs.

Of these 9 patients, 6 underwent axillary clearance and further axillary nodal involvement was found in 1 patient.

In these 9 patients, tumour grade was high in 7 patients, intermediate in 2 patients and low in 1 patient. Tumour size [on mammography] had mean 4.5cm, median 3.2cm and range 0.6-13.5cm.

DCISm:

3/31=10% of patients with DCISm had positive SNs.

All 3 patients underwent axillary clearance and no further positive axillary nodes were found.

In these 3 patients tumour grade was high in all 3 cases and tumour size [on mammography] was 0.3, 1.2 and 0.6cm respectively.

-

**General comments** Patients with DCIS or DCISm underwent SLNB only if they were considered high risk for metastatic disease. Retrospectively, patients had at least one of the following: palpable mass, mammographic mass, suspicious histology, multicentric disease, high nuclear grade, necrosis.

Pathology reported appears to be definitive, since a large pathology database was interrogated for the data.

Study does not report SN positivity by tumour size/grade subgroups, but describes these characteristics in SN positive patients.

Accordingly 21% of all patients with DCIS underwent SLNB and 82% of all patients with DCISm.

Liu, Yang & Chen . Sentinel lymph node mapping with emulsion of activated carbon particles in patients with pre-mastectomy diagnosis of intraductal carcinoma of the breast. Journal of the Chinese Medical Association: JCMA 66[7]. 2003.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: China (PRC), setting: Secondary care

**Inclusion criteria** 24 patients with DCIS by biopsy  
19 patients with DCISm by biopsy

Age not reported.

**Exclusion criteria** Not reported.

**Population** number of patients = 33.

**Interventions**

All patients underwent SLNB and further axillary surgery to some extent: dissection to level I/sampling of level II if the SN was negative and axillary clearance if the SN was positive.

SLNB technique: radiocolloid.

Histology technique: standard method.

**Outcomes** Rate of positive SNs/axillary nodes.

**Follow up** Not reported.

**Results** Rate of positive SNs:

Overall 3/33=9% of patients had positive SNs.

In patients with DCIS by biopsy, 2/24=8.3% had positive SNs.

In patients with DCISm by biopsy, 1/9=11.1% had positive SNs.

Of 3 patients with positive SNs, 1 patient had 1 further positive axillary node.

Upstaging by definitive surgery:

In 24 patients with DCIS by biopsy, 3 [12.5%] were upstaged to DCISm and 3 [12.5%] were upstaged to invasive disease.

In 9 patients with DCISm by biopsy, 3 [33.3%] were upstaged to invasive disease.

-

**General comments** In this series of patients the surgical team used activated carbon as the radiotracer.

All three patients with positive SNs were upstaged to invasive disease by definitive surgery.

Mittendorf, Arciero, Gutchell, Hooke & Shriver . Core biopsy diagnosis of ductal carcinoma in situ: An indication for sentinel lymph node biopsy. Curr.Surg 62[2]. 2005.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** 44 patients with biopsy diagnosis of DCIS but without evidence or suspicion of DCISm, who underwent SLNB, with successful SLNB in 41 patients.

**Exclusion criteria** Patients with biopsy diagnosis of DCISm; data for patients in whom SLNB was unseccessful (4/44=9.1%) is not reported.

**Population** number of patients = 41.

**Interventions** SLNB technique: radiocolloid.  
Histology technique: standard method, immunohistochemistry.

**Outcomes** Rate of positive SNs and further axillary nodes.

Rate of upstaging to invasive disease by biposy method (not shown).

**Follow up** Not reported.

**Results** 9/41=22% patients had positive SNs.

Of 9 patients with positive SNs, 5 underwent axillary clearance, of whom 1/5=20% had further involved axillary nodes.

Upstaging to invasive disease by definitive surgery:  
3/41=7.3% patients with biopsy diagnosis of DCIS who underwent successful SLNB had invasive disease revealed by definitive surgery.

-

**General comments** The 44 patients described above were identified form a series of 85 with biopsy diagnosis of DCIS. Therefore no SLNB was attempted in 41 patients.

Study does not report rate of positive SNs by tumour size or grade.

Pendas, Dauway, Giuliano, Ku, Cox & Reintgen . Sentinel node biopsy in ductal carcinoma in situ patients.[see comment]. Ann Surg Oncol 7[1]. 2000.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** 87 patients with pure DCIS by biopsy diagnosis.

No age data provided.

**Exclusion criteria** Patients with DCISm by biopsy diagnosis [n=9].

Pregnant women.

Patients with clinically palpably suspicious axillae.

**Population** number of patients = 87.

**Interventions** All patients underwent SLNB. Patients with any evidence of a metastatic SN underwent axillary clearance.

SLNB technique: radiocolloid, dye.

Histological technique: standard method, immunohistochemistry.

**Outcomes** Rate of positive SNs.

Histological features of tumours.

**Follow up** Not reported.

**Results** 5/87=5.7% of patients had positive SNs.

These 5 patients underwent axillary clearance; no further metastatic axillary nodes were identified.

-

**General comments** No information provided on whether definitive surgery revealed any invasive focus in the primary tumour.

Rate of positive SNs is not reported by tumour size or grade.

Trisal, Qian & Wagman . Axillary recurrence in DCIs: is axillary lymphadenectomy warranted? Am Surg 70[10]. 2004.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** Retrospective analysis of 171 patients with pure DCIS, of which 15 (9%) underwent SLNB.

Age data for the whole series of 171 patients: median 55 years, range 27-93 years.

**Exclusion criteria** None stated: implied by inclusion criteria.

**Population** -

**Interventions** Aim: to retrospectively evaluate recurrence and survival in patients with pure DCIS treated over a 14 year period at a single centre.

15 patients underwent SLNB.

SLNB technique: radiocolloid, dye.

Histological technique: standard method, immunohistochemistry.

**Outcomes** Survival.

Recurrence.

Histological outcomes.

**Follow up** Mean follow up 70 months for the whole series of 171 patients.

**Results** The rate of positive SNs was 0/15=0%.

At a mean follow up of 70 months for the larger series of 171 patients, no cases of axillary recurrence was seen, including in the 15 patients treated with SLNB.

-

**General comments** Small subset of patients underwent SLNB (n=15) .

Pathology reported appears to be definitive, since a large pathology database was interrogated for the data, plus medical notes.

Study does not report rates of positive SNs by tumour grade or size.

Veronesi, Intra, Vento, Naninato, Caldarella, Paganelli & Viale . Sentinel lymph node biopsy for localised ductal carcinoma in situ? Breast 14[6]. 2005.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Italy, setting: Secondary care

**Inclusion criteria** Patients with pure DCIS

**Exclusion criteria** Patients with DCISm

**Population** number of patients = 508.

**Interventions** Retrospective review of 508 patients with definitive diagnosis of DCIS who underwent SLNB.

SLNB technique: radiocolloid

Histology technique: not reported.

**Outcomes** Rate of positive SNs by tumour and treatment variables.

**Follow up** Study reports at 46 months of follow up for the 9 SN positive patients [not stated as minimum, median, etc.]

**Results** 9/508=1.8% of patients with pure DCIS had positive SNs and 499/508 patients had negative SNs.

8 of these patients underwent axillary clearance and in all 8 the SN was the only positive axillary node.

No pattern was observed between rate of positive SNs and grade:

Grade I: 2/9 = 22.2% of SN positive patients had Grade I disease compared to 90/499 = 18.1% of SN negative patients.

Grade II: 4/9 = 44.4% of SN positive patients had Grade I disease compared to 245/499 = 49.1% of SN negative patients.

Grade III: 3/9 = 33.3% of SN positive patients had Grade I disease compared to 164/499 = 32.8% of SN negative patients.

Similarly no correlation was observed between rate of positive SNs and clinical presentation, hormone receptor status, proliferative index or type of surgery.

T size had median 22.3mm in the 9 SN positive patients compared to median 12.1mm in the 499 SN negative patients.

2/9=22.2% of SN positive patients had comedo DCIS compared to 51/499 = 10.2% of SN negative patients.

-

**General comments** Diagnosis of DCIS appears to be definitive, based upon final histology and study hence retrospective.

Small number [9] of patients with pure DCIS and positive SNs: no statistical testing was performed.

Wilkie, White, Dupont, Cantor & Cox . An update of sentinel lymph node mapping in patients with ductal carcinoma in situ. Am J Surg 190[4]. 2005.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** 675 patients with biopsy diagnosis of DCIS [613] or DCISm [62].

**Exclusion criteria** None reported - retrospective review of whole series.

**Population** number of patients = 675.

**Interventions** Aim = to clarify the incidence [amongst patients with biopsy diagnosis of DCIS or DCISm] who are upstaged to invasive ductal carcinoma at the time of definitive resection.

All patients underwent SLNB.

SLNB technique: radiocolloid, dye

Histology technique: Intra-operative, standard method, immunohistochemistry

**Outcomes** Rate of change of diagnosis to invasive disease.

Rates of positive SNs by definitive diagnosis.

**Follow up** None reported.

**Results** Upstaging to invasive disease:

66/675 = 10% of patients were upstaged to invasive disease after definitive surgery [Of these 66 patients 58 had T1 tumours, 7 had T2 tumours and 1 had a T3 tumour].

Of 613 patients with biopsy diagnosis of DCIS 55 [9%] were upstaged to invasive disease.

Of 62 patients with biopsy diagnosis of DCISm 11 [18%] were upstaged to invasive disease.

Rates of positive SNs:

Of 559 patients with a definitive diagnosis of DCIS 27 [5%] had a positive SN.

Of 51 patients with a definitive diagnosis of DCISm 7 [14%] had a positive SN.

Therefore these rates combined reflect the rate of SN positivity in patients with DCIS, including DCISm: 34/610=5.6%.

Of 66 patients with a definitive diagnosis of invasive disease 15 [23%] had a positive SN.

Upstaging to invasive disease by grade of DCIS:

603 patients had biopsy grade data.

21/313 = 7% of patients with DCIS grade I, I-II or II were upstaged to invasive disease compared to 30/228 = 13% of patients with DCIS grade II-III or III [p=0.003, Chi square].

-

**General comments** Attributed grade was the highest grade seen by

histology.

603 patients had grade data. Grade data is dichotomised for Chi square analysis of rates of upstaging to invasive disease.

Study provides no data on rate of SN positivity by grade of DCIS, nor by size of DCIS tumour.

Zavagno, Carcoforo, Marconato, Franchini, Scalco, Burelli, Pietrarota, Lise, Mencarelli, Capitanio, Ballarin, Pierobon, Marconato & Nitti . Role of axillary sentinel lymph node biopsy in patients with pure ductal carcinoma in situ of the breast. BMC Cancer 5. 2005b.

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Italy, setting: Secondary care

**Inclusion criteria** 102 patients with a definitive diagnosis of pure DCIS who underwent SLNB.

**Exclusion criteria** Patients with DCISm

**Population** , age range 37 to 85 years, median age = 59 years.

**Interventions** Aim = to measure the incidence of SN metastases in patients with a definitive diagnosis of pure DCIS.

All patients underwent SLNB.

SLNB technique: radiocolloid.

Histology technique: standard method, immunohistochemistry.

**Outcomes** Rate of SN positivity.

**Follow up** Not reported.

**Results** 1/102=0.98% patients with pure DCIS had a positive SN.

In this patient the primary tumour was grade II and 16mm in diameter (T1c).

The tumour size and grade of 101 patients with negative SNs was as follows:

T size

0-5mm:	14 [13.9%]
5-10mm:	40 [39.6%]
10-15mm:	19 [18.8%]
15-20mm:	13 [12.9%]
20-30mm:	10 [9.9%]
>30mm:	2 [2.0%]
Unknown:	3 [3.0%]

Grade:

I:	21 [20.8%]
II:	36 [35.6%]
III:	44 [43.6%]

-

**General comments** -

Zavotsky, Hansen, Brennan, Turner & Giuliano . Lymph node metastasis from ductal carcinoma in situ with microinvasion. Cancer 85[11]. 1999.

Design: Retrospective case series (prognosis), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** 14 patients with DCISm who underwent SLNB, identified from a larger series.

DCISM was defined as follows (on the basis of initial triple assessment):

Single focus of size  $\leq 2\text{mm}$

$\leq 3$  foci of size  $\leq 1\text{mm}$

**Exclusion criteria** -

**Population** number of patients = 14.

**Interventions** Aim = to examine the role of SLNB in patients with DCISM.

All patients identified underwent SLNB.

SLNB technique: dye.

Histology technique: standard method, immunohistochemistry.

**Outcomes** Rate of positive SNs by size of tumour, size of invasive element of DCIS and tumour grade.

**Follow up** Not reported.

**Results** 2/14=14.3% of patients with DCISM had positive SNs:

SN positivity by T size:

$\leq 2\text{cm}$ : 0/5=0%

2-5cm: 2/5=40%

$>5\text{cm}$ : 0/4=0%

SN positivity by Tumour grade:

Grade I: 0/1=0%

Grade II: 0/2=0%

Grade III: 2/11=18.2%

Upstaging to invasive disease by definitive surgery:

4/14=28.6% of patients staged by SLNB were found, by definitive surgery, to have invasive foci of 1mm or more.

-

**General comments** The definition of true DCISM used is that of the American Joint Committee on Cancer: i.e. invasive focus  $<1\text{mm}$  in size on definitive histology.

Very small series of patients.

## Update 6B

Ansari, B., Ogston, S. A., Purdie, C. A., Adamson, D. J., Brown, D. C. & Thompson, A. M. (2008) Meta-analysis of sentinel node biopsy in ductal carcinoma in situ of the breast. *British Journal of Surgery*, 95: 547-554.

**Design:** Meta-analysis of case series studies, Evidence level 3

**Aim:** This study is a meta-analysis of the reported data on the incidence of SLN metastasis in patients with DCIS.

Some studies of SLN biopsy in DCIS assess the sentinel node biopsy-positive frequency in patients with a definitive (postoperative) diagnosis of DCIS, whereas others report this frequency in patients using the preoperative initial core biopsy diagnosis of DCIS. Given that 10–30 per cent of patients with a preoperative core biopsy diagnosis of DCIS will eventually turn out to have invasive cancers, the frequency of SLN metastatic involvement in these two patient groups may be different. Therefore, a meta-analysis of these two different sets of publications was performed separately.

### **Inclusion criteria**

- Case series studies that reported percentage SLN positivity in patients with a diagnosis of DCIS were included in the meta-analysis.
- Patients: patients with DCIS who were considered to be at high risk of having an invasive component, such as those with adverse clinical or histological features (large, palpable tumours, mammographic mass, high grade)

### **Exclusion criteria**

Publications that had not reported percentage SLN positivity data, review articles and editorials were excluded.

### **Population**

22 publications reporting SLN biopsy results in patients with the diagnosis of DCIS were included.

The combined study population = 3166 patients.

### **Interventions**

A comprehensive search was conducted for the studies: Medline, Embase, CINHALL, Ovid and The Cochrane Library, up to August 2007

### **Outcomes**

SLN positivity data

### **Results**

Studies that assessed the frequency of SLN positivity in patients with a preoperative diagnosis of DCIS reported values from 0 to 16.7%

The test for heterogeneity suggested that these 11 studies were not significantly heterogeneous ( $\chi^2 = 16.07$ , 10 df  $P = 0.098$ ).

A meta – analysis of the data on SLN positivity from these studies gave an overall positivity frequency (or overall incidence) of 7.4% (95 %CI 6.2 to 8.9)

There was significant between study heterogeneity in the 11 studies of patients with a definitive (postoperative) diagnosis of DCIS ( $\chi^2 = 27.82$ , 10 df,  $P = 0.002$ ).

A meta-analysis of the data on SLN positivity from these studies showed an overall positivity frequency (or overall incidence) = 3.7% (95%CI 2.8 – 4.8)

The overall frequencies of nodal metastasis between the two groups (preoperative versus

<p>definitive diagnosis) were significantly different with an odds ratio of 2.11 (95 %CI 1.15-2.93)</p> <p>From a subset of patients with a biopsy diagnosis of DCIS who were at high risk of an invasive component were presented (from a literature search with some inconsistencies occurring between studies):</p> <p>Most of these studies suggested that a palpable mass; a mammographic mass; a high-grade lesion and a large size were associated with a significant risk of invasive disease in the final resection specimen.</p>
<p><b>General comments</b></p> <p>Authors note that “Small patient numbers, evolving techniques of SLN biopsy and variations in methods of pathological examination, including differences in extent of tissue sampling and methods of metastasis detection, may all contribute to the variability in the reported frequencies of node positivity.”</p> <p>Conclusion: Patients with a preoperative diagnosis of DCIS should be considered for SLN biopsy.</p>
<p>Julian, T. B., Land, S. R., Fourchette, V., Haile, S. R., Fisher, E. R., Mamounas, E. P., Costantino, J. P. &amp; Wolmark, N. (2007) Is sentinel node biopsy necessary in conservatively treated DCIS? <i>Annals of Surgical Oncology</i>, 14: 2202-2208.</p>
<p><b>Design:</b> RCT – extended report of 2 RCTs (National Surgical Adjuvant Breast and Bowel Project (NSABP) trial B-17 and NSABP trial B-24)</p> <p><b>Country:</b> US</p> <p><b>Aim:</b> To identify the risk of axillary node involvement in patients with ductal carcinoma in situ (DCIS) and to determine whether axillary node assessment is necessary in these patients.</p>
<p><b>Inclusion criteria</b></p> <p>Patients included in the trials (NSABP trial B-17 and NSABP trial B-24): localised DCIS and disease-negative margins after local excision (LE)</p>
<p><b>Exclusion criteria</b></p>
<p><b>Population</b></p> <ul style="list-style-type: none"> <li>• 813 patients with localised DCIS and disease-negative margins after LE (NSABP) trial B-17</li> <li>• 1799 patients with DCIS treated with LE and radiotherapy (NSABP trial B-24)</li> </ul>
<p><b>Interventions</b></p> <ul style="list-style-type: none"> <li>• NSABP trial B-17 : records of 813 patients with localised DCIS and disease-negative margins after LE who were randomly assigned to no further therapy or to breast irradiation (ALND was performed in 253 patients, 31.1%)</li> <li>• NSABP trial B-24: 1799 patients randomised to receive placebo or tamoxifen after LE + radiotherapy (An ALND was performed in 162 in NSABP B-24, 9%)</li> </ul>
<p><b>Outcomes</b></p> <ul style="list-style-type: none"> <li>• Ipsilateral nodal recurrence (INR) rate</li> <li>• Pathological features for INR (assessed with standard hematoxylin and eosin staining)</li> </ul>
<p><b>Follow – up:</b> 15 years for B17 and 11 years for B-24</p>
<p><b>Results</b></p> <p><b>INR:</b></p>

In the NSABP trial B-17: Overall ipsilateral nodal recurrence (INR) rate = 0.83/1000 patient-years. (0.86%

In NSABP B-24: Overall INR rate = 0.36/1000 patient-years.

**Pathology:**

- Pathology was available for 76.6% of patients in the B-17 trial and 81% in the B-24 trial.
- Margins were involved in 17.2% of patients in B-17 trial and 29.5% in B-24 trial (with 9.3% unknown).
- For both trials: margin status; comedo necrosis; gross tumour size; nuclear grade and focality were assessed as a risk factor for nodal recurrence and no factor was statically significant related.

**General comments**

Authors' comments: INR can be considered a surrogate for axillary involvement at the time of DCIS diagnosis. INR in patients with DCIS treated conservatively is extremely rare. Findings from this study do not support the routine use of SNB in patients with conservatively treated, localised DCIS

## Health Economics Summary

The volume of economic evidence on SLNB is limited and refers only to question 6.a (i.e. it considered patients with invasive breast cancer but not those with DCIS). From a total of 80 references obtained from the search, six studies were identified that addressed topic 6.a from a health economics point of view: one of these studies was a full economic evaluation (Jeruss et al 2006), two of them were partial economic evaluations (Fortunato et al 2004 and Ronka et al 2004), and three of them were cost studies (Chirikos et al 2001, Gemignani et al 2000 and Perrier et al 2004). The identified studies do not provide a clear, reliable answer for the PICO question here presented. A full description of all these studies has been presented in the accompanying document containing the HE Evidence Tables.

The only economic evaluation identified in relation to this topic assessed two alternative ways of conducting SLNB (rather than comparing SLNB with ALND or axillary node sampling): intraoperatively and postoperatively, using analytic modelling techniques, and concluded that intraoperative SLNB seems to be cost-effective when compared to postoperative SLNB, although results were sensitive to the utilities used to estimate QALYs. The partial economic evaluation by Fortunato et al 2004 concluded that intraoperative SLNB resulted in significant cost savings derived from avoiding a second surgery on a subgroup of patients (i.e. those with negative nodes), although the comparator used in this study was not explicitly stated. Ronka et al (2004) compared three ways of conducting SLNB with ALND and found a false negative rate for SLNB of 13.24%, while ALND was the least costly staging strategy in terms of hospital costs; the authors mentioned that the benefits of intraoperative SLNB are likely to be found in the long-term (i.e. decreased arm morbidity) may be worth at relatively low false-negative rates because it avoids secondary surgery in patients undergoing staging.

None of the identified cost studies was conducted in UK. Two of these cost studies were conducted in the USA (Chirikos et al. 2001, and Gemignani et al 2000) and considered billing charges rather than costs for the estimation of the costs related to SLNB (which may not be representative of the UK setting and of the true costs of the intervention). The other study was conducted in France (Perrier et al. 2004). It was unclear whether SLNB was more or less expensive compared to ALND: Perrier et al (2004) concluded that SLNB seemed to be less expensive than ALND; according to Gemignani et al (2000), SLNB did not seem to result in significantly higher hospital-related charges compared to ALND; Chirikos et al (2001) highlighted that, although SLNB appeared to be more expensive procedure than ALND from the results of their study, the potential cost-savings they would expect from SLNB are likely to be observed in the long term. None of these studies considered the costs of post-operative complications, whose inclusion would have been required for an accurate cost assessment. Therefore, the studies seem to present limitations and to be either with limited applicability or non-applicable to the UK setting.

### Summary of individual studies

The only full economic evaluation identified (Jeruss et al 2006) was a cost-utility analysis conducted in USA that compared the cost-effectiveness of two alternative methods to carry out SLNB: intraoperative touch imprint cytology (TIC) and standard postoperative SLNB. No comparison was conducted with any of the comparators stated in the PICO question of the topic (i.e. no axillary surgery, axillary node sample or axillary lymph node dissection). A decision tree was constructed to estimate the incremental cost per QALY at 6 months. The baseline data used to populate the model was derived from a prospective cohort study developed at the authors' institution, although the parameters' ranges used in the sensitivity analyses were identified from the published literature. Health care resource utilisation and unit costs are likely to have reflected the clinical practice of the authors'

institution, and no statistical or sensitivity analyses were conducted for the estimated costs. Utility scores for the estimation of QALYs were obtained by surveying 4 surgical oncologists using the EuroQol-5D. The results of the analysis concluded that TIC was cost-effective compared to standard postoperative SLNB, with an incremental cost-per-QALY equal to: \$13,731 for T1 tumours and \$7,102 for T2 tumours for 2005 prices (equivalent to £8,497 and £4,395, respectively), and it was dominant (i.e. more effective and less costly) for T3 and T4 tumours, compared to standard postoperative SLNB. The results of the sensitivity analyses showed that the cost-effectiveness results were sensitive to the utility scores used for the estimation of QALYs.

The study by Fortunato et al (2004) was a cost-consequences analysis (CCA) conducted in Italy. The study assessed the accuracy of SLNB and the savings to the Italian Health System that could be achieved from avoiding second surgeries by means of SLNB. The reference standard used to assess SLNB accuracy was not explicitly stated, although it may have been ALND. The authors concluded that SLNB, with a sensitivity equal to 68% and a specificity of 99%, could result in significant cost savings for the Italian NHS derived from avoiding second surgeries. However, the cost estimation presented relevant limitations since the costs of SLNB were not included, only those of second operations; therefore, there is uncertainty regarding the reliability of the study results.

The study by Ronka et al (2004) was a CCA as well, and it was conducted in Finland. It assessed the number of patients that would undergo either 1, 2 or 3 surgeries depending on the staging strategy followed (i.e. ALND, SLNB with frozen section, SLNB without frozen section or SLNB as day care surgery), and the associated hospital costs per patient. The data were derived from a prospective cohort study evaluating SLNB frozen section, and from authors' assumptions about the other three staging strategies based on the results of this study. The accuracy of SLNB frozen section was additionally reported using the postoperative assessment as the reference standard. The authors concluded that ALND was the least costly strategy in terms of hospital costs, and that SLNB with frozen section may be worth at relatively low false-negative rates. The cost estimation did not include any long-term cost related to the alternative staging strategies (e.g. post-operative complications); therefore, it is likely not to accurately reflect the costs related to the staging strategies considered at analysis.

### Full Economic Evaluations

Jeruss JS et al. Is intraoperative touch imprint cytology of sentinel lymph nodes in patients with breast cancer cost-effective? Cancer, 2006. 107(10): p. 2328-2336.

**Design:**

Type of economic evaluation:

Cost-utility analysis using modelling (i.e. decision tree).

Clinical effectiveness:

From a prospective study conducted at their centre, assumptions, estimates of utilities from surgeons and some data from published literature.

Cost estimation:

Costs included were those of the procedures (TIC, postoperative SLNB, ALNC, either immediate or delayed) and postoperative complications.

**Country:** USA, **setting:** Hospital

**Inclusion criteria**

Breast cancer patients undergoing SLNB as staging procedure

**Exclusion criteria**

Not stated

**Population** number of patients = 342 patients from prospective study, 5 patients for cost estimation.

**Interventions**

Intraoperative touch imprint cytology (TIC) of SLNs  
Standard postoperative SLNB

**Follow up**

Time horizon = 6 months

**Data used to populate the model**

Assumptions:

- Patients with positive TIC would undergo immediate ALND
- Patients with metastases noted on standard postoperative SLNB have delayed ALND within 4 weeks after initial SLNB
- Probability of short-term surgical complications (e.g. infection and seroma) after ALND is 15%.

Health states: awaiting surgery, waiting for results of standard postoperative SLNB, recovering from ALND and recovering from ALND complications.

Data from prospective study:

OUTCOME OF INTEREST	TIC	Postoperative SLNB
Sensitivity	0.43	-
Specificity	0.99	-
Prevalence of SLN metastasis		
T1 tumours		0.17
T2 tumours		0.27
T3 tumours		0.40

T4 tumours

0.42

Utilities and costs: estimated by surveying 4 surgical oncologist, using EQ-5D:

Health States	Utility	Cumulative cost (2005 US\$)	Cumulative cost (2005 UK£)
TIC(+), Immediate ALND, No complications	0.71	8154	5046
TIC(+), Immediate ALND, Complications	0.56	8604	5324
TIC(-), SLNB(+), Delayed ALND, No complications	0.71	12040	7450
TIC(-), SLNB(+), Delayed ALND, Complications	0.62	12490	7729
TIC(-), SLNB(-), no ALND	0.89	5240	3243
Standard SLNB(+), Delayed ALND, No complications	0.66	11443	7081
Standard SLNB(+), Delayed ALND, Complications	0.58	11893	7359
Standard SLNB(-), No ALND	0.84	4643	2873

**Health care resource utilisation and costs:** To extract resource utilisation only 5 patients were identified, according to each treatment undergone and scenario proposed in the model.

Unit costs	2005 US\$	2005 UK£
TIC	600	371
Standard postoperative SLNB	4700	2908
ALND	6800	4208
TIC/Standard postoperative SLNB/Immediate ALND*	8200	5074
Postoperative complications	450	278

\* Not sure why they would conduct postoperative SLNB after having performed ALND

## Results

OUTCOME OF INTEREST	T1 tumours		T2 tumours		T3 tumours		T4 tumours	
	SLNB*	TIC	SLNB*	TIC	SLNB*	TIC	SLNB*	TIC
Average cost (2005 US\$)	5831	6160	6484	6652	7356	7311	7534	7445

ICER (2005 UK£)	-	8497	-	4395	-	Dominant	-	Dominant
# Procedures required to avoid one ALND	-	14	-	9	-	6	-	6
Patients with nodal metastasis	-	17%	-	27%	-	40%	-	42%

\*SLNB = Standard postoperative SLNB

### Sensitivity analysis:

The results were robust to changes in sensitivity and specificity of TIC, prevalence of metastases, probability of complications and most of the costs. TIC would not be longer cost-effective in the following analysed situations:

- When the cost for TIC with immediate ALND varied to 200% above the baseline estimate (presenting an ICER > £30,000 , or > US\$ 50,000).
- When the utility associated with postoperative SLNB was  $\geq 0.9$ .

### Authors' conclusions:

Overall, TIC is cost-effective in patients with clinically node-negative BC, and especially for those patients with larger tumours (who are more likely to have node metastasis and require ALND, in which case TIC would be less costly than postoperative SLNB).

### General comments –

There were some limitations in the cost analysis due to the small patients sample considered to collect cost data. The authors mentioned that the lower incidence of nodal metastasis and the lower sensitivity found for TIC may be due to the fact that the standard practice at their

centre is to use pre-treatment US+FNA in an initial stage to identify patients with positive nodes that can spare the SLNB procedure; these patients will typically receive preoperative chemotherapy (reducing or eradicating nodal metastasis before SLNB); therefore the patients included in this study are more likely to present micro metastasis, which are more difficult to detect through TIC.

## Partial Economic Evaluations

Fortunato L et al. Intraoperative examination of sentinel nodes in breast cancer: Is the glass half full or half empty? *Annals of Surgical Oncology* 2004; 11(11):1005-1010.

### **Design:**

#### Type of economic evaluation:

Partial economic evaluation (due to limitations in cost estimation)

#### Clinical effectiveness:

Derived from a prospective diagnostic study

#### Cost estimation:

It considered the savings to the Italian Health System derived from avoiding a second operation (i.e. ALND) for those patients with negative SLNs as identified through SLNB, minus the cost of the ALND on those false-positive cases.

**Country:** Italy, **setting:** Hospital

**Inclusion criteria** BC patients

**Exclusion criteria** Not stated

**Population number of patients** = 236 patients (median age = 64 years; median tumour diameter = 1.5cm): 201 (85%) of patients with ductal cancer, 21 (9%) with lobular and rest with other types of tumour (e.g. mucinous, tubular, medullary, metaplastic).

**Interventions** SLNB during surgical treatment for BC

The reference standard may have been ALND but this was not explicitly stated in the paper. (The authors mentioned that in addition to SLNB, non-SLNs were removed and analysed, and intra-operative SLNB accuracy was based on definitive pathological results).

**Follow up** Until test results

### **Results**

97% of patients had SLNs identified, with a median of 2 SLNs identified per patient. A median of 17 non-SLNs were removed in positive cases, and 2 in negative cases.

Accuracy = 86.5593%  $((52+157)/(77+159))$

Sensitivity = 67.5325%  $(77/52)$

Specificity = 98.7421%  $(157/(157+2))$

False negative = 13.7%  $(25/(157+25))$

False positive = 3.7%  $(2/(52+2))$

PPV = 96.2963%  $(52/(52+2))$

NPV = 86.2637%  $(157/(157+25))$

The savings to the Italian Health System were estimated to be €198,040 (or £164,162), based on 20% of patients (48/236) that avoided a second operation (i.e. ALND) due to the intraoperative SLNB minus the cost of the ALND for the two false-positive cases.

### **Authors' conclusions:**

Intraoperative SLNB resulted in significant cost savings derived from avoiding a second operation for completion lymphadenectomy on a subgroup of patients.

**General comments –**

The study may have been subject to bias since it was not clearly identified how the validation of the SLNB results was conducted (i.e. there was not an explicit identification of the reference standard used for validation of SLNB results, although as previously stated, the authors mentioned that in addition to SLNB, non-SLNs were removed and analysed). The authors mentioned they did not intend to conduct a cost-effectiveness analysis. For the estimation of the savings to the Italian Health System, not all the essential relevant costs were considered in the estimation (i.e. the costs of the SLNBs were excluded) and therefore there is uncertainty regarding the reliability of this cost estimation. They mentioned that there may be relevant differences in costs at the international level and therefore the results may not be generalisable to other settings.

Ronka, R., et al., The impact of sentinel node biopsy and axillary staging strategy on hospital costs. *Annals of Oncology*, 2004. 15(1): p. 88-94.

**Design:**Type of economic evaluation:

Partial economic evaluation: cost-consequences analysis that used modelling (i.e. decision tree).

Clinical effectiveness:

Prospective cohort study and authors' assumptions

Cost estimation:

Unit costs from Helsinki University Hospital.

Costs included:

- Hospital inpatient care (i.e. room and board, medication, blood products, laboratory costs, pre- and post-operative nursing care).
- Outpatient visits (i.e. pre- and post-operative check ups).
- Lymphoscintigraphy.
- Surgery (i.e. operation, anesthesia and recovery room).
- Pathological analysis (i.e. intra-operative frozen section, postoperative histological examination, breast specimens and ALND if conducted).

Price year: 2001.

**Country:** Finland, **setting:** Hospital

**Inclusion criteria** Patients with clinical T1-2, node-negative BC that underwent lymphatic mapping and SLNB at the authors' institution between September 2000 and August 2001.

**Exclusion criteria** Not stated

**Population** number of patients = 237

**Interventions**

- SLNB with intraoperative frozen section diagnosis (previous lymphoscintigraphy was conducted and Patent Blue dye was used), followed by ALNC (levels I and II) when there was evidence of axilla involvement (either after frozen section or after identifying a false negative result), SLNs not identified or were blue only without radioactivity, or if the tumour proved to be multifocal. ALNC (level III) was performed for palpable nodes suspicious of metastatic involvement.

Patients admitted to hospital in same day of surgery and discharged on first day after surgery for SLNB and second day after ALNC. Drainage removed by a breast nurse on fifth day after surgery.

Three hypothetical interventions were additionally assessed:

- Diagnostic ALND
- SLNB as day case surgery prior to breast surgery
- SLNB without frozen section diagnosis

**Follow up** Staging process

**Results**

OUTCOME OF INTEREST:	SLNB	SLNB	Total
Intraoperative and postoperative histological	Frozen	Frozen	

diagnosis in SLN metastases in 204 patients with successful identification of SLN	section (+)	section (-)	
Involved SLN	59	9	68 (33.33%)
Uninvolved SLN	1	135	136 (66.67%)
	60 (29.41%)	144 (70.59%)	204 (100%)

False negative rate for intraoperative SLNB = 9/68 = 13.24%

OUTCOME OF INTEREST	Diagnostic ALND	SNLB with frozen section	SLNB without frozen section	SLNB as day care surgery
Hospital costs per patient (€ 2001)	3020	3750	4087	4573
Hospital costs per patient (£ 2006)	2372	2945	3210	3592
Number (%) of patients with one operation	231 (97%)	218 (92%)	118 (49%)	-
Number (%) of patients with two operations	6 (3%)	19 (8%)	119 (51%)	237 (100%)
Number (%) of patients with three operations	-	-	-	13 (5%)

**Authors' conclusions –**  
ALND was the least costly staging strategy in terms of hospital costs. Intraoperative diagnosis of SLN metastases may be worth in the long terms, at relatively low false-negative rates, since the benefits of SLNB are likely to be observed in the long term. Further evaluation is required to identify long-term benefits of SLNB.

**General comments –**  
There was a clear description of the health care resource utilisation and unit costs used in the model, which would allow replications of the model using UK data. It seemed that the clinical parameters used in the model for the hypothetical staging/diagnostic strategies were inferred from the prospective cohort study. The lower costs found in this study for ALND were not consistent with the results of other studies (e.g. Gemignani et al 2000), which may have been due to differences in the type of patients included at analysis and to the fact that SLNB patients in this study had one day of hospitalisation after the staging procedure.

## Cost studies

Chirikos, T.N., et al., Cost consequences of sentinel lymph node biopsy in the treatment of breast cancer. A preliminary analysis. *International Journal of Technology Assessment in Health Care*, 2001. 17(4): p. 626-631.

### Design:

#### Type of study:

Cost study.

Multivariate analysis was conducted to identify the net effect of SLNB on charges, after controlling for other variables (e.g. age, number of cancers, stage at diagnosis, histology, node status, treatment and outcomes).

#### Cost estimation:

Data collected from cancer registry and from charge/billing system (to identify patients undergoing SLNB). Charges were considered for the cost estimation, which included: service encounters and charges for hospital room, board, outpatient visits, supplies, drugs, procedures, tests, etc.

**Country:** USA, **setting:** Hospital

**Inclusion criteria** All patients diagnosed of BC and who received the first course of treatment at the authors' centre between August 1995 and March 1998.

**Exclusion criteria** Patients who did not undergo any surgery, those treated by blood/marrow transplantation, and those diagnosed with stage IV.

**Population** number of patients = 555 in the SLNB group, 256 in the control group

**Interventions** SLNB versus Non-SLNB (not clearly specified)

**Follow up** From diagnosis to 44 months after diagnosis or death.

**Results**

OUTCOME OF INTEREST	SLNB (n = 555)	Control (n = 256)	P-value
Unadjusted average cumulative charges (\$)*	26,200	28,700	ns
Unadjusted average cumulative charges (UK£ 2006)*	23,046	25,245	-
Unadjusted SLNB charges as % of comparison group charges (%) at all follow up times	91.3	100	-
Adjusted SLNB charges as % of comparison group charges (%) at all follow up times	111.2	100	P < 0.01

\*Price year assumed to be 1998 for adjustments to UK£ 2006

**Authors' conclusions**

It is likely that the cost-savings related to SLNB will be observed in the long term and therefore they will be detected when more extensive follow up data become available.

**General comments –**

The price year was not explicitly stated (therefore, in the conversion exercises to UK£ it was assumed that it was 1998). As the authors highlighted, cumulative charges were used which did not include physician services, especially those of community physicians that care for long term treatment caused by adverse consequences. Therefore, bias against SLNB is likely to be present in the study.

Gemignani, M.L., et al., Impact of sentinel lymph node mapping on relative charges in patients with early-stage breast cancer. *Annals of Surgical Oncology*, 2000. 7(8): p. 575-580.

**Design:**

Type of study:

Cost study

Cost estimation:

A prospective cohort study with matched control group was used for the cost estimation. Three categories of costs included:

- Operating room (i.e. anesthesia, anesthesia medications and post-anesthesia care unit charges)
- Pathologic diagnosis (i.e. frozen section, gross and microscopic analyses, and immunohistochemical (IHC) staining).
- Hospital stay (room and board for patients admitted).

Total hospital charges included these three categories plus additional costs incurred (e.g. medication, supplies, laboratory tests, roentgenographic localisations and lymphatic mapping).

Total professional charges were obtained separately.

**Country:** USA, **setting:** Hospital

**Inclusion criteria**

T1 tumours, breast conservation therapy and absence of clinical suspicion of lymph node metastasis.

**Exclusion criteria**

Not stated

**Population**

Intervention group: 50 consecutive patients undergoing SLNB from July 1, 1997 to June 30, 1998.

Control group: 50 patients undergoing ALND during same period, matched by age, tumour size and lymph node status, staged during the same period.

\*Note than in the results section the authors reported the results of a retrospective study on

SLNB including 432 patients, but these were not considered for the cost analysis.

**Interventions**

SLNB versus ALND

Intraoperative frozen-section analysis was performed for SLNB. If metastases was detected in nodes, patients underwent ALND. Further serial sectioning and IHC staining was conducted after the procedure and for those with detected metastasis, ALND was offered later.

**Follow up** – Period related to the staging process

**Results**

OUTCOME OF INTEREST	SLNB (n = 50)	ALND (n = 50)	P-value
<b>Costs (\$):</b>			
Operating room	2509	3258	< 0.05
Hospital stay	820	1608	< 0.05
Pathologic examination	1747	969	< 0.05
Intraoperative frozen-section	528	158	< 0.05
Total hospital	6230	6331	
<b>Total hospital costs (UK£ 2006*)</b>	<b>4537</b>	<b>4611</b>	<b>ns</b>

\*Currency and price year assumed to have been Canadian\$ for 1997 in order to conduct cost adjustments.

There is some additional information reported in terms of health care resource utilisation (e.g. length of hospital stay, operating room time, etc.).

**Authors' conclusions** –

SLNB did not result in significantly higher hospital-related charges compared to those of ALND.

**General comments** –

The price year was not explicitly reported (although it may have corresponded to the period in which surgeries were performed, i.e. latter part of 1997). Currency not reported but it is likely to be Canadian\$. As the authors reported, one limitation was the use of charges rather than costs, which may not be a true reflection of the costs of the intervention/opportunity costs. In the discussion, the authors reported that intuitively, SLNB would offer financial advantages over ALND in patients with EBC since the procedure can be done in an outpatient basis and without general anaesthesia in most of the patients. However, if frozen-section is performed, the associated costs increase considerably. In addition, those patients with negative nodes from frozen-section but positive nodes from further analysis will need to receive further surgery (i.e. ALND). As the authors reported, “an intraoperative frozen-section analysis may help to reduce overall charges because it affords greater opportunity for identification of positive nodes at the time of the initial procedure, thereby decreasing the need for second surgical procedures.”

Perrier, L., et al., Cost comparison of two surgical strategies in the treatment of breast cancer: Sentinel lymph node biopsy versus axillary lymph node dissection. International Journal of Technology Assessment in Health Care, 2004. 20(4): p. 449-454.

**Design:**

Type of study:

Cost study

Cost estimation:

The cost analysis was based on micro-costing from a retrospective cohort study with random selection of patients from the intervention versus the control groups. Health care resource utilisation was obtained from patients' medical files and unit costs were obtained from the cost accounting department of the authors' institution.

Price year: 2001

**Country:** France, **setting:** Hospital

**Inclusion criteria** Patients treated for BC between 1998 and 2001 at the authors' institution.

**Exclusion criteria** Missing data or concomitant no cancerous pathological conditions requiring extensive hospital stay.

**Population** number of patients = 50 in the SLNB (with 2 finally excluded) versus 50 in the

ALND (with 7 excluded)

**Interventions** SLNB versus ALND

**Outcomes** Total direct medical costs of the staging procedures

**Follow up** During the staging of patients

**Results**

OUTCOME OF INTEREST	SLNB (n = 43)			ALND (n = 48)		
	Mean	%	SD	Mean	%	SD
Total direct medical costs without including ALND costs required after SLNB (€ 2001)	1444	81	401	2007	100	283
Total direct medical costs without including ALND costs required after SLNB (£ 2006)	1230	81	342	1710	100	241
Total direct medical costs (%) including ALND costs required after SLNB (€ 2001)	1777	100	645	2007	100	283
Total direct medical costs (%) including ALND costs required after SLNB (£ 2006)	1514	100	549	1710	100	241

Differences were statistically significant when total median costs were compared ( $p = 0.0076$ ).

**Authors' conclusions –**

SLNB appeared to be less expensive than ALND, and this difference may be even greater if indirect/societal costs were to be accounted for in the analysis.

**General comments –**

As the authors mentioned, comparisons of their results with those from other studies are difficult. However, Chirikos et al found as well lower costs for SLNB, while Gemignani found that the costs of SLNB were not significantly higher than those of ALND.

### 3.4 What are the indications for completion axillary clearance when the axilla has been found by biopsy to contain metastasis?

#### Short Summary

From RCT evidence there were no significant differences in overall survival between groups given axillary dissection or axillary sampling with regional node radiotherapy for lymph node positive patients (Chetty *et al.* 2000, Forrest *et al.* 1995); similarly there was no significant difference in overall survival between the groups receiving SLNB and axillary dissection and SLNB or axillary dissection only in SLNB positive patients (Veronesi *et al.* 2003). Finally there were no differences between these groups for locoregional recurrences or axillary recurrences (Chetty *et al.* 2000, Forrest *et al.* 1995, Veronesi *et al.* 2003). There were conflicting views from observational studies on whether patients with micrometastases can be spared axillary surgery from observational studies. The majority of patients with macrometastases in observational studies were given axillary clearance, unless there were clinical reasons not to, or refusal (Chagpar *et al.* 2006; EORTC Intergroup Study 2007; Ganaraj *et al.* 2003; Giard *et al.* 2004; Gipponi *et al.* 2006; Guenther *et al.* 2003; Katz *et al.* 2006; Langer *et al.* 2005; Lyman *et al.* 2005; Naik *et al.* 2004; Park *et al.* 2007; Pinkney *et al.* 2007; Viale *et al.* 2001). A retrospective case series by Samoilova *et al.* (2007) reported that the variable that most reliably separated N1a from N2-3 patients was the size of the tumour deposits in the sentinel lymph node. All patients with sentinel lymph node tumour deposits  $\leq 5$  mm had three or fewer positive nodes; 95% were sentinel lymph node positive only, and 91% had single-node involvement. The presence of lymphovascular invasion in the primary tumour was statistically significantly different between N1a and N2-3 patients and the presence of extracapsular extension of tumour in the sentinel lymph node was also statistically significantly different between N1a and N2-3 patients. The role of radiotherapy in reducing regional recurrence was unclear.

#### PICO question

POPULATION	INTERVENTION	COMPARISON	OUTCOME
Patients with invasive breast cancer with histologically-positive axillary nodes demonstrated by a surgical procedure i.e. SLNB or 4 node sampling	Completion axillary clearance	RT or no axillary treatment or change in systemic treatment	<ul style="list-style-type: none"> <li>• Disease Free Survival (DFS)</li> <li>• Axillary recurrence rate</li> <li>• Overall Survival (OS)</li> </ul>

The search strategy developed from this PICO table and used to search the literature for this question can be found in Appendix A

## Evidence Summary

Studies did not directly address the question outlined in the PICO table. Results of a RCT (AMAROS) that is relevant are awaited. This study compares axillary radiotherapy with axillary lymph node dissection in patients with proven axillary lymph node metastases determined by sentinel node biopsy. The NRS tended to focus on tumour characteristics and histology of the metastases without always providing data on follow-up after treatment. The RCTs provided data on recurrences, but not a great deal of detail about the histology of metastases.

Three RCTs were identified comparing axillary clearance/dissection with either axillary sampling and RT if node positive (Chetty *et al* 2000, Forrest *et al* 1995), or with axillary dissection only in patients with positive SNLB (Veronesi *et al* 2003). All three RCTs had a patient population of around 500 participants.

A larger number of non-randomized studies (NRS) were identified. However the majority of these had a very small proportion of patients with positive axillary lymph node metastases (range n = 15-48), many of these studies were descriptive, reported the incidence of metastases in non-SLNs, and most did not report any further interventions or follow-up. Patients found to have macrometastases usually had completion axillary dissection unless there were clinical reasons for not undertaking surgery, or they refused. The histological findings were sometimes modeled in univariate and multivariate analyses to quantify predictive factors for non-SLN metastases, some of these studies were underpowered for multivariate analysis. The conclusions of the smaller studies tended to favour the omission of completion axillary dissection for patients with micrometastases. The ten NRS included in the evidence table were comprised of 2 studies that were predictive using a scoring system (Pinkney *et al* 2007) or nomogram (Park *et al* 2007); the remaining 8 studies were either prospective or retrospective and largely descriptive. Not all studies classified metastases as micrometastases or macrometastases, some (n=4) provided later follow-up data of regional recurrences.

One guideline and one expert review were also included.

### Evidence from RCTs

In RCTs pathological tumour sizes were reported in the tables of characteristics. The proportion of node positive patients in RCTs was between 28-43%. For node positive patients metastases were not always sub-classified by size i.e. micrometastases or macrometastases. (Chetty *et al* 2000, Forrest *et al* 1995).

The RCT comparing Axillary sampling + RT vs. AXND (Chetty *et al* 2000) reported no differences between groups for the outcomes Overall Survival (Kaplan-Meier, log rank test p=0.2); time to axillary recurrence (p=0.94) or time to breast recurrence (p=0.97). The authors suggest a selective policy for the management of the axilla.

The earlier RCT (Forrest *et al* 1995) of Axillary node sampling (4 node sampling) + RT to nodes of patients with positive metastases vs axillary node clearance after total mastectomy found no difference in survival between the 2 groups at 11 years. There were more locoregional recurrences in the axillary clearance group than the axillary sampling group (29% vs 19%), however a statistical analysis was not reported. The authors suggested surgical clearance of the axilla is preferred to sampling + RT because of reduced morbidity. However this trial was conducted in the early 1980s.

In a trial comparing sentinel-node biopsy and total axillary dissection (the axillary-dissection group) versus sentinel-node biopsy followed by axillary dissection only if the sentinel node contained metastases (the sentinel-node group) (Veronesi *et al* 2003). No local recurrences were reported in the axilla after a median follow-up of 46 months. Other locoregional recurrences occurred in the supraclavicular fossa, ipsilateral and contralateral breasts. Event rates were small and no statistical analysis was performed between groups. There was no statistically significant difference between groups in the rate of overall survival over 60 months ( $p=0.15$ ).

**Table 3.3.1** Survival, recurrence and sites of relapse from RCTs

Study	Overall survival	Recurrence	Sites of relapse

**Evidence from non-randomized studies**

*Scoring systems*

A study (Pinkney *et al* 2007) validating a clinico-pathological score for patient selection for minimally invasive axillary surgery, suggested it may be possible to avoid a second axillary procedure in a large majority of patients. The sensitivity was 90% and specificity 64%, however the sample was small (n=99).

A similar larger retrospective study that used a nomogram for patient selection (Park *et al* 2007) and followed the trend in treatment options suggested that ALND could be omitted for a low-risk subset of SLN-positive patients.

#### *Other non-randomized studies*

The findings of the remaining NRS are reported in the associated table. Node metastases are classified and recurrences are reported where available. The findings can be grouped into those studies that recommend omission of axillary dissection when only micrometastases are found in the SN, those that recommend axillary dissection for all patients with positive SN, and those where a particular subgroup may avoid dissection.

Studies suggesting that axillary dissection could be avoided in patients with micrometastases in sentinel nodes were:

Naik *et al* 2004, Gipponi *et al* 2006, Langer *et al* 2005.

Naik *et al* (2004) suggested that there may be a subgroup of patients where axillary dissection is not required.

The study by Ganaraj *et al* (2003) suggests patients with micrometastases and ductal carcinoma may be spared axillary dissection, but those with lobular carcinoma still require axillary dissection.

Viale *et al* (2001) suggests that patients with micrometastases of less than 1mm may avoid axillary dissection, but trial data is required.

The study by Guenther *et al* (2003) recommends trials for evaluation of axillary dissection in patients with positive SNBs.

Studies that recommended axillary dissection for node positive metastases were:

Giard *et al* (2004) concluded that it is necessary to perform axillary clearance when the SNB contains micrometastatic disease, whatever the size or detection method of the metastasis.

Katz *et al* (2006) recommends that completion axillary dissection be performed for any subgroup of patients with +SLNs.

A retrospective case series by Samoilova *et al* (2007) predicted that the variable that most reliably separated N1a from N2-3 patients was the size of the tumour deposits in the sentinel node ( $P < .001$ ). All patients with sentinel node tumour deposits  $\leq 5$  mm had three or fewer positive nodes; 95% were sentinel node-positive only, and 91% had single-node involvement. The presence of lymphovascular invasion in the primary tumour was statistically significantly different between N1a and N2-3 patients ( $P < 0.025$ ) and the

presence of extracapsular extension of tumour in the sentinel node was also statistically significantly different between N1a and N2-3 patients ( $P < 0.01$ )

**Table 3.3.2** Node metastases and involved nodes

<b>Study (N of participants)</b>	<b>Intervention</b>	<b>Classification of metastases</b>	<b>Node involvement</b>	<b>Recurrence</b>

## Evidence Tables

### Randomized controlled trials

EORTC Intergroup Study. After mapping of the axilla: radiotherapy or surgery? AMAROS 13079. 2007. Report No.: EORTC 10981-22023.

Design: RCT EORTC trial  
Ongoing from 2001  
Country: Europe, setting: Multicentre

Aim: To prove equivalent local/regional control for patients with proven axillary lymph node metastasis by sentinel node biopsy with reduced morbidity if treated with axillary radiotherapy instead of axillary lymph node dissection. A second objective is to investigate whether adequate axillary control can be obtained by not subjecting patients with a negative sentinel lymph node to axillary lymph node dissection.

#### **Inclusion criteria :**

- Histologically or cytologically proven invasive breast cancer
- Tumour larger than 5mm and smaller than 30 mm at largest diameter
- Clinically negative axillary lymph nodes
- No previous treatment of the axilla

#### **Exclusion criteria**

**Population** number of patients = 3485

#### **Interventions**

After Mapping of the Axilla: Radiotherapy Or Surgery (AMAROS) is an international, multicentre, phase III study comparing a complete axillary lymph node dissection with radiotherapy to the axilla in sentinel biopsy positive patients. Sentinel node negative patients are also followed for the end-points of the study. The involved patients have an operable invasive breast cancer of over 5 mm and less than 3 centimeters, without clinically suspect regional lymph nodes. Patients will have FNA or core biopsy proven unifocal invasive breast cancer and should be fit to undergo either treatments. Patients are stratified by institution and type of breast surgery and randomized between complete axillary lymph node dissection and radiotherapy of the axilla. Sentinel node biopsies are performed by a combined technique using preoperative lymphoscintigraphy by intra- or peritumoural injection of a radioactive tracer, immediate preoperative injection of a dye. Followed by SN-retrieval by both discoloration and intra-operative use of a detection probe.

Randomization takes place before the sentinel node procedure. The patient knows before surgery whether she will have a complete axillary dissection or radiotherapy if the sentinel node(s) is (are) tumour positive on frozen section or definitive histology.

**Outcomes**

Axillary recurrence

Overall survival

Disease free survival

**Follow up****Results**

Ongoing

**General comments -**

Chetty U, Jack W, Prescott RJ, Tyler C, Rodger A. Management of the axilla in operable breast cancer treated by breast conservation: A randomized clinical trial. Br J Surg 2000;87(2):163-9.

Design: RCT (1987-1995)

Level 1+

Country: Scotland, setting: Not clear whether single or multicentre

Aim: To compare the efficacy of different surgical approaches (axillary node sample or node clearance) in patients with operable breast cancer treated by breast conservation, and to assess morbidity associated with these procedures and radiotherapy (RT).

#### **Inclusion criteria**

Age < 70 years

Unilateral invasive breast cancer

Clinical size 4cm or less

No evidence of metastatic disease

#### **Exclusion criteria**

Clinically multicentric tumour

Locally inoperable (T4)

Axillary nodes fixed (N2)

History of invasive carcinoma at any site (exception skin basal cell carcinoma)

**Population** number of patients = 466

Median age 54 years

Premenopausal n=170 (36%)

Perimenopausal n=12 (3%)

Post menopausal n=283 (61%)

Pathological tumour size:

≤ 1cm n=59 (13%)

> 1 ≤ 2cm n=209 (45%)

> 2 ≤ 3cm n=104 (22%)

> 3 cm n=103 (22%)

Node negative n=319 (68%)

Node positive n=144 (31%)

#### **Interventions**

Randomization by permuted blocks of eight to axillary clearance (n=232) or axillary node sample (n=234).

Arm 1) Axillary node sampling technique was to obtain at least 4 palpable axillary lymph nodes.

Arm 2) A level III axillary clearance was performed.

Postoperative RT to the breast with paired tangential fields was delivered to all patients (45Gy in 20 fractions over 4 weeks), and a boost to the tumour bed.

Patients receiving axillary clearance did not receive RT to the axilla.  
 Patients receiving axillary sampling that revealed involved nodes received RT to the axilla.  
 Patients receiving axillary sampling with no involved nodes did not receive RT to the axilla.  
 (Between 1987-1990 the policy was to treat all patients with axillary RT after axillary sampling, consequently 39 patients with negative nodes received axillary RT).

The regional lymph nodes were treated by direct anterior field to the axilla and supraclavicular fossa, and a posterior axillary boost. The dose was 45Gy in 20 fractions over 4 weeks.

**Outcomes**

Overall survival  
 DFS  
 Locoregional recurrence  
 Morbidity

**Follow up** Median 4.1 years

**Results**

Intention-to-treat analysis was conducted for assessment of recurrence and survival.  
 Of 466 randomized, 4 patients had benign disease and 8 a non-invasive cancer.  
 29 patients did not receive their allocated option.

*Survival*

No statistically significant differences in Overall Survival (Kaplan-Meier, log rank test  $p=0.2$ ) or disease-free survival (Kaplan-Meier, log rank test  $p=0.68$ ).

Estimated 5 year survival rates were:

Axillary sample 88.6% (SE2.5)  
 Axillary clearance 82.1% (SE3.1)

44 deaths occurred from breast cancer  
 9 deaths were from other causes

*Recurrence*

There were no differences between the 2 groups in time to axillary recurrence ( $p=0.94$ ) or time to breast recurrence ( $p=0.97$ ).

The sites and number of relapses are shown in the table below.

Site of relapse	Axillary clearance (n=232)	Axillary sample +RT (n=234)
-----------------	----------------------------	-----------------------------

Local:		
Breast	14	15
Regional:		
Axilla	8	7
Supraclavicular fossa	4	2
Axilla + supraclavicular fossa	0	1
Distant	29	29

**Author conclusions**

A selective policy for the management of the axilla is associated with no increase in axillary recurrence or mortality rate compared with routine axillary node clearance. Patients who are node negative after axillary sample can avoid radiotherapy or axillary clearance.

**General comments -**

Forrest AP, Everington D, McDonald CC, Steele RJ, Chetty U, Stewart, et al. The Edinburgh randomised trial of axillary sampling or clearance after mastectomy. Br J Surg 1995;82(11):1504-8.

Design: RCT (1980-1983)

Level 1+

Country: Scotland, setting: Single Centre

Aim: The aim of the study was to determine whether a standard 'four-node' axillary sample, followed by careful dissection of removed tissue, could accurately indicate the extent of local treatment required.

### **Inclusion criteria**

Patients fit for surgery and radiotherapy, with clinically operable invasive breast cancer (T1, T2, operable T3, N0, N1, M0).

### **Exclusion criteria**

Patients unlikely to participate in continuous follow-up, those with *in-situ* cancer including Paget's disease of the nipple, and those with multiple, ipsilateral, or contralateral breast cancer.

**Population** number of patients = 417

209 randomized to treatment by axillary node sampling (50 patients in this group had fewer than 4 nodes sampled)

208 randomized to axillary node clearance

Pathological tumour size:

< 2cm n=181 (45%)

> 2-5cm n=163 (40%)

> 5cm n=9 (2%)

Not known n=53 (13%)

### **Interventions**

Patients were randomized either to a total mastectomy and lower axillary node sampling or to total mastectomy and complete axillary node clearance. The first 282 patients were randomized before operation; the last 135 cases the option was drawn after mastectomy and node sampling, this was extended to full axillary dissection if selected.

Methods for pathological examination of nodes were not described but predate recent techniques.

Radical postoperative 6-MeV radiotherapy was given to 82 of 86 patients with proven metastatic involvement of sampled nodes and to one where no node was identified. RT was delivered to the chest wall, internal mammary node chain, and supraclavicular fossa. RT dose and fractionation were changed during the course of the trial. No patient in the axillary clearance group received radiotherapy.

### **Outcomes**

Survival

Locoregional relapse

**Follow up**

11 years (range 2-13)

**Results**

The mean number of nodes identified in the axillary sampling group was 6 (median 4, range 0-19) and in the clearance group 20 (median 20, range 5-46).

The incidence of positive nodes in patients undergoing sampling was no different from that in the full axillary clearance group (43.3%, n=88 and 39.4%, n=80 respectively).

*Survival*

There were 147 (35%) deaths.

71 deaths in the RT/node sampling group (breast cancer deaths n=57)

78 deaths in the axillary clearance group (breast cancer deaths n=54)

Kaplan-Meier Hazard Ratio 1.11 (95% CI 0.80-1.53) – not significant.

*Locoregional relapse*

The hazard ratio for axillary node sampling was 1.35 (95% CI 0.83-2.19) – not significant (reference axillary clearance)

Sites of locoregional relapse are shown in the table below.

There was an increased incidence of chest wall relapse in node positive patients treated by axillary clearance (No RT), but this was not statistically significant (17/80 cleared *versus* 11/88 sampled;  $\chi^2$  1.72 > 0.1, P < 0.25).

Site of relapse	Axillary sampling			Axillary clearance		
	Node negative n=115	Node positive (+RT) n=88	Total n=203	Node negative n=123	Node positive n=80	Total n=203
Chest wall	8 (7.0%)	11 (12%)	19 (9.4%)	9 (7.3%)	17 (21%)	26 (12.8%)
Axilla	5 (4.3%)	6 (7%)	11 (5.4%)	3 (2.4%)	3 (4%)	6 (3.0%)
Supraclavicular	4 (3.5%)	8 (9%)	12 (5.9%)	6 (4.9%)	9 (11%)	15 (7.4%)
Any locoregional recurrence	12 (10.4%)	17 (19%)	29 (14.3%)	14 (12.2%)	23 (29%)	38 (18.7%)

**Author conclusions**

There was only a minor difference in axillary relapse, favouring axillary clearance (3.0% versus 5.4%). In patients with operable breast cancer, mastectomy with axillary node sampling gives equal control to mastectomy with axillary node

clearance but, as morbidity is greater, surgical clearance of the axilla is the preferred option.

**General comments -**

Veronesi U, Paganelli G, Viale G, et al. A Randomized Comparison of Sentinel-Node Biopsy with Routine Axillary Dissection in Breast Cancer N Engl J Med, Volume 349(6).August 7, 2003.546-553.

Design: RCT (1998-1999)  
Level 1+  
Country: Italy, setting: Single setting

**Inclusion criteria**

Patients with primary invasive breast cancer, no history of another cancer, and a tumour  $\leq$  2cm in diameter.

**Exclusion criteria**

Patients with a multicentric cancer or had previously undergone excisional biopsy.

**Population** number of patients = 649 enrolled, 532 randomized, 516 evaluable.

SNB and total axillary dissection n=257

SNB and axillary dissection if node +ve n= 259

Age range 40-75 years.

Tumour size:

< 1cm n=130 (25%)

1.1-1.5cm n=243 (47%)

> 1.5cm n=143 (28%)

**Interventions**

All patients had breast conserving surgery (BCS) and were then randomized (on detection of a sentinel node by the gamma probe) to either SNB and total axillary dissection or SNB and axillary dissection only in patients with metastases in the sentinel node.

SNB was performed using radioactive colloid and lymphoscintigraphy for injection and a gamma probe for detection.

Sentinel nodes were examined by frozen section, staining was performed with haemotoxylin and eosin, cytokeratin was used when results were ambiguous.

All patients received breast irradiation and a boost to the surgical scar.

**Outcomes**

Sensitivity and specificity of SNB

Survival

Locoregional recurrence

Distant metastases

**Follow up** Median 46 months

**Results**

Sensitivity of SNB = 91.2%

Specificity of SNB = 100%  
Negative predictive value 95.4% (95% CI 91.1-98)

A total of 429 sentinel nodes were removed from 257 patients having axillary dissection (mean 1.7 nodes / patient).

A total of 424 sentinel nodes were removed from 259 patients having SNB (mean 1.6 nodes / patient).

Mean number of 24 non-SLN were removed from each group.

92/259 (35.5% 95%CI 29.7-41.7) of sentinel node group had a positive sentinel node and underwent axillary dissection.

91/257 (35.4%) of the axillary dissection group had axillary metastases. 83/91 (96.9%) of these had a positive SNB (83/257; 32.3% 95% CI 26.6-38.4).

60/175 patients with a positive sentinel node had micrometastases only ( $\leq$  2mm).

10/60 (17%) of these patients had another positive axillary node.

Axillary dissection group n=29 with micrometastases. In 24 of these patients all other axillary nodes were negative, 5 patients had one other positive node.

Sentinel node group n= 31 with micrometastases. In 26 of these patients all other nodes were negative, in 5 patients one other node was positive.

### *Survival*

6 deaths in axillary dissection group and 2 in the sentinel node group. There was no statistically significant difference between groups in the rate of overall survival over 60 months ( $p=0.15$ ).

### *Recurrence*

Number of events:

21 in axillary dissection group and 13 in the sentinel node group ( $p=0.13$ ).

25 events were associated with breast cancer: 15 in axillary dissection group, 10 in sentinel node group.

Cumulative incidence of breast cancer events (recurrence in ipsilateral breast, tumour in contralateral breast, distant metastases) were not statistically significantly different between groups ( $p=0.26$ ).

These findings are shown in the table below:

<b>Event</b>	<b>Axillary dissection group n=257</b>	<b>Sentinel node group n=259</b>
Axillary metastases	2	0
Supraclavicular	0	0

metastases		
Recurrence in ipsilateral breast	1	1
Cancer in contralateral breast	2	3
Distant metastases	10	6
Other primary tumour	6	3
Total	21	13
Death from breast cancer	2	1
Death from other causes	4	1
<b>General comments -</b>		

**Observational Studies (eg. Prospective Cohort or Retrospective Cohort or Case Series):**

**Scoring systems**

Pinkney TD, Nightingale P, Carmichael AR. A prospective study of use of a clinicopathological score to select patients for the type of axillary surgery. Eur J Surg Oncol 2007;33(2):153-6.

Design: NRS consecutive series  
 Level 3  
 Country:UK, setting: Single hospital

Aim: To prospectively assess a previously described and independently validated clinicopathological score for counselling and selecting patients for sentinel node biopsy or axillary clearance.

**Inclusion criteria** Patients presenting with breast cancer

**Exclusion criteria**

**Population** number of patients = 99

**Interventions**

Based on a previously validated clinicopathological score, patients with a score of 10 or below were classed as less likely to have positive lymph nodes and hence were offered for minimally invasive axillary surgery and patients with a score of 11 or above were regarded to have high risk of nodal involvement and were counselled for axillary clearance.

<b>Score</b>	<b>0</b>	<b>1</b>	<b>2</b>	<b>3</b>	<b>4</b>
Age years		>60	40-60	<40	
Palpable		No	Yes		
Grade		1		2-3	
Size mm		0.1-10	11-19	20-40	>40
Lymphovascular invasion	No				
Quadrant		Inner	Outer		

31 patients were classified as low score (10 or less)  
 43 patients were classified as high score (11 or more)

**Outcomes**

Predictive values

ROC

Sensitivity

**Follow up**

**Results**

Exclusions n=25

Lowest score was 6, highest score 16.

True positive n=27

True negative n=28

False positive n=16

False negative n=3

3 /31 (10%) patients in the low score group had axillary metastasis and needed further axillary treatment (Negative predictive value = 90%).

27/43 (63%) underwent axillary clearance for a high score and had positive axillary nodes (positive predictive value = 63%)

From this data the sensitivity and specificity of the scoring system with a cut-off value of  $\geq 11$  as the indicator for axillary dissection are:

Sensitivity =  $27/30 = 90\%$

Specificity =  $28/44 = 64\%$

An ROC curve found the Area Under the Curve (AUC) to be 0.83 (95% CI 0.74-0.93). This was better than tumour size only (AUC 0.72) or size and grade of tumour (AUC 0.71).

**Author Conclusions:** Until preoperative axillary staging becomes widely available, by using the clinico-pathological score for patient's selection for minimally invasive axillary surgery, it may be possible to avoid a second axillary procedure in a large majority of patients.

**General comments -**

Park J, Fey JV, Naik AM, Borgen PI, Van Zee KJ, Cody III HS. A declining rate of completion axillary dissection in sentinel lymph node-positive breast cancer patients is associated with the use of a multivariate nomogram. *Ann Surg* 2007;245(3):462-8.

Design: NRS (Consecutive retrospective) (1997-2004)  
Level 3

Country: USA, setting: Single Cancer Centre

Aim: To compare sentinel lymph node (SLN)-positive breast cancer patients who had completion axillary dissection (ALND) with those who did not, with particular attention to clinicopathologic features, nomogram scores, rates of axillary local recurrence (LR), and changes in treatment pattern over time.

**Inclusion criteria**

SLN positive patients on the MSKCC database.

**Exclusion criteria**

Planned “backup” ALND

Failed mapping

Nonmalignant lesions, nonmammary cancers, pure ductal carcinoma in situ, inflammatory cancer, bilateral cancers

Prophylactic mastectomy, nonaxillary SLN, and male breast cancer

**Population** number of patients = 1673 SLN positive

1673 (85%) had SLN +ALND

287 (15%) had SLN no ALND

**Interventions**

SLN biopsy included a radioisotope and blue dye combination.

Intraoperative and final pathological examination of frozen sections

(intraoperative) and by immunohistochemical (IHC) anticytokeratin staining (FS negative).

**Outcomes**

Axillary local recurrence (LR)

**Follow up** Median 23 months (6-87) SLN+/ no ALND

Median 30 months (6-93) SLN+/ ALND

**Results**

Patients in the SLN+/no ALND group were significantly older, more likely to have breast conservation, and had more favourable tumour types. Tumour size was smaller, low grade lesions were more frequent, and both LVI and multicentricity were less frequent.

The distribution of nodes removed and number of positive nodes are shown below:

	<b>SLN+ / no ALND n=287 (%)</b>	<b>SLN+/ALND n=1673 (%)</b>
SLN excised		
1	48 (17)	395 (24)
2	77 (27)	438 (26)
3	47 (16)	341 (20)
>3	115 (40)	499 (30)
Non-SLN excised		
0	149 (52)	3 (0.2)
1-3	97 (34)	22 (1.3)
4-9	35 (12)	213 (12.7)
≥10	6 (2)	1435 (85.8)
Total nodes excised		
1-3	122 (43)	4 (0.2)
4-9	121 (42)	68 (4.1)
≥10	44 (15)	1601 (95.7)
Positive SLN		
1	258 (89.9)	1211 (72)
2	23 (8)	336 (20)
3	4 (1.4)	82 (5)
>3	2 (0.7)	44 (3)
Positive non-SLN		
0	279 (97)	1029 (62)
1-3	8 (3)	410 (25)
4-9	0 (0)	142 (8)
≥10	0 (0)	92 (5)
Total positive nodes		
1-3	283 (99)	1308 (78)

4-9	4 (1)	253 (15)
≥10	0 (0)	112 (7)

SLN = sentinel lymph node  
ALND = axillary lymph node dissection  
NonSLN = nonsentinel lymph node

The proportion of SLN excised was similar between groups, however the extent of involved nodes was greater in the SLN+/ALND group.

Twelve patients developed axillary local recurrence (LR), 6 in the SLN+/ALND group and 6 in the SLN+/no ALND group. The rate was marginally higher in the SLN+/no ALND group (2% vs. 0.4%, P = 0.004) at a median 23 to 30 months follow-up. Half of all axillary LR in SLN+/no ALND patients were coincident with other local or distant sites. The pattern of local relapse are shown in the table below:

Intervention	Axillary LR as first event	Axillary LR coincident with breast recurrence	Axillary LR coincident with distant recurrence	Axillary LR overall
SLN+/no ALND N= 287	1% (3)	0.7% (2)	0.3% (1)	2% (6)
SLN+/ALND N=1673	0.2% (3)	0.2% (3)	0%	0.4% (6)
P	<0.044	NS	NS	0.004

There was no consistent pattern of clinicopathologic features in the 12 patients developing axillary LR. Lymphovascular invasion was present in all 6 patients who had SLN+/ALND. Among the SLN+/no ALND group, 15% of patients with complete follow-up (41 of 269) received additional radiotherapy to the axilla and/or supraclavicular nodes. None of the 6 patients with axillary local recurrence in this group received axillary and/or supraclavicular radiotherapy.

**Author conclusions:** SLN+/no ALND breast cancer patients, a selected group with relatively favourable disease characteristics, had a 9% predicted likelihood of residual axillary disease by nomogram but an observed axillary LR of 2%. A gradual and significant decline over time in the rate of completion ALND is associated with, but not entirely explained by, the institution of a predictive nomogram. It is reasonable to omit ALND for a low-risk subset of SLN-positive patients.

**General comments –**

This study overlaps with an earlier study by Naik (2004) which is also an analysis of the MSKCC database.

## Prospective NRS

Giard S, Baranzelli MC, Robert D, Chauvet MP, Robin YM, Cabaret V, et al. Surgical implications of sentinel node with micrometastatic disease in invasive breast cancer. Eur J Surg Oncol 2004 Nov;30(9):924-9.

Design: NRS prospective (2001-2003)

Level 3

Country: France setting:

Aim: To assess the rate of positive axillary clearance (AC) when the sentinel node biopsy (SNB) contains micrometastatic disease in invasive breast cancer and to evaluate factors that could predict positivity.

### Inclusion criteria

Patients with a unifocal invasive breast cancer (histological diagnosis by previous percutaneous biopsies), T0- T1 (<20 mm on ultrasound measurement) N0 M0 with no previous treatment.

### Exclusion criteria

**Population** number of patients = 542 SLN procedures

### Interventions

A combined technique of patent blue dye and radio-colloid with a peritumoral injection for palpable lesions (217/542, 40%) and a sub-areolar injection for non-palpable lesions.

Patients with a N0 detected SN or a positive SNB at intraoperative examination had immediate complementary AC.

Patients with a negative SNB had no lymphadenectomy.

Patients with a metastasis in the final histological report had an axillary clearance.

### Outcomes

Characteristics of micrometastatic disease

Characteristics of complementary axillary clearance

(Definitions: micrometastasis UICC, size 2mm or less

Isolated cells UICC, single tumour cells or small clusters 0.2mm or less)

### Follow up

### Results

525 sentinel nodes (SN) were found, 142 contained metastases.

87 positive SN were macrometastatic.

55 of the positive SN contained micrometastatic disease only (44 true micrometastases, 6 had isolated cells).

40/55 patients with micrometastases underwent completion AC.

6/40 (15%) patients with micrometastatic SN had a positive AC (5 had micrometastasis

between 0.2 and 2 mm (5/6), one had isolated cells in the SN (1/6). Four of the AC had 1 involved node, and 2 ACs had 2 involved nodes.

SNs were not found in 17 cases and 8 of these axillary clearances were positive.

A univariate analysis of tumour and patient factors [age (< or > 50 years), histological tumour size (< or > 5mm), histological grade, estradiol receptor (ER), histological tumour type, size and method of micrometastasis detection] did not significantly predict the status of the AC.

The authors also showed that the frequency of micrometastases increased with pathological tumour size as shown in the table from the paper below:

Pathological Tumour (mm)	No detected SN	%SN+	%SN+ macrometastatic	%SN+ micrometastatic	SN micro/SN+
0-0.99	141	9.9	2.8	7.1	71.4
10-14.9	179	22.3	15.1	7.3	32.5
15-19.9	112	31.2	21.4	9.8	31.4
20-24.9	62	54.8	30.6	24.2	44.1
25-29.9	31	61.3	41.9	19.4	31.6

**Author conclusions:** As long as the results of ongoing prospective randomised studies are unknown, it remains necessary to perform AC when the SNB contains micrometastatic disease, whatever the size or the detection method of the metastasis.

**General comments –**

Gipponi M, Canavese G, Lionetto R, Catturich A, Vecchio C, Sapino A, et al. The role of axillary lymph node dissection in breast cancer patients with sentinel lymph node micrometastases. *Eur J Surg Oncol* 2006 Mar;32(2):143-7.

Design: NRS prospective (1998-2004)

Level 3

Country: Italy, setting: Two oncology centres

Aim: To identify by means of clinical and histopathological features a subset of breast cancer patients with sentinel lymph-node (sN) micrometastases and metastatic disease confined only to the sN in order to spare them an unnecessary axillary lymph node dissection (ALND).

#### **Inclusion criteria**

Patients with early-stage (T1–2 N0 M0), invasive breast cancer who underwent sN biopsy and ALND, with histologically detected micrometastases (0.2mm-2.0mm).

Solitary nodule < 3cm (echography)

Clinically N0

#### **Exclusion criteria**

Previous breast or axillary operations

Multifocal or locally advanced breast cancer

Pregnancy

**Population** number of patients = 116

Mean age 61 years (24-84)

Primary tumour size:

≤10 mm n=19

11-20 mm n=66

>20 mm n=31

Size of SN micrometastases

≤1 mm n=26

1.01-2mm n=90

No of tumour positive SN

1 n=110

>1 n=6

#### **Interventions**

SNB procedure involved breast lymphoscintigraphy 16-18 hours before surgery using radioactive colloid and detection with a gamma probe.

Pathological staging was by the UICC TNM classification.

SNB samples were examined by frozen section and stained with haematoxylin-eosin, and if negative stained with keratin antibodies.

#### **Outcomes**

Tumour involvement of the non-SN in patients with SN micrometastases.

### **Follow up**

### **Results**

Median primary tumour size 16mm

Mean primary tumour size 17mm

Mean number of SN examined per patient = 2 (range, 1–6: SD, 1.2)

Mean number of non-SN examined = 12.6 (range, 6–29: SD, 5.0).

16/116 (13.7%; 95% CI 8-22%) with SN micrometastases had tumour involvement of the non-SN.

6 had non-SN micrometastases

10 had non-SN macrometastases

Mean tumour size in patients with non-SN involvement was 21.3 mm (range, 12–38 mm).

All 15 patients with Grade 1 tumours and SN micrometastases had negative non-SNs.

All 19 patients with tumours <10mm had negative non-SNs.

On multivariate logistic regression analysis primary tumour size ( $P=0.011$ ), lymphovascular invasion ( $P=0.001$ ), and size of SN micrometastases were the only variables remaining in the model (the latter was not significant).

An odds ratio for metastasis in a non-SN was 8 times higher for patients with a lymphovascular invasion, 6 times higher for patients with a primary tumour diameter over 16 mm, and 5 times higher for patients with a micrometastasis diameter of greater than 1 mm. (OR test values not reported).

### **Author conclusions**

In patients with SN micrometastases, primary tumour size and lymphovascular invasion significantly predict non-SN status; notably, no patient with T1a-T1b and/or Grade 1 tumours had non-SN metastases so that they could be spared an unnecessary ALND.

### **General comments –**

This is an incidence study, the effects of further treatments were not reported. Although described as a prospective study, the records were reviewed retrospectively.

Guenther JM, Hansen NM, DiFronzo LA, Giuliano AE, Collins JC, Grube BL, et al. Axillary dissection is not required for all patients with breast cancer and positive sentinel nodes.[see comment]. Arch Surg 2003 Jan;138(1):52-6.

Design: NRS prospective (1996-2001) Level 3

Country: USA, setting: 2 hospital breast centres

Aim: To assess the value of axillary lymph node dissection (ALND) in patients with positive sentinel node metastases.

#### **Inclusion criteria**

Women with positive SN metastases who refused ALND or were recommended to omit ALND due to serious comorbid conditions.

#### **Exclusion criteria**

Not reported

**Population** number of patients = 46

Mean patient age was 61.6 years (age range, 36-92 years).

Mean tumour size was 1.65 cm (range, 0.4-5.5 cm).

#### **Interventions**

Lymphatic mapping was performed using isosulfan blue dye, no radioisotopes were used. All blue stained nodes were removed, and the remainder of the axilla inspected and palpated to exclude suspicious non-SNs.

Breast surgery included segmentectomy or total mastectomy.

Patients with positive SNs received adjuvant therapy and breast irradiation.

Axillary, internal mammary and supraclavicular fields were not used with one exception (received supraclavicular RT).

#### **Outcomes**

Axillary recurrence

**Follow up** Mean 32-month follow-up, (range 4-61)

#### **Results**

35 (76%) of 46 tumours were ductal carcinomas

39 (87%) of 45 were estrogen receptor-positive

A mean of 2.6 SNs were identified (median, 2; range, 1-7)

39/46 patients (85%) had a single positive SN

7/46 patients (15%) had 2 positive SNs

7/46 (15%) had macrometastases (>2 mm)

16/46 (35%) had micrometastases (<2 mm)

23/46 (50%) had clustered or cellular metastases (IHC staining)

There were no axillary recurrences during the follow-up period.

One patient (ER progesterone -ve, T1c tumour and 2 SN metastases) developed distant metastases during follow-up.

**Author conclusions:**

Patients with SN metastases who did not have ALND had a low incidence of regional failure. To confirm this observation, we suggest that patients with SN metastases are ideal candidates for trials evaluating the necessity of ALND.

Langer I, Marti WR, Guller U, Moch H, Harder F, Oertli D, et al. Axillary recurrence rate in breast cancer patients with negative sentinel lymph node (SLN) or SLN micrometastases: prospective analysis of 150 patients after SLN biopsy. *Ann Surg* 2005 Jan;241(1):152-8.

Design: NRS Prospective (1998-2002)

Level 3

Country: Switzerland, setting: single centre

Aim: To evaluate midterm follow-up data, focusing on axillary recurrences and outcome of breast cancer patients with negative SLN and SLN micrometastases undergoing SLN biopsy only.

### Inclusion criteria

Palpable breast cancer

Tumour size  $\leq$  3cm

Absence of clinically palpable axillary nodes

### Exclusion criteria

None reported

**Population** number of patients = 234 patients (236 SLN procedures)

224 mappings

SLN alone n=150

SLN and ALND n=74

T stage	SLN alone	SLN and ALND	
T1a	8 (5.3%)	1 (1.3%)	p<0.0001
T1b	24 (16%)	2 (2.7%)	
T1c	76 (50.7%)	24 (32.4%)	
T2	39 (26%)	40 (54.1%)	
T3	0 (0%)	3 (4.1%)	
T4	3 (2%)	4 (5.4%)	

### Interventions

SNB procedure involved breast lymphoscintigraphy using radioactive colloid and blue dye, then detection with a gamma probe. All hot and/or blue lymph nodes were excised and labeled separately as SLNs.

Frozen sections were examined intraoperatively and stained with haematoxylin and eosin.

Negative SLNs were assessed using cytokeratin antibodies.

Patients with SLN macrometastases immediately underwent level I and II ALND. Conversely, no ALND was performed in patients with SLN micrometastases and tumour-free SLN.

Definitions:

Micrometastases (AJCC classification) diameter  $>0.2 \leq 2$  mm.

Submicrometastases  $\leq 0.2$  mm were considered node negative.

### Outcomes

Deaths

Recurrence

**Follow up** Median 42 months (12-64)

### Results

Mean age was 59.9 ( $\pm 11.7$ ) years in the SLN alone group (n=150), and 63.5 ( $\pm 12.0$ ) years in the SLN and ALND group (n=74) (p=0.008).

Mean tumour size was 16.5 ( $\pm 11.2$ mm) for the SLN alone group and 26.9 ( $\pm 11.7$ ) mm for the SLN and ALND group (p<0.0001).

Number of SLN/ patient:

	<b>SLN alone (n=150)</b>	<b>SLN and ALND (n=74)</b>
Mean	2.07 $\pm$ 1.4	2.14 $\pm$ 1.4
Range	(1-9)	(1-8)

Number of non-SLN/ patient:

Mean	17 $\pm$ 5.8
Range	(2-32)

SLN macrometastases were found in 33% (74/224) and micrometastases ( $>0.2$  mm to  $\leq 2$  mm) in 12% (27/224) of patients.

99% (222/224) of evaluable patients were reassessed.

There were 11 deaths, 5 of these were due to metastatic disease.

One patient with a negative SLN developed axillary recurrence (0.7%, 1/122)

All 27 patients with SLN micrometastases were disease-free at the last follow-up control.

10 local recurrences occurred in the breast, and 2 in the axilla.

Characteristics of the treatment and tumour of the one recurrence in the ALND group were:

Age 60 years, postmenopausal, mastectomy, SLN biopsy, and formal ALND for a pT2 invasive, poorly differentiated lobular carcinoma, estrogen and progesterone-receptor positive, with a tumour size of 25 mm. The SLN contained a macrometastasis, and another 14 out of 23 axillary lymph nodes were involved.

Postoperative adjuvant therapy consisted of a combination of tamoxifen and chemotherapy. No radiotherapy was applied.

The second axillary recurrence was in a 47-year-old premenopausal woman who had a tumorectomy and SLN biopsy only for a pT2 invasive, moderately differentiated lobular carcinoma, estrogen- and progesterone-receptor positive, with a tumour size of 41 mm and a tumour-free SLN.

Postoperative radiotherapy to the breast and tamoxifen plus chemotherapy

were administered. The axillary lymph node metastases, as well as the remaining level I and II lymph nodes, were then removed.

None of the patients with SLN micrometastases developed axillary recurrences.

Axillary recurrence rate in the subset with negative SLN was 0.8% (1/122), in patients with SLN micrometastases 0% (0/27), and in patients with SLN macrometastases 1.4% (1/73).

Distant metastases were detected in 10 of 222 patients (4.5%). Seven of those had SLN macrometastases. Three SLN-negative patients developed distant metastases.

OUTCOME OF INTEREST	SLN alone (n=150)	SLN+ALND (n=74)	RESULT
Metastatic disease	2 (1.3%)	9 (12.1%)	P=0.001
Deaths			
Tumour related	1 (0.7%)	4 (5.4%)	P=1.0
Non-tumour related	2 (1.4%)	4 (5.4%)	
Local recurrence			
Breast	6	4	
Axilla	1 (-ve SLNB)	1	

**Author conclusions:** Axillary recurrences in patients with negative SLN or SLN micrometastases did not occur more frequently after SLN biopsy alone compared with results from the recent literature regarding breast cancer patients undergoing formal ALND. Based on a median follow-up of 42 months-one of the longest so far in the literature-the present investigation does not provide evidence that the presence of SLN micrometastases leads to axillary recurrence or distant disease and supports the theory that formal ALND may be omitted in these patients.

## Retrospective NRS

Naik AM, Fey J, Gemignani M, Heerdt A, Montgomery L, Petrek J, et al. The risk of axillary relapse after sentinel lymph node biopsy for breast cancer is comparable with that of axillary lymph node dissection: a follow-up study of 4008 procedures. *Ann Surg* 2004 Sep; 240(3):462-8.

Design: NRS Retrospective (1996-2003)

Level 3

Country: USA, setting: Single cancer centre

Aim: To assess the experience of SLN biopsy, with particular emphasis on the incidence and pattern of axillary LR.

### Inclusion criteria

Patients undergoing SLN biopsy who were entered into the Memorial Sloan-Kettering Cancer Centre (MSKCC) SLN database. At least one year of follow-up.

### Exclusion criteria

- (1) failed SLN mapping
- (2) benign disease (primarily cases of prophylactic mastectomy)
- (3) bilateral breast cancer
- (4) intraductal carcinoma (DCIS)
- (5) inflammatory cancer
- (6) primary breast tumors of non-mammary origin
- (7) incomplete data

**Population** number of patients = 4008

Mean age across subgroups 53-59 years.

Breast conservation n=2843 (71%)

Mastectomy n=1166 (29%)

Tumour size:

T1ab n=1552 (39%)

T1c n=1657 (41%)

T2 n=700 (17%)

T3 n=47 (1%)

Tx n=52 (1%)

Patients were categorized into 4 groups:

SLN-negative with axillary lymph node dissection (ALND, n = 326)

SLN-negative without ALND (n = 2340)

SLN-positive with ALND (n = 1132)

SLN-positive without ALND (n = 210)

### Interventions

SLN mapping with radioisotope and isosulfan blue dye.

Intraoperative and final pathological examination of frozen sections

(intraoperative) and by immunohistochemical (IHC) anticytokeratin staining (FS negative).

ALND defined as removal of at least 10 lymph nodes.

In the SLN-positive without ALND (n = 210) subgroup 149 patients had breast conserving treatment, and 53 (36%) of these also had radiotherapy.

23/53 (43%) had RT to the breast only

30/53 (57%) also received tangential fields to the axilla.

### Outcomes

Local recurrences (LR) were categorized as:

- (1) axillary LR as the first site of treatment failure
- (2) axillary LR coincident with breast LR
- (3) axillary LR coincident with distant disease.

**Follow up** median follow-up of 31 months (range 1-75)

### Results

SLN procedure failed in 2.7% of cases.

Number of SLN and non-SLN removed were comparable between the ALND and no-ALND groups.

The distribution of nodes excised is shown in the table below:

	SLN-		SLN+	
	ALND n=326	No ALND n=2340	ALND n=1132	No ALND n=210
No SLN excised	3.0	2.0	2.0	2.0
Median	4.0	2.6	3.1	2.9
Mean	1-23	1-9	1-18	1-8
Range				
No non-SLN excised				
Median	11.0	0.0	17.0	1.0
Mean	12.9	1.0	18.1	1.9
Range	0-57	0-8	0-63	0-8
No total SLN excised				
Median	14.0	3.0	20.0	5.0
Mean	17.0	3.6	21.2	4.8
Range	10-58	1-9	10-65	1-9

Axillary LR occurred in 10/4008 (0.25%) patients overall.

In 3 cases (0.07%) the axillary LR was the first site of treatment failure.

In 4 cases (0.1%) LR was coincident with breast LR.

In 3 cases (0.07%) LR was coincident with distant metastases.

7/1342 (0.5%) axillary recurrences in +SNB patients.

4/7 recurrences in ALND group.

3/7 recurrences in no ALND group.

The authors reported that axillary LR was more frequent among the unconventionally treated SLN-positive/no ALND patients than in the other 3 conventionally treated cohorts (SLN negative/ALND, SLN negative/no ALND, and SLN positive/ALND) [1.4% (n=3) versus 0.18% (n=7), P = 0.013].

None of the subgroup receiving RT (n=53) either to the breast or to the axilla and breast developed an axillary recurrence.

The pattern of axillary recurrence by category is shown in the table:

Procedure	At first event	Coincident with breast recurrence	Coincident with distant recurrence	Total
SNLB-/ALND n=326	0	0	0	0
SNLB-/no ALND n=2340	1 (0.04%)	1 (0.04%)	1 (0.04%)	3 (0.12%)
SNLB+/ALND n=1132	1 (0.09%)	2 (0.18%)	1 (0.09%)	4 (0.35%)
SNLB+/no ALND n=210	1 (0.5%)	1 (0.5%)	1 (0.5%)	3 (1.4%)

A comparison of axillary recurrence rates by type of treatment is shown in the table below:

(conventional treatment:  
SLN- with or without ALND  
SLN+ with ALND  
Unconventional treatment:  
SLN+ without ALND)

Axillary local recurrence	Conventional treatment (n=3798)	Unconventional treatment (n=210)	P value
At first event	2	1	NS
Coincident with breast recurrence	3	1	NS
Coincident with distant recurrence	2	1	NS
Total axillary recurrence	7 (0.18%)	3 (1.4%)	0.013

**Author conclusions:**

Axillary LR after SLN biopsy, with or without ALND, is a rare event, and this

low relapse rate supports wider use of SLN biopsy for breast cancer staging. There is a low-risk subset of SLN-positive patients in whom completion ALND may not be required.

**General comments –**

Data from SLN negative patients was included for comparison with SLN + patients.

Ganaraj A, Kuhn JA, Jones RC, Grant MD, Andrews VR, Knox SM, et al. Predictors for nonsentinel node involvement in breast cancer patients with micrometastases in the sentinel lymph node. *Baylor University Medical Center Proceedings* 2003 Jan;2003 Jan; 16(1):3-6

Design: NRS retrospective (1997-1999)

Level 3

Country: USA, setting: Single hospital centre

Aim: To correlate size of nodal metastasis and tumour histology as predictors of involvement of non-SLNs based on serial sectioning and IHC of all non-SLNs.

**Inclusion criteria**

Not reported

**Exclusion criteria**

Not reported

**Population** number of patients = 84 of 305 (28%) patients having SLNB had metastases

Median age 53 years (range, 33-83)

**Interventions**

SLN biopsy then completion axillary dissection

17 patients with micrometastases refused axillary dissection

**Outcomes**

**Follow up** 30 months

**Results**

84/305 positive SLN metastases.

50% of positive patients had T1c tumour.

17 had infiltrating lobular carcinoma

67 had infiltrating ductal carcinoma

*Micrometastases*

Micrometastases identified in 41/84 (49%)

12 had infiltrating lobular carcinoma - 7 had completion axillary dissection 2 (29%) had additional positive nodes.

29 had infiltrating ductal carcinoma – 17 had completion axillary dissection none had additional positive nodes.

17 patients refused axillary dissection.

*Macrometastases*

Macrometastases identified in 43/84 (51%)

5 had infiltrating lobular carcinoma – 4 had completion axillary dissection 3 (75%) had additional positive nodes.

38 had infiltrating ductal carcinoma – 35 had completion axillary dissection 11 (31%) had additional positive nodes.

	Infiltrating ductal carcinoma		Infiltrating lobular carcinoma	
	Macrometastases	Micrometastases	Macrometastases	Micrometastases
N of patients	38	29	5	12
N of AXD	35	17	4	7
N additional +ve nodes on H&E staining	11 (31%)	0	3 (75%)	2 (29%)

No axillary recurrences among the 17 with micrometastases who refused axillary dissection.

#### **Author conclusions**

These data suggest that patients with micrometastasis in the SLN from infiltrating lobular carcinoma have a significant risk of harbouring additional nodal disease and should undergo completion axillary dissection. However, those with micrometastatic disease from infiltrating ductal carcinoma have a very low incidence of additional metastasis and may not need completion axillary dissection.

Viale G, Maiorano E, Mazzarol G, et al. Histologic detection and Clinical Implications of Micrometastases in Axillary Sentinal Lymph Nodes for Patients with Breast Carcinoma. *Cancer* 2001, 92 (6), 1378-84.

Design: NRS Retrospective (1997-1999) Level 3

Country: Italy, setting: Single centre

Aim: To determine the risk of axillary non-SLNs metastases in patients with micrometastatic SLNs ( an additional objective was to assess the detection rate of SLN micrometastases in relation to the sectioning interval and the number of sections examined).

#### **Inclusion criteria**

Patients with clinical T1 and small T2N0 breast carcinoma who underwent SLN biopsy.

#### **Exclusion criteria**

**Population** number of patients = 684

366 had immediate ALND

318 were part of a trial (see Veronesi 2003) and were randomized to immediate ALND or to axillary dissection only if the SLN was metastatic.

#### **Interventions**

SLNB procedure was described in an earlier publication (Viale 1999).

Sections (adjacent pairs) were stained with H&E or IHC.

Patients with metastatic SLNs had ALND.

#### **Outcomes**

Frequency of additional axillary metastases in non-SLNs

#### **Follow up**

#### **Results**

250 (36.5%) patients had SLN metastases.

#### *Micrometastases*

109/250 (43.6%) had micrometastases (included 1 male patient):

Pathological type	Tumour size (cm)	N (%)
pT1a	< 0.5 cm	3 (2.7%)
pT1b	0.6-1.0cm	21 (19.1)
pT1c	1.1-1.5cm	47 (42.7)
pT1c	1.6-2.0	22 (20)
pT2	>2	17 (15.5)

109 patients had 164 SLNs removed (mean 1.5/patient; range 1-6, median 1)  
113/164 SLNs had micrometastases (1 patient had 3 micrometastatic SLNs, 1 had 2 micrometastatic SLNs)

34/113 (30.1%) had multiple micrometastases.

12 of 77 dissections (15.6%) in patients with SLN micrometastases  $\leq 1$  mm had additional metastases in non-SLNs.

12 of 33 dissections (36.4%) in patients with SLN micrometastases  $> 1$  mm had additional metastases in non-SLNs ( $P=0.02$ ).

2388 axillary non-SLNs were obtained:

Mean 22 lymph nodes  $\pm 7$  per patient

Median 21 lymph nodes, range 3-49.

Additional non-SLN metastases were found in 24/110 (21.8%) dissections after intraoperative detection of micrometastases (mean 2 metastases; median 1 metastasis; range 1-16 metastases).

6/24 had only micrometastases in the non-SLNs

18/24 had additional metastases  $> 2$ mm in non-SLNs

#### *Macrometastases*

141/250 patients had macrometastases ( $> 2$ mm) in SLNs

63/141 (44.7%) had non-SLN metastases.

#### **Author conclusions**

Outside of clinical trials, patients with T1 and small T2 breast carcinoma and micrometastatic SLNs should undergo complete ALND for adequate staging. However, patients with SLN micrometastases up to 1 mm in greatest dimension have a significantly lower risk of additional axillary metastases, raising the question of whether ALND may be avoided in this subgroup of patients.

#### **General comments -**

## Studies from related topic 11

Katz, Niemierko, Gage, Evans, Shaffer, Fleury & Smith . Can axillary dissection be avoided in patients with sentinel lymph node metastasis? J.Surg.Oncol. 93[7], 550-558. 2006.

### Design

Design: Retrospective case series (therapy), evidence level: 3

Country: USA, setting: Tertiary care

Aim: To identify potential prognostic factors for the involvement of non-SLNs in patients with SLN metastases, and identify a subgroup who may avoid completion axillary dissection.

### Inclusion criteria

Patients treated with SLNB between 1998 and 2003.

110 patients had DCIS, out of a larger series of 1133 patients.

307 patients underwent mastectomy and 833 breast conserving surgery. In 8 patients the type of definitive surgery was unknown.

367 patients had disease-positive SNs.

### Exclusion criteria

Retrospective study: none reported.

### Population

number of patients = 246 with +SLN (367 +SLN procedures), age range 30 to 96 years, median age = 57 years.

### Interventions

Retrospective analysis of 1148 SLNB procedures in 1133 patients treated at a single centre and recorded on a pathology database.

All patients underwent SLNB and were found to have positive SNs. 246 patients underwent ALND.

Histology technique:

1. SNs: Frozen section intraoperatively; H&E analysis of 2 levels at 60 micron spacing; IHC performed on all SNs negative on H&E and for all invasive carcinomas.

2. Non-SNs: H&E, 1 level.

Size classification for SN metastases:

$\leq 0.2\text{mm}$  (i+)

0.21-2.0mm (IHC)

<=2.0mm (H&E)  
 2.1-4.0mm (H&E)  
 4.1-10.0 (H&E)  
 >10.0 (H&E)  
 Unknown

**Outcomes**

Node involvement in +SLN and non-SLNs  
 Type of metastases.

**Follow up**

No follow-up reported, study assesses predictive factors for SN and non SN axillary nodal involvement.

**Results**

367 patients had disease-positive SNs of these 246 (67%) underwent ALND.  
 121 patients had involved SNs and did not undergo axillary clearance.  
 98/246 (40%) had involved non-SLNs.

Size of the largest SN metastasis ( $p < 0.001$ ) as follows:

Size of largest SN metastasis	n		%
<=0.2mm (i+)	7	1	14%
0.21-2.0mm (IHC)	10	0	0%
<=2.0mm (H&E)	48	11	21%
2.1-4.0mm (H&E)	26	7	30%
4.1-10.0 (H&E)	74	35	55%
>10.0 (H&E)	67	43	59%
Unknown	21	2	25%

Rates of metastases:

Micrometastases

71/367 (19%) +SLN procedures.

Macrometastases

292/367 (80%) +SLN procedures.

Involved SLNs per patient:

1 SLN 26% (63/246)

2 SLN 11% (27/246)

=>3 SLN 3% (7/246)

Involved non-SLNs per patient:

1 SLN 9% (21/246)

2 SLN 4% (11/246)

=>3 SLN 1% (2/246)

Number of involved and uninvolved SLNs in patients who had + SLN and axillary dissection (n=246):

Number of SLNs involved (p=0.05)		
	Non-SLN positivity	%
1	64/180	36
2	27/55	49
=>3	7/11	63
Number of uninvolved SLNs (p<0.001)		
0	64/121	53
1	21/61	34
2	11/33	33
=>3	2/31	6

When tumour size was classified into 2 groups (tumours less than 2cm or greater than 2cm) then patients with >2cm tumours had higher rates of non-SLN involvement than those with tumours <2cm (48% vs. 34%, p=0.02).

Another subgroup with SLN metastases <2.0mm, primary tumour <2.0cm and no LVSI, 14% (4/29) had additional involved non-SLNs on completion axillary dissection.

No subgroup was identified that did not have a significant rate of non-SLN involvement on completion axillary dissection, exceptions were those with a large number of negative SLNs (> or =3) and small size of the largest SLN metastasis (<10 mm).

**Author conclusions:**

The data does not support eliminating completion axillary dissection for any subgroup of patients with +SLNs.

**General comments**

Patients with disease-positive SNs underwent ALND or not, at the discretion of the treating surgeon in consultation with the patient.

## Expert reviews

Chagpar AB, McMasters KM. Treatment of sentinel node-positive breast cancer. [Review] [59 refs]. Expert Review of Anticancer Therapy 2006 Aug;6(8):1233-9.

This review addresses the controversies regarding the management of sentinel node-positive breast cancer patients. One of the key conclusions relating to the finding of a positive sentinel node biopsy, was that axillary dissection is still recommended. Patients not choosing to undergo completion axillary dissection when a positive sentinel node is detected, should be informed of the potential increased risk of regional nodal recurrence.

## Guidelines

The most recent guideline relating to sentinel lymph node biopsy and axillary lymph node dissection was published by ASCO.

Lyman GH, Giuliano AE, Somerfield MR, son III AB, Bodurka DC, Burstein HJ, et al. American Society of Clinical Oncology guideline recommendations for sentinel lymph node biopsy in early-stage breast cancer. J Clin Oncol 2005;23(30):7703-20.

Design: Guideline

Country: USA

Aim: To develop a guideline for the use of sentinel node biopsy (SNB) in early stage breast cancer.

### Inclusion criteria

### Exclusion criteria

### Population

### Interventions

An American Society of Clinical Oncology (ASCO) Expert Panel conducted a systematic review of the literature available through February 2004 on the use of SNB in early-stage breast cancer. The panel developed a guideline for clinicians and patients regarding the appropriate use of a sentinel lymph node identification and sampling procedure (SNB). The guideline was reviewed by selected experts in the field and the ASCO Health Services Committee and was approved by the ASCO Board of Directors.

### Outcomes

### Follow up -

### Results

The literature review identified one published prospective randomized controlled trial in which SNB was compared with axillary lymph node dissection (ALND), four limited meta-analyses, and 69 published single-institution and multicentre trials in which the test performance of SNB was

evaluated with respect to the results of ALND (completion axillary dissection). There were no data on the effect of SLN biopsy on long-term survival of patients with breast cancer. However, a review of the evidence demonstrated that, when performed by experienced clinicians, SNB appeared to be a safe and acceptably accurate method for identifying early-stage breast cancer without involvement of the axillary lymph nodes.

**Conclusions:**

SNB is an appropriate initial alternative to routine staging ALND for patients with early-stage breast cancer with clinically negative axillary nodes. Completion ALND remains standard treatment for patients with axillary metastases identified on SNB. Appropriately identified patients with negative results of SNB, when done under the direction of an experienced surgeon, need not have completion ALND. Isolated cancer cells detected by pathologic examination of the SLN with use of specialized techniques are currently of unknown clinical significance. Although such specialized techniques are often used, they are not a required part of SLN evaluation for breast cancer at this time. Data suggest that SNB is associated with less morbidity than ALND, but the comparative effects of these two approaches on tumour recurrence or patient survival are unknown.

### **3.5 What is the prognostic significance of small metastatic deposits in sentinel nodes?**

#### **Short Summary**

Five observational studies report the proportion of patients who undergo axillary lymph node dissection (ALND) after the finding of metastatic sentinel lymph node is made by SLNB, out of all patients with metastatic sentinel lymph nodes. The range of values is 63.2%-95.2% with the highest rate reported by a small, prospective study (de Widt-Levert *et al.* 2003) and the remainder of values from larger, but retrospective, studies.

Eight observational studies indicate a trend whereby larger size of the metastasis in the sentinel lymph node is associated with higher rates of non sentinel lymph node metastases. The mean proportion of patients with metastatic non sentinel lymph nodes is 10% for sentinel lymph node isolated tumour cells (ITCs), 17.7% for sentinel lymph node micrometastases and 53.2% for sentinel lymph node macrometastases (de Widt-Levert *et al.* 2003; Goyal *et al.* 1990; Bolster *et al.* 2007; Calhoun *et al.* 2005; Houvenaeghel *et al.* 2006; Katz *et al.* 2006a; van Rijk *et al.* 2006; Viale *et al.* 2005). From two systematic reviews (Cserni *et al.* 2004; Degnim *et al.* 2003) the pooled estimate for the rate metastatic non sentinel lymph nodes in patients with sentinel lymph node metastases of size 2mm or less was 20.2% (95% CI 15.5%-24.9%) when the sentinel lymph node metastases are detected by haematoxylin and eosin (H&E) staining, and 9.4% (95% CI 6.2%-12.6%) when the sentinel lymph node metastases are detected by immunohistochemistry (IHC) techniques.

Evidence from observational studies suggests that size of the sentinel lymph node metastasis was frequently a statistically significant independent predictive factor along with several other tumour/treatment related variables (Goyal *et al.* 2004; Bolster *et al.* 2007; Degnim *et al.* 2005; Houvenaeghel *et al.* 2006; Katz *et al.* 2006a; Viale *et al.* 2005).

From four studies reporting on the size of metastasis in non sentinel lymph nodes in patients with metastatic sentinel lymph nodes who then undergo ALND (Bolster *et al.* 2007; Calhoun *et al.* 2005; van Rijk *et al.* 2006; Viale *et al.* 2005), (see Tables 5-7 of full evidence review for this topic on the accompanying CD-ROM) the data indicates that patients with sentinel lymph node ITCs (<0.2mm in size) and those with sentinel lymph node micrometastases (of size 0.2-2mm in size) may be found to have larger non-sentinel lymph node metastases when ALND is performed, and at potentially high rates, although due to small numbers, estimates of rates are unreliable.

Of the included studies only one (Calhoun *et al.* 2005) provides data for recurrence and survival. All patients were alive at a mean follow-up of 80.5 months (6 years, 8 months).

## PICO

Population	Intervention	Comparison	Outcome
Patients who receive SLNB as staging surgery	Close pathological examination of sentinel nodes	Meaningful comparison is the detection rate (% of cases) and prognostic value of: Isolated tumor cells versus: micrometastases versus: macrometastases	Macrometastases: Rate of occurrence of further positive nodes (ie 2 <sup>nd</sup> , 3 <sup>rd</sup> or 4 <sup>th</sup> nodes etc) and size of nodal deposits  Rates of axillary dissection based upon attribution of positive sentinel node status  Axillary recurrence rate  Overall survival, disease-free survival  Cost Effectiveness

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

### Evidence Summary

There is moderate evidence on the importance of size of the largest sentinel node (sentinel lymph node) metastasis, including two systematic reviews and a number of observational studies. The studies have good applicability in that each considers subgroups based on the size of the largest metastasis in the sentinel lymph node.

All studies address the use of histology capable of detecting small sentinel lymph node metastases (e.g. serial sectioning, IHC) although the precise technique is a source of inconsistency

The included studies provide no reliable data on rates of recurrence or survival by subgroup for size of sentinel lymph node metastasis with survival data presented in only one observational study.

There is considerable heterogeneity across the studies in terms of histological assessment of sentinel lymph nodes and non-sentinel lymph nodes

All but one study report consistently that increasing size of sentinel lymph node metastases is associated with a greater likelihood of metastatic non-sentinel lymph nodes.

**Table 1: Histology techniques used for assessment of SNs and non-SNs**

Study	Design	Histology technique	
		Sentinel nodes	Non-sentinel nodes
(Cserni <i>et al.</i> 2004)	Systematic review & meta-analysis	Reported by method of detection: either standard H&E or IHC, or detected by IHC alone	H&E
(Degnim <i>et al.</i> 2003)	Systematic review & meta-analysis	Not reported: implied H&E and IHC	Standard H & E staining - 5 studies; H & E staining with additional sections and IHC - 3 studies as follows: i) 2 levels with a 250-micron interval - 1 study ii) 2 levels with a 40-micron interval - 1 study, iii) 3-8 levels in the subgroup of patients with primary tumors measuring < 2 cm and micrometastasis in the SN - 1 study Histology with and without IHC - 1 study Not specified - 3 studies
(de Widt-Levert <i>et al.</i> 2003)	Prospective case series	Interoperative imprint cytology (giemsa & papanicolaou) Definitive technique: H&E; at least 3 levels at 500 micron interval; also IHC using CAM 5.2 (Becton & Dickenson, 1:20)	H&E; 2 levels
(Goyal <i>et al.</i> 2004)	Prospective case series	Bisection if < 5 mm or sliced at 3 mm intervals if > 5 mm. Single sections stained with H&E. No intraoperative examination.	Bisection if < 5 mm or sliced at 3 mm intervals if > 5 mm. Single sections stained with H&E. No intraoperative

Study	Design	Histology technique	
		Sentinel nodes	Non-sentinel nodes
			examination.
(Bolster <i>et al.</i> 2007)	Retrospective case series	>=3 levels; >= 150 micron intervals, by H&E analysis. If no metastasis detected by this method: IHC analysis.	1-2 levels; H&E
(Calhoun <i>et al.</i> 2005)	Retrospective case series	Cytokeratin IHC if negative by H&E	H&E
(Degnim <i>et al.</i> 2005)	Retrospective case series	'method of detection' classified as by IHC only, routine/serial or frozen.	Single H&E section
(Houvenaeghel <i>et al.</i> 2006)	Retrospective case series	Intraoperative assessment in 53% of cases by imprint cytology, scrapings or both; serial sections with H&E analysis (54% of cases) and IHC analysis in 73% of cases	Not reported
(Katz <i>et al.</i> 2006a)	Retrospective case series	Frozen section interoperatively; H&E analysis of 2 levels at 60 micron spacing; IHC performed on all SNs negative on H&E and for all invasive carcinomas	H&E, 1 level
(Katz <i>et al.</i> 2006b)	Retrospective case series	Frozen section interoperatively; H&E analysis of 2 levels at 60 micron spacing; IHC performed on all SNs negative on H&E and for all invasive carcinomas	H&E, 1 level
(van Rijk <i>et al.</i> 2006)	Retrospective case series	Bisection or section in 2 mm slices. Paraffin blocks cut at 3 levels with minimally 150 micron intervals. IHC assessment in the case of a tumor-negative sentinel node by H&E.	3 nodes evaluated at 1 level and stained with H&E; IHC not routinely performed.
(Viale <i>et al.</i> 2005)	Retrospective case series	15 pairs of adjacent sections, 5 microns thick, cut at 50 micron intervals from both lymph node halves, i.e. 60 sections per node. For remaining tissue: sections at 100 micron intervals. H&E analysis of one section of each pair and cytokeratin analysis by MNF116 monoclonal antibody for the other section.	3-6 H&E-stained sections per node, at 100- to 500 micron intervals.

### Rate of performance of axillary lymph node dissection

Five observational studies report the proportion of patients who undergo axillary lymph node dissection (ALND)<sup>10</sup> after the finding of metastatic SN is made by SLNB, out of all patients with metastatic SNs (in the remainder of studies, 100% of patients underwent ALND by design). The range of values is 63.2%-95.2%. Unfortunately there are no data from these studies by size of the SN metastasis (Table 2). The highest rate reported is by a small, prospective study (de Widt-Levert *et al.* 2003) and the remainder of values are from larger, but retrospective, studies.

**Table 2: Rates of performance of ALND**

Study	Population (stage)	n cases (+ve SN)	n (ALND)	% (ALND/+ve SN)
(de Widt-Levert <i>et al.</i> 2003)	Clinical/radiological T1N0	21	20	95.2%
(Bolster <i>et al.</i> 2007)	T size <=5cm	203	186	91.6%
(Calhoun <i>et al.</i> 2005)	SN ITCs only; stage N0(i+)	78	61	78.2%
(Katz <i>et al.</i> 2006a)	Approx. 10% of parent series had DCIS	367	246	71.0%
(van Rijk <i>et al.</i> 2006)	SN micrometastases/ITCs	253	160	63.2%

### Rate of occurrence of further positive nodes

#### Rate of positive non-SNs by subgroup for size of SN metastasis

The included observational studies indicate a trend whereby larger size of the metastasis in the SN is associated with higher rates of non-SN metastases (Table 3). Across eight studies that contribute data, the mean proportion of patients with metastatic non-SNs is 10% for SN ITCs (size <0.2mm), 17.7% for SN micrometastases (size 0.2-2.0mm) and 53.2% for SN macrometastases (size >2mm) (de Widt-Levert *et al.* 2003; Goyal *et al.* 1990; Bolster *et al.* 2007; Calhoun *et al.* 2005; Houvenaeghel *et al.* 2006; Katz *et al.* 2006a; van Rijk *et al.* 2006; Viale *et al.* 2005).

**Table 3: Proportion of patients with metastatic non-SNs by SN metastasis size as reported in eight primary studies**

---

<sup>10</sup> During the period of definitive treatment; excluding that performed for subsequent axillary recurrence

Study	Sample size	Proportion of patients with metastatic non-SNs by SN metastasis size					
		ITCs	Micrometastases		Macrometastases		
		<0.2mm	0.2-2mm	All <=2mm grouped	All >2mm grouped	2-10mm	>10mm
(de Widt-Levert <i>et al.</i> 2003)	21	0	25	6.3	75		
(Goyal <i>et al.</i> 2004)	64			7		45	100
(Bolster <i>et al.</i> 2007)	203	12.9	26.4	19.6	36.5		
(Calhoun <i>et al.</i> 2005)	61	4.9					
(Houvenaeghel <i>et al.</i> 2006)	488	16	14.3	15			
(Katz <i>et al.</i> 2006a)	367	14	0	18.5	50.9	42	59
(van Rijk <i>et al.</i> 2006)	160	7.4	18.9	15			
(Viale <i>et al.</i> 2005)	1228	14.7	21.4		50.3		
Mean		10	17.7	13.6	53.2		
Median		12.9	20.1	15	50.6		
lowest		0	0	6.3	36.5		
highest		16	26.4	19.6	75		

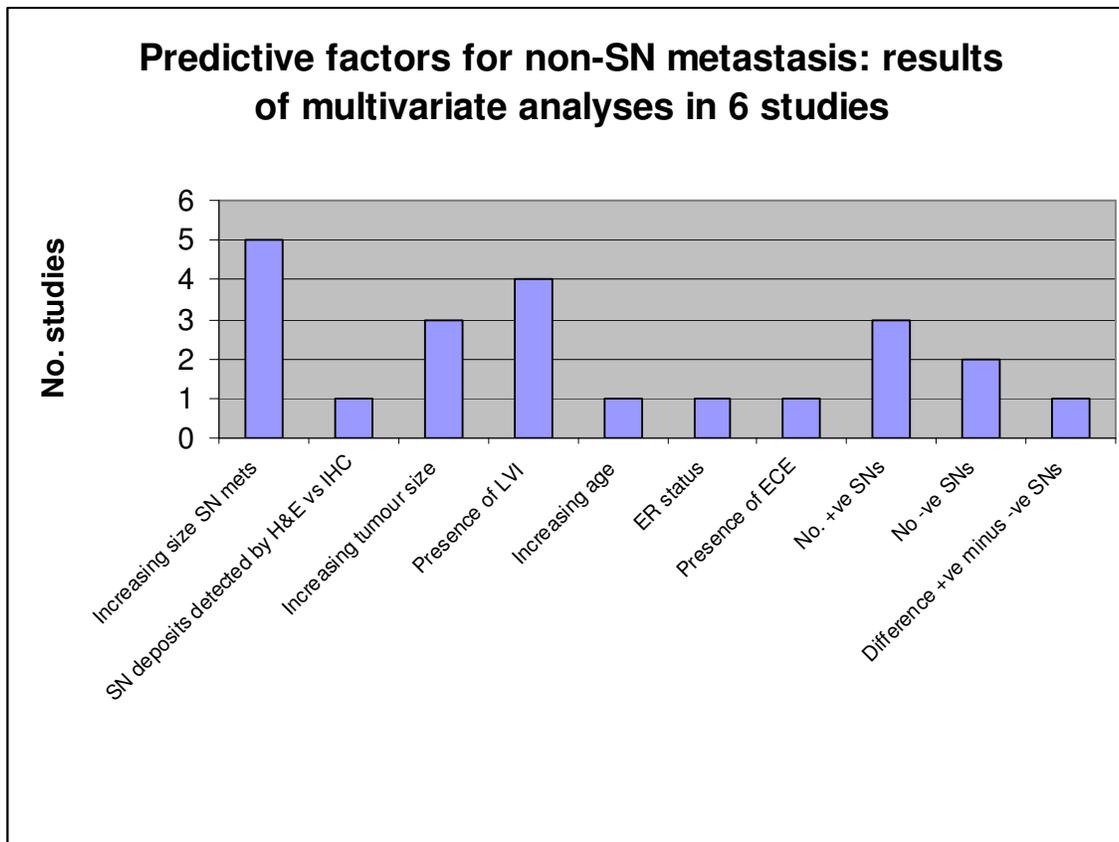

Two systematic reviews (Cserni *et al.* 2004; Degnim *et al.* 2003) which preceded these studies summarised previous primary data for the rate of metastatic non-SNs in patients with SN metastases of size 2mm or less (including both micrometastases of size 0.2-2mm and isolated tumour cells (ITCs) of size <0.2mm). The pooled estimate of this proportion reported by Cserni and co-workers was 20.2% (95% CI 15.5%-24.9%) when the SN metastases are detected by haematoxylin and eosin (H&E) staining, and 9.4% (95% CI 6.2%-12.6%) when the SN metastases are detected by immunohistochemistry (IHC) techniques. Degnim and co-workers reported a mean value of 18% (range 13%-22%) for this proportion, without subgrouping by the histological method that detected the SN metastases. In contrast the corresponding rate when the SN is macrometastatic (deposits >2mm in size) had a mean value across studies of 58% (range 45% to 79%) (Degnim *et al.* 2003). The pooled estimates

should be interpreted with caution due to a high level of heterogeneity across the primary studies (Cserni *et al.* 2004; Degnim *et al.* 2003).

### SN metastasis size as a predictive factor for non-SN metastasis

Observational studies have performed multivariate analyses to identify predictive factors for non-SN metastases (Goyal *et al.* 2004; Bolster *et al.* 2007; Degnim *et al.* 2005; Houvenaeghel *et al.* 2006; Katz *et al.* 2006a; Viale *et al.* 2005). In these studies size of the SN metastasis was frequently a statistically significant independent predictive factor along with several other tumour/treatment related variables (Figure 1).

Figure 1

#### Abbreviations:

- SN: sentinel node
- H&E: haematoxylin and eosin staining
- IHC: immunohistochemistry analysis
- LVI: primary tumour lympho-vascular invasion
- ER: oestrogen receptor
- ECE: sentinel node extra-capsular extension

#### Notes:

1. No. of –ve SNs was the only variable with a negative (protective) association with non-SN metastases.
2. SN deposits detected by H&E vs. IHC may be related to size of the SN metastasis, with IHC likely to detect smaller deposits.

### Strength of size of SN metastasis as a predictive factor for non-SN metastasis

Four studies provide odds ratios to indicate the strength of association between SN metastasis size and the rate of metastatic non-SNs (Table 4).

**Table 4: Odds ratios for metastatic non-SNs according to size of SN metastasis**

Study	Analysis	SN deposit size variable	OR	95% CI
(Bolster <i>et al.</i> 2007)	Multivariate	pN0(i+)(sn) <= 0.2 mm	1.0	
		pN1mi(sn) 0.2 mm – 2 mm	3.1	0.99-9.8
		pN1+(sn) > 2mm	4.0	1.4-11.5
(Degnim <i>et al.</i> 2003)	Meta-analysis (Mantel-Haenszel method for common odds ratios)	>2mm vs. <=2mm	6.2	4.5-8.5
(Degnim <i>et al.</i> 2005)	Univariate	per 1.0 mm increase in size	1.16	1.12-1.21
(Viale <i>et al.</i> 2005)	Multivariate	<= 1mm	1.0	
		1-2 mm	2.24	1.35-3.73
		>2 mm	4.57	3.27-6.38

### Size of non-SN metastases

Four studies reported on the size of metastasis in non SNs in patients with metastatic SNs who then undergo ALND (Bolster *et al.* 2007; Calhoun *et al.* 2005; van Rijk *et al.* 2006; Viale *et al.* 2005), (Tables 5-7). The data indicate that patients with SN ITCs (<0.2mm in size) and those with SN micrometastases (of size 0.2-2mm in size) may be found to have larger non-SN metastases when ALND is performed, and at potentially high rates, although due to small numbers, estimates of rates are unreliable. In one study (van Rijk *et al.* 2006), of a total of 18 patients upstaged by ALND, 7 (all with micrometastasis in the SN) were offered systemic treatment that would not have been offered without the information from ALND. In the remaining 11 patients, systemic therapy was indicated by other patient/disease factors.

**Table 5. Size of metastases in non-SNs: patients with SN ITCs; size  $\leq 0.2$  mm; stage by SLNB: pN0(i+)(sn)**

Study	n cases	No. with positive non-SNs (% of cases)	Size of non-SN metastatic deposits (ALND)			% of +ve SNs with larger metastases in non-SNs
			$\leq 0.2$ mm	0.2 mm – 2mm	> 2mm	
(Bolster <i>et al.</i> 2007)	54	7 (12.9%)	0	2	5	(5+2)/7=100%
(Calhoun <i>et al.</i> 2005)	61	3 (4.9%)		2	1	(2+1)/3=100%
(van Rijk <i>et al.</i> 2006)	54	4 (7.4%)	2	0	2	(2+0)/4=50%
(Viale <i>et al.</i> 2005)	116	17 (14.7%)	1	3	13	(13+3)/17=94%

**Table 6. Size of metastases in non-SNs: Patients with SN micrometastases; size 0.2-2 mm; stage by SLNB pN1mi(sn)**

Study	n cases	No. with positive non-SNs (% of cases)	Size of non-SN metastatic deposits (ALND)			% of +ve SNs with larger metastases in non-SNs
			$\leq 0.2$ mm	0.2 mm – 2mm	> 2mm	
(Bolster <i>et al.</i> 2007)	53	14 (26.4%)	4	4	6	6/14=43%
(van Rijk <i>et al.</i> 2006)	106	20 (18.9%)	0	4	16	16/20=80%
(Viale <i>et al.</i> 2005)	318	68 (21.4%)	6	20	42	42/68=62%

**Table 7. Size of metastases in non-SNs: Patients with SN macrometastases; size >2 mm; stage by SLNB pN1(sn) and above**

Study	n cases	No. with positive non-SNs (% of cases)	Size of non-SN metastatic deposits (ALND)		
			<= 0.2 mm	0.2 mm – 2mm	> 2mm
(Bolster <i>et al.</i> 2007)	96	35 (36.5%)	0	5	30
(Viale <i>et al.</i> 2005)	794	399 (50.3%)	12	27	360

NB: Uppermost stage considered here is pN1 and above, based on node deposit >2mm in size.

### Multiple positive axillary nodes

One observational study (Katz *et al.* 2006b) examined the occurrence of four or more metastatic axillary nodes in patients with SN metastases. Overall, 19% of patients had four or more metastatic axillary nodes, with distribution by size of SN metastasis as follows (Table 8):

**Table 8: Proportion of patients with >= 4 involved axillary nodes by size of SN metastasis, reported by Katz et al. 2006**

Size of largest SN metastasis	no. cases	no. with >=4 involved nodes	%
<=0.2mm	56	0	0%
2.1-4.0mm	26	1	4%
4.1-10.0 mm	74	17	23%
>10.0 mm	68	24	35%
Unknown	4	1	25%

On multivariate analysis the following variables were statistically significant predictors of four or more metastatic nodes (Katz *et al.* 2006b) (Table 9):

**Table 9: Predictors of four or more metastatic axillary nodes, reported by Katz et al. 2006**

Variable	OR	95% CI	p value
LVI	3.2	1.4-7.6	0.008
No. +ve SNs	2.6	1.4-4.9	0.003
Size of SN deposit	1.1	1.0-1.2	<0.001
Histology (ductal vs. lobular)	0.2	0.1-0.6	0.002

### Recurrence and survival

Of the included studies only one (Calhoun *et al.* 2005) provides data for recurrence and survival, which is based on a small series and which has only moderate follow-up. Of 78 patients with ITCs only in the SN, 61 patients underwent ALND. All patients were alive at a mean follow-up of 80.5 months (6 years, 8 months). In this time there were no axillary recurrences, including the 17 patients in whom ALND was omitted. There were two cases of

distant metastases, both in patients who underwent ALND: one who had positive non-SN status, and one whose status was negative (Calhoun *et al.* 2005).

#### UPDATE EVIDENCE

Using the SEER database, a retrospective study assessed whether micrometastatic disease (N1mi) alone can predict a poorer prognosis for patients with early breast cancer (Chen *et al.* 2007). Specifically the study investigated whether the survival of patients with solely micrometastatic disease (N1mi) would be intermediate to patients with 1-3 tumour-positive lymph nodes (N1) and those with no positive lymph nodes (N0) (Chen *et al.* 2007).

#### Results

- N1mi diagnoses increased from 2.3% to 7% among the 209,720 study patients ( $p < 0.001$ ).
- Overall, N1mi patients had a statistically worse survival than N0 patients and better than N1 patients.
- In a T-stage stratified univariate analysis, N1mi patients had a poorer prognosis when compared to N0 patients. However, this was only significant for patients with T2 lesions (univariate analysis,  $p < 0.001$ )
- There was statistical better survival in N1mi patients compared to N1 patients with T1-T3 lesions.
- 5 and 10 year survival was intermediate for N1mi patients when compared to N0 and N1 patients.
- On multivariate analysis, N1mi remained a significant prognostic indicator across all patients ( $p < 0.0001$ ).
- HR (hazard ratio)= 1.35 (compared to N0 disease)
- HR = 0.82 (compared to N1 disease)

Other negative prognostic factors included male gender, oestrogen-receptor negativity, progesterone-receptor negativity, lobular histology, higher grade, older age, higher T-stage, and diagnosis in an earlier time period.

Author's Conclusion: Nodal micrometastasis of breast cancer carries a prognosis intermediate to N0 and N1 disease, even after adjusting for tumour and patient related factors. Adjuvant therapy trials should consider using N1mi as a stratification factor when determining nodal status. Prospective studies will confirm results with less bias involved.

## Evidence Tables

### Systematic review of combined study designs

Cserni, Gregori, Merletti, Sapino, Mano, Ponti, Sandrucci, Baltas & Bussolati . Meta-analysis of non-sentinel node metastases associated with micrometastatic sentinel nodes in breast cancer.[see comment]. Br.J.Surg. 91[10], 1245-1252. 2004.

#### Design

Design: Systematic review of combined study designs (therapy), evidence level: 2-  
Country: Various, setting: Tertiary care

#### Inclusion criteria

25 articles reporting the incidence of non-SN metastases in association with small metastases in the SN.

Patient population represented is patients with SN micrometastases (size 0.2-2mm) or ITCs (size <0.2mm).

#### Exclusion criteria

Conference proceedings and unpublished papers.

#### Population

number of patients = 789.

#### Interventions

Aim: to estimate non-SN tumour involvement associated with small metastases in the SN.

Patients underwent SLNB (all patients had low burden SN metastasis; see 'inclusion criteria). The majority of patients underwent axillary dissection.

Histology technique: Results are reported according to the histology technique used to detect the SN metastases: either any method (standard H&E or IHC), or detected by IHC alone. Non sentinel node assessment was always by standard H&E technique.

#### Outcomes

Pooled proportion of non-SN involvement of any type, including metastases larger than 2 mm, micrometastases and ITCs (non-SN+) in patients with SN involvement by micrometastasis or ITCs (microSN+), referred to as non-SN+/microSN+. This outcome was presented in two ways:

a) Proportion of non-sentinel node (SN) involvement identified by standard

histology (non-SN+) in patients with SN involvement by micrometastases (regardless of the method of detection) (microSN+).

b) Proportion of non-sentinel node (SN) involvement identified by standard histology (non-SN+) in patients with SN involvement by micrometastases detected by immunohistochemistry (microSN+ (IHC)).

Subgroup analysis was performed after classifying papers according to five criteria:

1. Performance of axillary dissection;
2. Level of the axillary dissection;
3. Number of levels of histological examination;
4. Frequency of levels assessed by IHC;
5. Study quality ('high' or 'low').

### Follow up

Not reported.

### Results

Pooled proportions of non-SN+/microSN+ detected either by standard haematoxylin and eosin staining or by immunohistochemistry (25 studies)

	<b>Pooled proportion</b>	<b>95% confidence interval</b>	<b>P (homogeneity)</b>
<b>Non-SN+/microSN+(H&amp;E)</b>	0.202	0.155, 0.249	<0.001
<b>Non-SN+/microSN+ (IHC)</b>	0.094	0.062, 0.126	0.430

Subgroup analysis of pooled proportions

	<b>No. of studies</b>	<b>Non-SN+/microSN+</b>	<b>No. of studies</b>	<b>Non-SN+/microSN+ (IHC)</b>
Back-up dissection				
Yes	17	0.170 (0.142, 0.198)	10	0.105 (0.049, 0.161)
No	1	0.025 (0, 0.103)	2	0.130 (0, 0.426)
Level of axillary dissection				
I-III (complete)	5	0.214 (0.121, 0.308)	5	0.153 (0.012, 0.223)

All levels	7	0.229 (0.143, 0.315)	6	0.117 (0.043, 0.194)
Quality				
High	11	0.152 (0.106, 0.199)	6	0.100 (0.001, 0.198)
Low	9	0.244 (0.183, 0.305)	6	0.135 (0.039, 0.232)

### General comments

A Medline search using the term 'breast and sentinel' was performed on title and abstract for papers published between January 1998 and June 2003. All papers written in English, German or French were considered.

Each paper was assessed as of 'high' or 'low' quality by nine reviewers (three epidemiologists, three surgeons and three pathologists) who used a common quality assessment form. Technical and statistical details, validation, performance of axillary dissection and detailed histopathology formed the main aspects of the quality assessment.

Study heterogeneity was assessed prior to meta-analysis. For one of two pooled results (Non-SN+/microSN+(H&E)) the test revealed significant heterogeneity between studies ( $p < 0.001$ ). This was also evident from individual study data (not shown) and also Forrest plots (for both results), so the results should be interpreted with caution.

The finding in the subgroup analysis that a higher rate of non-SN involvement occurs where axillary dissection is performed (for Non-SN+/microSN+; since the 95% confidence intervals do not overlap) is not surprising - and may arise because only 1 study omitted axillary clearance, or because axillary recurrence may take a long time to become apparent, or because the decision to perform axillary dissection considered also other tumour and patient factors.

Degnim, Griffith, Sabel, Hayes, Cimmino, Diehl, Lucas, Snyder, Chang & Newman . Clinicopathologic features of metastasis in nonsentinel lymph nodes of breast carcinoma patients. Cancer 98[11], 2307-2315. 2003.

### **Design**

Design: Systematic review of combined study designs (therapy), evidence level: 2 -

Country: Various, setting: Tertiary care

### **Inclusion criteria**

Primary studies that reported the association between patient/disease characteristics and the likelihood of positive non-SNs were selected by the following criteria:

- 1) the study identified the population of patients with a positive SN and who underwent completion axillary clearance;
- 2) original data were reported on the number of SN-positive patients who had positive non-SNs stratified by various patient/tumour characteristics;
- 3) statistical analysis for these characteristics was not based on groups that included patients with negative SNs;
- 4) the study population included patients with both micrometastatic and macrometastatic disease in the SNs.

### **Exclusion criteria**

Defined by inclusion criteria.

### **Population**

number of patients = 1535.

### **Interventions**

Aim: to assess the strength of association between primary tumour/sentinel node characteristics and likelihood of further disease-positive non sentinel nodes.

Patients underwent SLNB followed by axillary clearance due to the finding of disease-positive SNs.

Histology technique for non-SNs:

Standard H & E staining - 5 studies;

H & E staining with additional sections and IHC - 3 studies as follows:

- i) 2 levels with a 250-micron interval - 1 study
- ii) 2 levels with a 40-micron interval - 1 study,
- iii) 3-8 levels in the subgroup of patients with primary tumors measuring < 2 cm and micrometastasis in the SN - 1 study

Histology with and without IHC - 1 study

Not specified - 3 studies

## Outcomes

Common odds ratios across studies for odds of positive non-SNs, by each factor studied

Crude rates of positive non-SNs

Factors found to be predictive of positive non-SNs, by multivariate analysis in primary studies

## Follow up

Not reported

## Results

Crude rates of positive non-SNs

There was a positive association between the size of the metastasis in the SN and the proportion of patients with positive non-SNs. In patients with micrometastatic ( $\leq 2$  mm) SN disease, approximately 13–22% had additional metastasis by H & E staining in non-SNs, in contrast to 45–79% of patients with macrometastatic ( $>2$  mm) disease.

**Table: Proportion of patients with positive non-SNs (determined by H&E) by subgroup for size of SN deposit (8 studies, 1 of which included non-SN deposits detected by IHC):**

SN deposit size	% positive non-SN		
	mean	lowest	highest
$\leq 2$ mm	18	13	22
$> 2$ mm	58	45	79

In those studies that classified the SN metastasis size as detected by IHC only,  $\leq 2$  mm excluding IHC-detected disease, or  $> 2$  mm, there was a trend toward further discrimination among patients with micrometastatic disease.

**Table: Proportion of patients with positive non-SNs (determined by H&E) by subgroup for characteristic of SN deposit i.e. detected by IHC only,  $\leq 2$ mm excluding IHC-detected, or  $> 2$ mm (4 studies):**

SN deposit size	% positive non-SN		
	mean	lowest	highest
IHC only	13	8	20
$\leq 2$ mm excluding IHC	24	18	33
$> 2$ mm	61	49	79

Factors found to be statistically significantly predictive of positive non-SNs, by multivariate analysis performed in primary studies:

Larger tumour size (6 studies)

SN metastases size >2mm (5 studies)  
 Extracapsular extension of SN metastases (2 studies)  
 Tumour LVI (2 studies)  
 >1 positive SN (1 study)

**Mantel-Haenszel meta-analysis of common odds ratios across studies for odds of positive non-SNs, by each factor studied**

Factor	OR	95% CI
Size of metastases: >2mm vs. ≤2mm	6.2	4.5-8.5
SN extranodal extension: present vs. absent	4.8	3.2-7.4
Tumour size: >2cm vs. ≤2cm	2.6	2.1-3.3
No. positive SNs: ≥2 vs. 1	2.5	1.8-3.4
LVI: present vs. absent	2.2	1.6-3.1
Lobular vs. ductal histology	1.9	1.0-3.7
ER status: negative vs. positive	1.8	1.1-3.0
HER-2 status: positive vs. negative	1.8	0.9-3.7
No. SNs removed: 1-2 vs. ≥3	1.6	1.1-2.3
Tumour grade: III vs. I-II	1.5	1.1-2.0
Palpable tumour: yes vs. no	1.4	0.7-2.9
PR status: negative vs. positive	1.4	0.9-2.3
Age group: <50 years vs. ≥50 years	0.9	0.6-1.3

**General comments**

Literature search: performed on MEDLINE database using the following keywords: nonsentinel node, non-sentinel node, nonsentinel lymph node, non-sentinel lymph node, sentinel lymph node biopsy; combined with: breast neoplasms and characteristics, sentinel lymph node biopsy; combined with: breast neoplasms and predictors, and breast neoplasms; combined with: axillary dissection and metastasis.

Data extraction was checked by an external consultant.

Study-specific odds ratios were calculated from the abstracted data, and the common odds ratios across studies were estimated using the Mantel-Haenszel method. For the meta-analysis, data regarding non-SNs found to be positive by H & E evaluation were used whenever available, but data from studies in which IHC was performed on non-SNs were included.

The 11 studies included in the meta-analysis were published between 1999 and 2003.

NB - All of the included studies were also included in the meta-analysis by Cserni et al. (2004), but this paper provides a different analysis of some of the same data.

The study sample sizes (patients with a positive SN who underwent completion ALND) ranged from 60-389 patients. Patient age, the number of SNs obtained, and the number of non-SNs obtained appeared similar across studies. There was variation across studies in disease stage distribution; the proportions of patients with tumors  $\leq 2$  cm and with SN micrometastasis ranged from 30-78% and 25-57%, respectively. The authors report that the variation in histology technique (see 'interventions') is likely to be the most important source of heterogeneity between studies.

## Prospective case series

de Widt-Levert, Tjan-Heijnen, Bult, Ruers & Wobbes . Stage migration in breast cancer: surgical decisions concerning isolated tumour cells and micro-metastases in the sentinel lymph node. Eur.J.Surg.Oncol. 29[3], 216-220. 2003.

### Design

Design: Prospective case series (therapy), evidence level: 3  
Country: Holland, setting: Tertiary care

### Inclusion criteria

Patients with clinical & radiological T1N0 breast cancer treated consecutively in the year 2000-2001.

Of 38 patients who underwent SLNB, the SN was localised in 34, of whom 21 had histologically proved SN metastases.

### Exclusion criteria

See inclusion criteria.

### Population

number of patients = 21.

### Interventions

Aim: to investigate the clinical significance of isolated tumour cells and micrometastases in the SN.

Histology techniques:

SNs:

Interoperative imprint cytology (giemsa & papanicolaou)

Definitive technique: H&E; at least 3 levels at 500 micron interval; also IHC using CAM 5.2 (Becton & Dickenson, 1:20).

Non-SNs:

H&E only; 2 levels.

### Outcomes

Crude rate of disease-positive non-SNs in patients with positive SNs.

### Follow up

Not reported - study reports on the time of definitive surgical treatment.

### Results

The rate of non-SN metastases in 21 patients with metastatic SNs was as follows (numbers = patients):

Size of SN deposit	No.	Rate of axillary clearance	Rate of positive non-SNs
Macrometastases (>2mm)	4	4/4	3/4
Micrometastases (<= 2mm)	4	4/4	1/4
ITCs	13*	12/13*	0/12

\*NB 1 patient did not undergo axillary clearance at the time of definitive treatment and experienced a later axillary recurrence, and underwent delayed axillary clearance.

Matched controls (n=75):

The rate of positive axillary nodes attributed by standard H&E histology was 52/75 = 69%.

### General comments

Prospective cases series with comparison to historical control group, treated before the era of SLNB.

Small subgroups based on only 21 patients that meet the population specified for this question lead to unreliable crude rates.

Staging scheme applied to the SLNB study group was that of UICC International Union Against Cancer (Hermanek P, Hutter RVP, Sobin LH, Wittekind CH. Communication of the UICC International Union against cancer: classification of isolated tumour cells and micrometastases. Cancer 1999; 86: 2668-73), as follows:

pN0: No regional lymph node metastasis histologically, no examination for isolated tumor cells (ITC).

pN0(i-): No regional lymph node metastasis histologically, negative morphologic findings for ITC.

pN0(i1): No regional lymph node metastasis histologically, positive morphologic findings for ITC.

pN0(mol-): No regional lymph node metastasis histologically, negative nonmorphologic findings for ITC.

pN0(mol1): No regional lymph node metastasis histologically, positive nonmorphologic findings for ITC.

Goyal, Douglas-Jones, Newcombe, Mansel & Almanac . Predictors of non-sentinel lymph node metastasis in breast cancer patients. European journal of cancer (Oxford, England.: 40[11], 1731-1737. 1990.

## **Design**

Design: Prospective case series (therapy), evidence level: 3  
Country: UK, setting: Tertiary care

## **Inclusion criteria**

64 patients treated at a single centre with SLNB plus axillary clearance between Feb 1998 - Dec 2001. All patients had disease-positive SNs and were identified from a larger series of 618 patients treated with the same protocol at numerous centres, of whom 201 had positive SNs.

## **Exclusion criteria**

Patients with disease-negative SNs.  
Patients who underwent, in addition to SLNB, four node sample instead of axillary clearance.  
Pregnant women.  
Patients with known multi-centric tumours.  
Patients with a history of previous surgery to the same breast or axilla.

## **Population**

number of patients = 64, age range 35 to 89 years, median age = 54 years.

## **Interventions**

Aim: to identify a subgroup of patients with a positive SN who do not need to be exposed to the morbidity and cost associated with completion axillary clearance.

All patients underwent SLNB and axillary clearance during the centre's validation period for SLNB.

Histology technique:

The SNs and non-SNs were bisected if less than 5 mm or sliced at 3 mm intervals if greater than 5 mm and assessed using single sections stained with haematoxylin and eosin (H&E). Intraoperative histological examination was not utilised.

SN deposit size groups:

Micrometastases: <2mm

Macrometastases: >=2mm.

## **Outcomes**

Association between clinicopathological factors and the finding of disease-positive non-SNs. (Univariate analysis: Chi square test for binary and

unordered categorical variables; Mann-Whitney test for ordinal/continuous variables. Factors found to be statistically significant in univariate analyses were entered into a stepwise logistic regression (multivariate analysis)).

Factors examined were age; tumour size; tumour grade; No. SNs removed; No. positive SNs; No. negative SNs, tumour pathological subtype; multifocality; size of SN metastasis; extracapsular extension; LVI; % replacement of SN by tumour.

### **Follow up**

Not relevant; study is of peri-operative period.

### **Results**

#### 1. Data from the centre reporting size of largest SN metastasis:

On univariate analysis, increasing size of the SN metastasis, percentage replacement of SN by tumour and extracapsular extension around the SN, all were significantly associated with non-SN involvement ( $P < 0.001$ ,  $P < 0.001$ ,  $P = 0.01$ , respectively). The rate of non-SN involvement was 7% in the presence of SN micrometastasis ( $<2$  mm), compared with 60% when the SN had a macrometastasis ( $>2$  mm). All patients with metastasis of  $>10$  mm had additional positive nodes in the axilla.

Crude rate of positive non-SNs by size of SN deposit:

$<2$ mm: 7%

2-10mm: 45%

$>10$  mm: 100%;  $p < 0.001$ .

82% of patients with extracapsular extension around the SN had non-SN involvement, while only 40% of patients without extracapsular extension around the SN had non-SN metastasis.

On multivariate analysis, size of the SN metastasis was the only statistically significant factor, predictive of non-SN involvement: ( $P < 0.001$ ); multiple logistic regression equation:

Logit (proportion with positive non-SNs) =  $0.257 \times$  size of largest metastasis (mm) - 1.732.

#### 2. Data from all centres (no variable for size of largest SN metastasis)

Increasing tumour size, tumour grade and number of positive SNs were all associated with an increased likelihood of NSLN metastasis on univariate analysis ( $P = 0.002$ ,  $P = 0.040$ ,  $P = 0.019$ , respectively). The total number of sentinel nodes removed and number of negative sentinel nodes were significant negative predictors ( $P = 0.014$ ,  $P < 0.001$ , respectively).

Only the difference in the number of positive and negative SNs removed remained predictive of non-SN involvement on multivariate analysis ( $P <$

0:001); multiple logistic regression equation:

Logit (proportion with positive non-SNs) = 0.614 x positive SNs - 0.864 x negative SNs - 0.36.

**General comments**

Study presents data from the non-randomised validation phase of the ALMANAC RCT. Only one centre assessed the size of metastatic deposit in the SN (n=64) whereas results from the larger series (n=201) are also cited.

Authors report that using only single-centre data may be underpowered to detect potentially important predictive variables by multivariate analysis.

## Retrospective case series

Bolster, Peer, Bult, Thunnissen, Schapers, Meijer, Strobbe, van Berlo, Klinkenbijn, Beex, Wobbes & Tjan-Heijnen . Risk factors for non-sentinel lymph node metastases in patients with breast cancer. The outcome of a multi-institutional study. Ann.Surg.Oncol. 14[1], 181-189. 2007.

### Design

Design: Retrospective case series (therapy), evidence level: 3  
Country: The Netherlands, setting: Tertiary care

### Inclusion criteria

203 patients with a positive SN, identified from a larger series of 541 patients treated with SLNB over an 18 month period within the years 2002 - 2003 in 4 centres. Patients had tumours of  $\leq 5$ cm in size.

### Exclusion criteria

Pre-surgical proof of axillary metastases;  
Multifocal tumours;  
Previous axillary surgery/RT;  
Neo-adjuvant systemic therapy;  
Patients in whom the SN was not detectable.

### Population

number of patients = 203.

### Interventions

Aim: to measure the rate of positive non-SNs in patients, by size of SN metastasis, and to assess predictive factors for positive non-SNs.

Patients underwent SLNB. A completion ALND was indicated in the presence of ITCs, micrometastases or macrometastases.

Histology technique:

1. SNs:  $\geq 3$  levels;  $\geq 150$  micron intervals, by H&E analysis. If no metastasis detected by this method: IHC analysis.
2. ALND: 1-2 levels; H&E analysis

SN metastasis size classification - based on TNM (2002):

pN0(i+): solitary tumour cells or clusters of size  $\leq 0.2$  mm

pN1mi: micrometastases of size 0.2 mm - 2 mm

pN1+ Macrometastases:  $> 2$ mm in size

pNtotal: refers to final stage attributed after inclusion of non-SNs.

For SN findings the term 'sn' was added to the terms, and for ALND findings, 'n'.

## Outcomes

Rate of performance of ALND

Rate of positive non-SNs and size of these deposits

Factors associated with positive non-SNs. Factors explored were age, size of SN deposit, tumour size, grade, ER-PR status, presence/absence of LVI.

## Follow up

Not applicable

## Results

203 patients had positive SNs. Of these, 186 underwent ALND (91.6%).

Rate of further non-SNs: 56/186 = 30.1%

SN deposit size	n cases	No. with positive non-SNs (% of cases)	Size of non-SN metastasis		
			pN0(i+)(n) <= 0.2 mm	pN1mi(n) 0.2 mm – 2 mm	pN1+(n) > 2mm
pN0(i+)(sn) <= 0.2 mm	54	7 (12.9%)	0	2	5
pN1mi(sn) 0.2 mm – 2 mm	53	14 (26.4%)	4	4	6
pN1+(sn) > 2mm	96	35 (36.5%)	0	5	30
	203	56	4	11	41

The difference in the rate of positive non-SNs by size of SN metastatic deposit (ITCs vs. micrometastases vs. macrometastases: 14.6%, 28.6% and 38.0%, respectively) was statistically significant (Chi square;  $p < 0.0001$ ).

Upstaging of patients on the basis of final stage attributed after inclusion of non-SNs:

Of 107 patients with micrometastases or ITCs only in the SN, 13 (12.1%) were upstaged by non-SNs. This broke down as 7/54 = 13.0% for SN ITCs and 6/53 = 11.3% for SN micrometastases.

SN deposit size	n cases(%)	pNtotal: final stage attributed after inclusion of non-SNs		
		pN0(i+)(n) <= 0.2 mm	pN1mi(n) 0.2 mm – 2 mm	pN1+(n) > 2mm

pN0(i+)(sn) ≤ 0.2 mm	54 (26.6%)	47	2	5
pN1mi(sn) 0.2 mm – 2 mm	53 (26.1%)	-	47	6
pN1+(sn) > 2mm	96 (47.3%)	-	-	96
Total	203 (100%)	47	49	107

#### Predictive factors for positive non-SNs

On univariate analysis and multivariate analysis, size of SN deposit and size of primary tumour were statistically significantly associated with positive non-SNs.

Multivariate analysis (logistic regression model):

		OR	95% CI	p
	pN0(i+)(sn) ≤ 0.2 mm	1.0		
SN deposit size	pN1mi(sn) 0.2 mm – 2 mm	3.1	0.99-9.8	
	pN1+(sn) > 2mm	4.0	1.4-11.5	0.03
Primary tumour size	< 3 cm	1.0		
	> 3 cm	3.1	1.2-8.1	0.001
LVI	Absent	1.0		
	Present	2.0	0.9-4.2	0.17

#### General comments

Re: rate of performance of ALND, of 17 patients with a positive SN in whom ALND was omitted, in 3 patients non-sentinel nodes were also examined and found to be negative for metastasis. Of 338 patients excluded from the analysis, positive non-SNs were removed during SLNB along with the SNs.

Some subtle inconsistencies between paper & data tabulated here exist; re: % of +ve non-SNs by size of SN deposit - may arise from this data extraction and from nomenclature of SN stage and final stage. The discrepancy is difficult to source or to otherwise explain, but is minor: ITCs vs. micrometastases vs. macrometastases: 14.6%, 28.6% and 38.0%,

respectively in text, and 12.9%, 26.4% and 36.5% tabulated here.

Calhoun, Hansen, Turner & Giuliano . Nonsentinel node metastases in breast cancer patients with isolated tumor cells in the sentinel node: implications for completion axillary node dissection. Am.J.Surg. 190[4], 588-591. 2005.

## **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: USA, setting: Tertiary care

## **Inclusion criteria**

78 patients treated with SLNB between January 1995 and December 1999 who were found to have at least 1 ITC positive SN i.e. stage N0(i+). Patients were identified from a total series of 634 patients.

Patient and tumour characteristics: reported by subgroup, but inconsistently (not cited).

## **Exclusion criteria**

See inclusion criteria.

## **Population**

number of patients = 78.

## **Interventions**

Aim: to assess the rate of positive non-SNs in patients staged as N0(i+) by SLNB.

All patients (78) underwent SLNB. ALND was recommended for patients with positive SLNs, including those with ITCs only.

61 patients underwent ALND; 17 patients did not.

Pathological assessment:

SNs: cytokeratin IHC if negative by H&E.

ALND: (non-SNs): H&E.

All SN specimens were either prospectively or retrospectively (i.e. re-examination) classified as macrometastatic, micrometastatic, or ITC, according to the AJCC staging system (2002).

## **Outcomes**

Rate of positive non-SNs.

Disease-related events.

## **Follow up**

Mean 80.5 months.

## **Results**

Non-SN status in patients who underwent ALND:

Positive on H&E: 3/61 = 4.9%

Negative on H&E: 58/61 = 95.1%

Of 3 cases with positive non-SNs, 2 patients had only micro-metastases in the non-SNs and 1 had macrometastasis (3 mm) in their non-SN.

#### Recurrence & survival

	Axillary recurrence	Breast recurrence	Distant metastasis	Death
Non-SN + (n=3)	0	0	1	0
Non-SN - (n=58)	0	3	1	0
No ALND (n=17)	0	0	0	0

No patients experienced axillary recurrence (all patients i.e. including 17 patients who did not undergo ALND). Crude rate = 0/78 = 0%.

Disease-free survival (crude rate, by subgroup):

Non-SN +: 2/3 = 67%

Non-SN -: 54/58 = 93%

No ALND: 17/17 = 100% (small numbers make data unreliable)

Overall survival (crude rate; all patients): 78/78 = 100%

#### General comments

Staging criteria:

Macrometastasis:  $\geq 2$  mm foci;

Micrometastasis:  $\geq 0.2$  mm to 2 mm foci; [N1mi];

ITCs: disease detected by IHC analysis: 0- to 0.2 mm foci; [N0(i+)]

No metastases detected by IHC: N0(i-).

'A majority' of the 61 patients with negative non-SNs received adjuvant chemotherapy, and 77.6%, adjuvant hormone therapy. All 3 patients with positive non-SNs received 'adjuvant therapy'. 15/17 women who did not undergo ALND received adjuvant systemic therapy.

Subgroups, particularly for patients with positive non-SNs and those who did not undergo ALND, are small; crude rates for disease-free and overall-survival are unreliable.

Degnim, Reynolds, Pantvaidya, Zakaria, Hoskin, Barnes, Roberts, Lucas, Oh, Koker, Sabel & Newman . Nonsentinel node metastasis in breast cancer patients: assessment of an existing and a new predictive nomogram. Am.J.Surg. 190[4], 543-550. 2005.

## **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: USA, setting: Tertiary care

## **Inclusion criteria**

574 patients who underwent SLNB then completion ALND for SN metastases between October 1997 and June 2004 at two centres as follows:

1. University of Michigan (n=109)
2. Mayo Clinic (n=465)

## **Exclusion criteria**

None reported.

## **Population**

number of patients = 574, age range 26 to 88 years, mean age = 57 years.

## **Interventions**

Aim: to assess the validity of a previously published Memorial Sloan Kettering Cancer Center (MSKCC) nomogram (<http://www.mskcc.org/mskcc/html/15938.cfm>) using patient data from this series and assess whether the addition of further variables to the model improves its performance.

Data from both institutions were used to assess the performance of the MSKCC model. A new predictive model was developed from the Mayo dataset of 465 patients by adding the following variables: size of SN metastasis, location of SN metastasis, presence/absence of extracapsular extension, proportion of SN replaced by metastasis and location of metastasis: subcapsular, parenchymal or both subcapsular and parenchymal. This Mayo model was applied to the Michigan dataset for performance analysis (data not cited).

Histology techniques:

1. SNs: not directly reported, but 'method of detection' classified as IHC only, routine/serial or frozen.
2. Non-SNs: Single H&E section

## **Outcomes**

## Predictive factors for non-SN metastasis.

Factors examined were: age, pathologic size of primary invasive breast tumour, tumour type, Nottingham tumour grade, presence of lymphovascular invasion, multifocality of primary tumour, estrogen and progesterone receptor status, method of detection of SN metastasis (frozen section analysis, routine/serial hematoxylin-eosin staining, or immunohistochemistry), total number of SNs removed, number of positive and negative SNs, measured size of largest metastasis in the SN, proportion of SN replaced by metastasis, location of metastasis (subcapsular, parenchymal, or combined subcapsular and parenchymal), and the presence or absence of extracapsular extension. Tumour type and grade were combined into 4 categories: ductal carcinoma grade I, ductal carcinoma grade II, ductal carcinoma grade III, and lobular carcinoma.

### Follow up

Not applicable

### Results

Univariate analysis: Associations between clinicopathologic features and positive non-SNs:

Variable	OR	95% CI	p
Age (per 10 y)	0.96	0.8-1.1	0.56
Tumor size (per 1.0 cm)	1.3	1.2-1.5	<0.0001
Tumor type and grade			
Ductal, tumor grade II versus I	2.1	1.0-4.3	0.04
Ductal, tumor grade III versus I	2.6	1.2-5.6	0.01
Lobular versus ductal, tumor grade I	3.8	1.8-8.2	0.0007
Lymphovascular invasion (yes vs no)	2.0	1.1-3.7	0.03
Multifocality (yes vs no)	1.3	0.8-2.1	0.32
Estrogen receptor status (positive vs negative)	0.9	0.5-1.5	0.61
Method of detection			
IHC versus frozen	0.2	0.08-0.5	0.001
Routine/serial versus frozen	0.3	0.1-0.6	0.0003
Number of positive SNs (per node)	1.6	1.2-2.1	0.001
Number of negative SNs (per node)	0.8	0.7-0.9	0.001
Size of metastasis (per 1.0 mm)	1.16	1.12-1.21	<0.0001
Parenchymal metastasis	3.3	2.1-5.1	<0.0001

Extracapsular extension	4.0	2.7-5.9	<0.0001
Proportion of SLN involved with metastases (per .10 involved)	1.3	1.2-1.4	<0.0001

On multivariate analysis the following variables were statistically significantly predictive of non-SN metastases: age of the patient, size of primary tumor, estrogen receptor status, size of SN metastasis, extracapsular extension, and number of positive and negative SNs.

**General comments**

In the development of the predictive model, 3 Mayo Clinic patients had no tumour size data, hence the sample size was 462.

Houvenaeghel, Nos, Mignotte, Classe, Giard, Rouanet, Lorca, Jacquemier, Bardou & Groupe des Chirurgiens de la Federation des Centre . Micrometastases in sentinel lymph node in a multicentric study: predictive factors of nonsentinel lymph node involvement--Groupe des Chirurgiens de la Federation des Centres de Lutte Contre le Cancer.[see comment]. J.Clin.Oncol. 24[12], 1814-1822. 2006.

## **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: France, setting: Tertiary care

## **Inclusion criteria**

700 patients with micrometastatic SNs revealed SLNB, who underwent in addition ALND, treated between January 1998 and December 2003 at 16 centres.

Mean tumour size 19 mm (range 1-170 mm).

## **Exclusion criteria**

None defined; study provides no data for patients with SN deposits >2mm in size.

## **Population**

number of patients = 700, age range 25 to 86 years, mean age = 56 years, median age = 55 years.

## **Interventions**

Aim: to determine:

- (1) the rate of non-SN involvement at ALND in the case of SN micrometastasis,
- (2) predictive factors of non-SN involvement at ALND,
- (3) a subpopulation of patients in whom ALND can be omitted.

All patients had SN micrometastases revealed by SLNB, and underwent in addition, ALND.

Histological technique:

1. SNs: Intraoperative assessment in 53% of cases by imprint cytology, scrapings or both; serial sections with H&E analysis (54% of cases) and IHC analysis in 73% of cases
2. Non-SNs: not reported

SN deposit size criteria:

ITCs: < 0.2 mm (also referred to as 'submicrometastases')

Micrometastases:  $\geq 0.2$ mm but  $< 2$  mm

Macrometastases:  $\geq 2$  mm

## Outcomes

Rate of positive non-SNs

Predictive factors for positive non-SNs: factors examined were menopausal status, T stage, tumour grade, LVI, tumour histology, size of SN metastasis, method of detection of SN micrometastases (H&E vs. IHC), no. of sections, section interval, localisation of the SN (outer, inner, central), ER status, PR status.

## Follow up

Not applicable

## Results

Of 700 patients, size of SN deposits was known for 488 patients as follows:

ITCs  $\leq 0.2$  mm: 187

Micrometastases  $> 0.2$  but  $\leq 2$  mm: 301

Unknown: 212.

Of 700 patients 94 (13.4%) had disease-positive non-SNs.

Rate of positive non-SNs by size of SN deposit:

ITC  $\leq 0.2$  mm:  $30/187 = 16\%$

Micrometastases  $> 0.2$  mm but  $\leq 2$  mm:  $43/301 = 14.3\%$

Unknown:  $21/212 = 9.9\%$  ( $p=0.16$ )

On univariate analysis the following variables were significantly associated with a higher rate of non-SNs: increasing T stage, presence of LVI, mixed tumour histology, and SN metastases detected by H&E analysis (c.f IHC).

On multivariate analysis the following variables were significantly associated with a higher rate of non-SNs:

T stage  $\leq 20$  mm vs.  $> 20$  mm: OR 2.54 (95% CI 1.607-4.014);  $p<0.0001$

Micrometastases detected by H&E vs. IHC alone: OR 1.734 (95% CI 1.084-2.773);  $p=0.027$

Presence of LVI: OR 1.706 (95% CI 1.082-2.690);  $p=0.021$

## General comments

Since 212 patients had micrometastases of unknown size, this may reduce the study power to detect an association between SN deposit size and positive non-SNs.

Variables analysed as predictive factors reflect the manner in which data was available for collation retrospectively, across 16 centres.

Katz, Niemierko, Gage, Evans, Shaffer, Fleury & Smith . Can axillary dissection be avoided in patients with sentinel lymph node metastasis? J.Surg.Oncol. 93[7], 550-558. 2006.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: USA, setting: Tertiary care

### **Inclusion criteria**

Patients treated with SLNB between 1998 and 2003.

110 patients had DCIS, out of a larger series of 1133 patients.

307 patients underwent mastectomy and 833 breast conserving surgery. In 8 patients the type of definitive surgery was unknown.

367 patients had disease-positive SNs.

### **Exclusion criteria**

Retrospective study: none reported.

### **Population**

number of patients = 367, age range 30 to 96 years, median age = 57 years.

### **Interventions**

Retrospective analysis of 1148 SLNB procedures in 1133 patients treated at a single centre and recorded on a pathology database.

All patients underwent SLNB and were found to have positive SNs. 246 patients underwent ALND.

Aim: to identify predictive factors for the involvement of non-SNs in patients with a SN metastasis.

Histology technique:

1. SNs: Frozen section intraoperatively; H&E analysis of 2 levels at 60 micron spacing; IHC performed on all SNs negative on H&E and for all invasive carcinomas.

2. Non-SNs: H&E, 1 level.

Size classification for SN metastases:

$\leq 0.2\text{mm}$  (i+)

0.21-2.0mm (IHC)

$\leq 2.0\text{mm}$  (H&E)

2.1-4.0mm (H&E)  
4.1-10.0 (H&E)  
>10.0 (H&E)  
Unknown

## Outcomes

Risk factors for the presence of SN metastases.

Risk factors for the presence of further axillary node metastases in patients who undergo axillary clearance for positive SLNB result.

Factors examined were: age, primary surgery/histology, size of the lesion, nuclear grade, LVI, number of SNs involved, number of SNs uninvolved, number of SNs examined, size of the largest SN metastasis, method of SN metastasis detection, extranodal extension, and estrogen and progesterone receptor status

## Follow up

No follow-up reported, study assesses predictive factors for SN and non SN axillary nodal involvement.

## Results

367 patients had disease-positive SNs of these 246 (67%) underwent ALND. 121 patients had involved SNs and did not undergo axillary clearance.

Prevalence of axillary disease =  $367/1148 = 32\%$

Risk factors for involvement of non-SNs

By Pearson Chi square (univariate analysis) the proportion of patients with positive further nodes varied significantly by subgroup for the following variables (as categorical variables):

Presence of lymphovascular invasion ( $p=0.001$ );

Number of SNs examined (higher rates of further nodal involvement where fewer SNs were examined,  $p=0.03$ );

Histological method to detect SN metastasis (higher rates of further nodal involvement for H&E,  $p=0.03$ );

Number of involved SNs (higher rates of further nodal involvement where  $\geq 3$  SNs involved,  $p=0.002$  for H&E histology and  $P=0.05$  for any histological technique);

Number of uninvolved SNs (higher rates of further nodal involvement where fewer SNs uninvolved,  $p<0.001$ );

Size of the largest SN metastasis ( $p<0.001$ ) as follows:

Size of largest SN metastasis	n		%
$\leq 0.2\text{mm}$ (i+)	7	1	14%
0.21-2.0mm (IHC)	10	0	0%

<=2.0mm (H&E)	48	11	21%
2.1-4.0mm (H&E)	26	7	30%
4.1-10.0 (H&E)	74	35	55%
>10.0 (H&E)	67	43	59%
Unknown	21	2	25%

By Pearson Chi square the proportion of patients with involved non-SNs did not vary significantly by subgroup for the following variables (as categorical variables):

Age;

Type of definitive surgery;

Tumour size;

Histology.

On multiple logistic regression analysis the presence of lymphovascular invasion, increasing number of positive SNs, increasing size of the largest SN metastasis and decreasing number of negative SNs were statistically significantly associated with further axillary node involvement (no further details reported).

#### **General comments**

It is not reported, but this series of patients appear to have been treated in an operational phase for SLNB i.e. without planned axillary clearance for any patients irrespective of SN status.

Patients with disease-positive SNs underwent ALND or not, at the discretion of the treating surgeon in consultation with the patient.

Katz, Niemierko, Gage, Evans, Shaffer, Smith, Taghian & Magnant . Factors associated with involvement of four or more axillary nodes for sentinel lymph node-positive patients. *Int.J.Radiat.Oncol.Biol.Phys.* 65[1], 40-44. 2006.

## **Design**

Design: Retrospective case series (therapy), evidence level: 3

Country: USA, setting: Secondary care

## **Inclusion criteria**

224 patients who underwent SLNB and ALND due to disease-positive SNs. Patients were treated at a single centre between 1998 and 2003.

## **Exclusion criteria**

22 patients who did not undergo ALND in spite of a positive SN (at the discretion of the treating physician).

## **Population**

number of patients = 224, age range 32 to 90 years, median age = 52 years.

## **Interventions**

Retrospective analysis of 1148 SLNB procedures in 1133 patients treated at a single centre and recorded on a pathology database.

All patients underwent SLNB and were found to have positive SNs. 246 patients underwent ALND.

Aim: to identify predictive factors for the involvement of non-SNs in patients with a SN metastasis.

Histology technique:

1. SNs: Frozen section interoperatively; H&E analysis of 2 levels at 60 micron spacing; IHC performed on all SNs negative on H&E and for all invasive carcinomas.

2. Non-SNs: H&E, 1 level.

Size classification for SN metastases:

<=2.0 mm

2.1-4.0 mm

4.1 - 10.0mm

>10.0mm

## **Outcomes**

Rate of occurrence of four or more nodes, by subgroup for SN deposit size.

Risk factors for the presence of four or more involved nodes in patients who undergo axillary clearance for positive SLNB result.

Factors examined were: age, primary surgery, size of the lesion, nuclear grade, LVI, number of SNs involved, number of SNs uninvolved, number of SNs examined, size of the largest SN metastasis, method of SN metastasis detection, extranodal extension, and estrogen and progesterone receptor status.

**Follow up**

Not applicable

**Results**

The rate of axillary dissection in patients with positive SNs was 224/246 = 91.1%.

42/224 = 18.8% of patients had four or more positive axillary nodes as follows:

Size of largest SN metastasis	no. cases	no. with $\geq 4$ involved nodes	%
$\leq 0.2$ mm	56	0	0%
2.1-4.0mm	26	1	4%
4.1-10.0 mm	74	17	23%
$> 10.0$ mm	68	24	35%
Unknown	4	1	25%

On univariate analysis, increasing tumour size, lobular histology, LVI, increasing no. of involved SNs, fewer uninvolved nodes and size of SN metastasis (as shown above;  $p < 0.001$ ) were all statistically significantly associated with four or more positive nodes.

On multivariate analysis the following variables were statistically significant predictors of four or more metastatic nodes:

Variable	OR	95% CI	p value
LVSI	3.2	1.4-7.6	0.008
No. +ve SNs	2.6	1.4-4.9	0.003
Size of SN deposit	1.1	1.0-1.2	$< 0.001$
Histology (ductal vs. lobular)	0.2	0.1-0.6	0.002

**General comments**

Paper reports on the same patient series as in a second paper by the same team of authors (also included), but with a different outcome measure.

Paper states 'four or more involved nodes' which taken literally, includes the

SN.

van Rijk, Peterse, Nieweg, Oldenburg, Rutgers & Kroon . Additional axillary metastases and stage migration in breast cancer patients with micrometastases or submicrometastases in sentinel lymph nodes. Cancer 107[3], 467-471. 2006.

## **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: The Netherlands, setting: Tertiary care

## **Inclusion criteria**

160 patients who underwent SLNB followed by ALND due to the finding of SN micrometastases/ITCs. Patients were identified from a larger series of 2150 who underwent SLNB, of whom 649 had disease-positive SNs.

## **Exclusion criteria**

349 patients with SN macrometastases (> 2 mm in size);  
93 patients with SN micrometastases/ITCs (<= 2mm in size) who did not undergo ALND.

## **Population**

number of patients = 160.

## **Interventions**

Aim: to investigate the incidence of micrometastases and ITCs in the sentinel lymph node, to estimate the risk of additional metastasis in the remaining axillary lymph nodes, and to consider the implications for staging and treatment.

All patients underwent SLNB plus ALND.

Authors performed a retrospective review of SN histology slides.

Histological assessment:

1. Sentinel nodes: bisected or sectioned in 2 mm slices and completely embedded. Paraffin blocks cut at 3 levels with minimally 150 micron intervals. H&E assessment with in case of a tumor-negative sentinel node with H&E staining.

2. Non-sentinel nodes from ALND: 3 nodes evaluated at 1 level and stained with H&E; IHC not routinely performed.

SN deposit size criteria:

ITCs: <= 0.2 mm

Micrometastases: 0.2 mm to <=2 mm

Macrometastases: >2 mm

Stage criteria:

pN0(i+): no regional lymph node metastasis histologically, positive morphological findings;

pN1mi: micrometastases; 0.2 mm <=2 mm;

pN1a, 1-3 involved axillary nodes;

pN2a, 4-9 involved axillary lymph nodes

### Outcomes

Rate of performance of ALND;

Prevalence of disease-positive non-SNs revealed by ALND;

Rate of understaging by SLNB, in the light of further staging information by ALND.

### Follow up

Not applicable

### Results

Of 253 patients with ITC/micrometastatic SN deposits, 160 underwent ALND i.e. rate 160/253 = 63.2%.

Rate of further positive axillary nodes revealed by ALND by size of SN deposit:

Size of SN deposit	No. cases	No. with further positive nodes by ALND (%)	Size of non-SN deposit by ALND		
			Submicro <= 0.2 mm	Micro 0.2 mm to <=2 mm	Macro >2 mm
ITCs: <= 0.2 mm	54	4 (7.4%)	2	0	2
Micrometastases: 0.2 mm to <=2 mm	106	20 (18.9%)	-	4	16

Of 24 patients with further positive non-SNs, 18 were upstaged by ALND. Of these 18, 7 (all with micrometastasis in the SN) were offered systemic treatment that would not have been offered without the information from ALND. In the remaining 11 patients, systemic therapy was indicated by other patient/disease factors.

Stage Migration in Patients With Micrometastases and submicrometastases after ALND

SN stage	n cases	pN0 (i+)	pN0 (i+)	ALND stage	
				pN1a	pN2a
pN0 (i+)	54	2	0	2	0

pN1mi	106	0	4	10	6
-------	-----	---	---	----	---

**General comments**

Histological classification uses the terms 'ITC' and 'submicrometastasis' synonymously.

The rate of performance of ALND is not an outcome specified by the paper, although data permit its use. However in this retrospective study the performance of ALND is not the result of a prospective study protocol.

Viale, Maiorano, Pruneri, Mastropasqua, Valentini, Galimberti, Zurrada, Maisonneuve, Paganelli & Mazzarol . Predicting the risk for additional axillary metastases in patients with breast carcinoma and positive sentinel lymph node biopsy.[see comment]. Ann.Surg. 241[2], 319-325. 2005.

## **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Italy, setting: Tertiary care

## **Inclusion criteria**

1228 patients with breast cancer of tumour size  $\leq 3$ cm who were treated at a single centre within the years 1997-2003 with SLNB and also axillary clearance due to metastatic SNs.

## **Exclusion criteria**

No further details reported.

## **Population**

number of patients = 1228, age range 26 to 82 years, mean age = 53 years.

## **Interventions**

Aim: to assess the actual prevalence of ITC only in the axillary SLN of patients with breast cancer and its predictive implications on the status of the remaining axillary lymph nodes.

The authors performed a pathology review and measured the largest axis of the SN metastasis.

Histology technique:

### 1. Sentinel nodes:

Fifteen pairs of adjacent 5 micron thick sections cut at 50 micron intervals from both lymph node halves, i.e. 60 sections per node; for remaining tissue: sections at 100 micron intervals. H&E analysis of one section of each pair and cytokeratin analysis by MNF116 monoclonal antibody for the other section.

### 2. Non-sentinel nodes:

3-6 H&E-stained sections per node, at 100- to 500 micron intervals.

SN deposit size criteria:

ITC:  $< 0.2$  mm

Micrometastases: 0.2-2 mm (also analysed as  $\leq 1$ mm and 1-2mm)

Macrometastases:  $> 2$ mm

## **Outcomes**

Prevalence of further positive non-SNs

Size of SN metastasis as a predictive factor for positive non-SNs in univariate and multivariate analyses. Co-variables included age, sex, tumour diameter and histology, grade and proliferative fraction, multifocality, ER, PR and HER2-neu receptor status, LVI, no. of positive SNs.

### Follow up

Not applicable

### Results

Distribution of non-SN metastases by size of SN metastases:

SN metastases size	No. cases	No. with +ve non-SNs (%); p	Non-SN metastases size		
			ITC: <0.2 mm	Micrometastases: 0.2 mm – 2 mm	Macrometastases: >2 mm
ITC: <0.2 mm	116	17 (14.7%)	1	3	13
Micrometastases: 0.2 mm – 2 mm	318	68 (21.4%); p=0.15	6	20	42
Macrometastases: >2 mm	794	399 (50.3%); p<0.0001	12	27	360
Total	1228	484 (39.4%)	19	50	415

Distribution of non-SN metastases by size of SN metastases (data for 318 patients with micrometastases):

SN metastases	SN metastases size	No. cases	No. with +ve non-SNs (%)	p
Micrometastases	0.2-1 mm	212	36 (17.0%)	
	1-2 mm	106	32 (30.2%)	0.009
Total		318		

On univariate analysis, the following variables were found to statistically significantly predict non-SN involvement in patients with positive SNs: SN metastasis size, no. of positive SNs, tumour size, tumour grade and presence of LVI.

On multivariate analysis the following variables were found to statistically significantly predict non-SN involvement in patients with positive SNs: SN metastasis size; no. of positive SNs, tumour size, tumour grade and presence of LVI.

Results of multivariate analysis: factors predictive of non-SN involvement in patients with positive SNs.

Factor	Value	OR	p
SN metastasis size	<= 1 mm	1.00	
	1-2 mm	2.24 (95% CI 1.35-3.73)	0.0019
	> 2 mm	4.57 (95% CI 3.27-6.38)	<0.0001
No. +ve SNs	1	1.00	
	>=2	2.47 (95% CI 1.68-3.62)	<0.0001
LVI	Absent	1.00	
	Present	2.12 (95% CI 1.64-2.75)	<0.0001
Tumour size	<=1 cm	1.00	
	1-2 cm	0.88 (95% CI 0.61-1.26)	0.47
	> 2 cm	1.24 (95% CI 0.82-1.87)	0.32
Tumour grade	I	1.00	
	II-III	1.37 (95% CI 0.96-1.94)	0.08

Using the statistically significantly predictive variable on multivariate analysis, the authors applied a predictive model to the same series of patients as follows:

SN metastases size	LVI	No. +ve SNs	No. cases	% of cases with +ve non-SNs	OR	p
<= 1 mm	Absent	1 SN +ve	217	13.4%	1.00	
		2 SN +ve	7	14.3%		
	Present	1 SN +ve	99	22.2%	1.84 (95% CI 1.00-3.35)	0.0480
		2 SN +ve	5	20.0%		<0.0001
> 1 mm	Absent	1 SN +ve	459	34.9%	3.46 (95% CI 2.25-5.32)	<0.0001
		2 SN +ve	69	66.7%	12.93 (95% CI 6.88-24.3)	<0.0001
	Present	1 SN	308	57.8%	8.85 (95% CI 5.67-	<0.0001

		+ve			13.8)	
		2 SN +ve	64	73.4%	17.87 (95% CI 9.10- 35.1)	<0.0001

### General comments

The predictive model is based on the predictive variables from multivariate analysis and is applied to the same patient series. For this reason it is not surprising that cumulative negative disease factors are associated with increasing odds of positive non-sentinel nodes. Some odds ratios are missing, possibly for subgroups with few patients.

Chen, S. L., Hoehne, F. M. & Giuliano, A. E. (2007) The prognostic significance of micrometastases in breast cancer: A SEER population-based analysis. *Annals of Surgical Oncology*, 14: 3378-3384.

**Design:** Retrospective Study  
**Country:** US

**Aim:** To assess whether micrometastatic disease (N1mi) alone can predict a poorer prognosis for patients with early breast cancer.

This study investigated whether the survival of patients with solely micrometastatic disease (N1mi) would be intermediate to patients with 1-3 tumour-positive lymph nodes (N1) and those with no positive lymph nodes (N0).

**Inclusion criteria**

The surveillance, epidemiology and end results (SEER) database for all patients between 1992 and 2003 with invasive ductal or lobular breast cancer without distant metastases and  $\leq$  n3 axillary nodes with macroscopic disease.

- Patients had a diagnosis of histologically confirmed infiltrating ductal or infiltrating lobular breast cancers.
- Study population contained either no regional lymphatic spread (N0), or patients with nodal spread limited to micrometastases, no larger than 2 mm (N1 mi) and patients with macrometastases in no more than 3 nodes (N1).

**Exclusion criteria**

Patients with an unknown number of tumour- involved nodes, insufficient staging information and evidence of distant mets.

**Population**

N= 209,720 patients

**Interventions**

- All patients were restaged with AJCC 6<sup>th</sup> ed. criteria for T-stage and N-stage.
- Patients were stratified by nodal involvement and compared using the Kaplan-Meier method.

**Outcomes**

Cox proportional hazards regression was used to compare survival after adjusting for patient and tumour characteristics.

**Results**

- N1mi diagnoses increased from 2.3% to 7% among the 209,720 study patients ( $p < 0.001$ ).
- Overall, N1mi patients had a statistically worse survival than N0 patients and better than N1 patients.
- In a T-stage stratified univariate analysis, N1mi patients had a poorer prognosis when compared to N0 patients. However, this was only significant for patients with T2 lesions (univariate analysis,  $p < 0.001$ )
- There was statistical better survival in N1mi patients compared to N1 patients with T1-T3 lesions.
- 5 and 10 year survival was intermediate for N1mi patients when compared to N0 and N1

patients.

- On multivariate analysis, N1mi remained a significant prognostic indicator across all patients ( $p < 0.0001$ ).
- HR (hazard ratio)= 1.35 (compared to N0 disease)
- HR = 0.82 (compared to N1 disease)
- Other negative prognostic factors included male gender, oestrogen-receptor negativity, progesterone-receptor negativity, lobular histology, higher grade, older age, higher T-stage, and diagnosis in an earlier time period.

**General comments**

Author's Conclusion: Nodal micrometastasis of breast cancer carries a prognosis intermediate to N0 and N1 disease, even after adjusting for tumour and patient related factors. Adjuvant therapy trials should consider using N1mi as a stratification factor when determining nodal status. Prospective studies will confirm results with less bias involved.

### **3.6 When is it appropriate to perform immediate breast reconstructive surgery?**

#### **Short Summary**

A moderate volume of observational studies exists for breast reconstruction following mastectomy for breast cancer. There are few direct comparisons of immediate reconstruction versus delayed reconstruction.

With respect to psychological outcomes one systematic review of observational studies suggests that better psychological outcomes arise in patients treated with immediate reconstruction compared to delayed reconstruction (Fischbacher *et al.* 2002). Subsequently published observational studies suggest that psychological outcomes are generally good following immediate reconstruction (Drucker-Zertuche and Robles-Vidal 2007; Gendy *et al.* 2003).

There is high heterogeneity with regard to assessment of cosmetic outcome between the studies. No evidence was identified from one systematic review of observational studies and subsequent observational studies to suggest superiority of immediate versus delayed reconstruction in terms of cosmetic result. The majority of the observational studies report high rates of acceptable cosmetic results between 80% and 96% (Anderson *et al.* 2004; Drucker-Zertuche and Robles-Vidal 2007; Gendy *et al.* 2003; Cordeiro *et al.* 2004; Vandeweyer *et al.* 2003) whereas in one study the reported rate is only 20% (Knottenbelt *et al.* 2004).

Two systematic reviews of observational studies suggest that immediate reconstruction may be associated with a higher rate of complications compared to delayed reconstruction (Fischbacher *et al.* 2002; Javaid *et al.* 2006). A third less rigorous review found similar rates of capsular contraction between immediate and delayed reconstruction with implants, but with a trend for unfavourable results with immediate autologous tissue reconstruction (Taylor *et al.* 2005). Apart from radiotherapy, studies that examined potential risk factors for complications following reconstruction did not consistently identify any other factors (Anderson *et al.* 2004; Woerdeman *et al.* 2006).

No reliable evidence was identified on whether immediate breast reconstruction following mastectomy delays the start of adjuvant chemotherapy or radiotherapy. Whilst a minority of observational studies included in an expert review (Taylor and Kumar 2005) indicated that such delays occur after immediate reconstruction, the review's authors concluded that the evidence was inconclusive. Subsequently published observational studies have demonstrated little difference in the interval from surgery to adjuvant therapy in patients treated with immediate reconstruction compared to those for whom reconstruction is delayed, or those who do not receive reconstruction (Gouy *et al.* 2005; Taylor & Kumar 2005; Wilson *et al.* 2004; Rey *et al.* 2005).

No reliable evidence was identified to suggest that recurrence or survival differs in patients treated with immediate reconstruction compared to those who receive delayed reconstruction. One systematic review citing observational studies reported no difference in recurrence and survival following mastectomy with immediate reconstruction compared to mastectomy with no reconstruction. One expert review (Taylor *et al.* 2005), summarised the rate of local

recurrence with a median value of 5%, drawn from observational studies of patients treated with mastectomy and immediate reconstruction. The rate of distant metastasis in 16 studies of similarly treated patients had a median value 10.5%.

Evidence from observational studies suggests that in general, patients are satisfied with their reconstructed breasts following either immediate reconstruction, or delayed reconstruction. However some patients are not satisfied with their reconstructions and the impact of this is not further explored by the identified studies (Tykka *et al.* 2002; Ascherman *et al.* 2006; Cordeiro *et al.* 2004; Vandeweyer *et al.* 2003). Very little direct evidence for women’s preference for immediate versus delayed breast reconstruction was identified.

**PICO**

Population	Intervention	Comparison	Outcome
Patients with breast cancer who undergo total breast reconstruction following mastectomy.	Immediate total breast reconstruction	Delayed total breast reconstruction (e.g. >6 months after definitive surgery)	<ul style="list-style-type: none"> <li>• Patient preferences</li> <li>• Effect on type of procedure offered</li> <li>• Cosmetic outcome – including longterm</li> <li>• Psychological outcome</li> <li>• Complication rates (short and long term)</li> <li>• Local recurrence rates</li> <li>• Delay in oncological treatment</li> </ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

**Evidence Summary**

A moderate volume of evidence from observational studies of breast reconstruction following mastectomy for breast cancer exists including two systematic reviews and an expert review of observational studies.

There are few direct comparisons of immediate reconstruction versus delayed reconstruction with the majority of recent studies appearing to focus on immediate reconstruction.

The studies vary in their inclusion of patient series who were treated with autologous tissue reconstruction (commonly TRAM or latissimus dorsi flap reconstructions) or prosthetic implants (permanent or possibly using a temporary expander) or with a combination of autologous tissue and implant. The studies vary also with regard to adjuvant therapies; radiotherapy and chemotherapy may affect some outcomes.

The majority of data originate from observational studies, many of them representing small patient series or samples with high heterogeneity across studies. As such the findings in this report should be interpreted cautiously.

Evidence suggests that better psychological outcomes arise in patients treated with immediate reconstruction compared to delayed reconstruction.

There is no high quality evidence on cosmetic outcome following immediate versus delayed reconstruction.

Poor quality evidence suggest that immediate reconstruction may be associated with a higher rate of complications compared to delayed reconstruction

There is no evidence differences in overall survival or recurrence in immediate versus delayed surgery.

Evidence from a single retrospective study from the UK suggests that the use of immediate reconstruction increased over the period 1997-1999, and also reconstruction with autologous tissue.

### **Psychological outcomes**

One systematic review of observational studies suggests that better psychological outcomes arise in patients treated with immediate reconstruction compared to delayed reconstruction (Fischbacher *et al.* 2002). A randomised trial included in the same systematic review found that patients treated with immediate reconstruction had similar psychological outcomes over the first post-operative year compared to patients who could expect reconstruction at a later date.

One prospective case series study (Drucker-Zertuche and Robles-Vidal 2007) measured patients' satisfaction with their reconstructions, perception of body image and quality of life following immediate reconstruction (autologous, expander/implant or in combination). Patient perception of body image was reported as 'very good' or 'good' in 84% of cases. 90% of patients reported that their sexual life was unchanged following surgery and 94% that their social life was unchanged following surgery.

A prospective case series study (Gendy *et al.* 2003) measured quality of life in patients treated with immediate latissimus dorsi myocutaneous flap reconstruction, 21% of whom received adjuvant RT. Quality of life was assessed using 4 different quantitative scales. Results were as follows:

Anxiety as measured with the Hospital anxiety and depression scale (HADS) was as follows:

Normal (score 0-7): 65%

Mild (score 8-10): 21%

Moderate (score 11-14): 14%

Severe (score 15-21): 0%

HADS anxiety score had mean 5 (range 0-14) NB (score range 0-21; low score represents low anxiety)

Depression as measured with the Hospital anxiety and depression scale (HADS) was as follows:

Normal (score 0-7): 93%  
Mild (score 8-10): 5%  
Moderate (score 11-14): 2%  
Severe (score 15-21): 0%

HADS depression score had mean 1 (range 0-10) NB (score range 0-21; low score represents low depression)

Mean Rosenberg self-esteem scale (RSE) was 24 (range 10-29) NB score range 10-40; low score indicates high self esteem

Mean Hopwood body image scale (HBIS) was 5 (range 0-21) NB score range 0-30; low score represents less disturbance of body image

Concern regarding residual cancer had a mean score of 45 (visual analogue scale; possible range 1-100).

### **Cosmesis**

There is no high quality evidence on cosmetic outcome following immediate versus delayed reconstruction, so findings should be interpreted with caution. There is high heterogeneity with regard to assessment of cosmetic outcome between the studies. No evidence was identified from one systematic review of observational studies and subsequent observational studies to suggest superiority of immediate versus delayed reconstruction in terms of cosmetic result.

One systematic review of observational studies suggests that study results for cosmesis following immediate versus delayed reconstruction are inconclusive (Fischbacher *et al.* 2002).

One retrospective comparative study (Anderson *et al.* 2004) found in univariate analysis that the sequencing of breast reconstruction (immediate or delayed until after adjuvant radiotherapy) was not a statistically significant risk factor for adverse cosmetic outcome. Cosmetic result was assessed as 'excellent/good' in 85% of the whole series (immediate plus delayed reconstruction) and as 'fair/poor' in 15% of the whole series.

One retrospective comparative study (Spear *et al.* 2005) found no statistically significant difference between patients who underwent TRAM after RT and those who underwent TRAM before RT with regard to scores for aesthetic result, symmetry or hyperpigmentation. In this study cosmesis was assessed by 16 blinded, independent individuals. Patients who received no RT had generally better cosmetic outcomes than patients in either RT-treated subgroup

One prospective case series (Drucker-Zertuche and Robles-Vidal 2007) assessed aesthetic outcome using 8 separate ordinal scales (shape with brassiere, shape without brassiere, contralateral match, inframammary fold, mobility, consistency, overall result, projection) in patients treated with immediate reconstruction. There was no difference in overall aesthetic result between the three types of reconstruction (TRAM flap versus expander/implant versus Latissimus dorsi flap + implant);  $p = \text{NS}$ . For individual scales, mobility and consistency in the reconstructed breast was closer to that of the contralateral breast in patients who received TRAM reconstruction ( $p=0.015$ ) but for all other aesthetic scales, there were no statistically significant differences between reconstruction groups. The surgeon evaluated the aesthetic result as 'excellent' or 'good' (rather than 'fair' or 'poor') in 91% of cases.

In one prospective case series (Gendy *et al.* 2003) patients underwent skin sparing mastectomy with immediate latissimus dorsi myocutaneous flap reconstruction; 21% of whom received adjuvant RT. Cosmesis was assessed by patients, a blinded multi-disciplinary panel of 5 assessors and by breast retraction assessment (BRA). Overall a good cosmetic result was achieved. A marked degree of retraction by BRA was observed in 14% of patients. Patients rated their cosmetic result with a mean score of 72 out of a highest possible 100, but with wide range in score (3-100).

One retrospective case series (Ascherman *et al.* 2006) studied cosmesis following immediate reconstruction with tissue expander/implant. Mean symmetry score was statistically significantly higher in patients who received no RT compared to those who received RT.

One retrospective case series (Cordeiro *et al.* 2004) studied patients treated with immediate tissue expander/implant reconstruction and found the Proportion of patients with 'good' or 'excellent' aesthetic result to be 80% where RT was subsequently given compared with 88% where no radiotherapy was subsequently given ( $p=0.006$ ).

One retrospective case series (Knottenbelt *et al.* 2004) examined cosmetic result in patients who underwent immediate reconstruction with subpectoral tissue expander. Cosmesis was assessed by the plastic surgeon and surgical oncologist as 'excellent' or 'good' in 20% of patients.

One retrospective case series (Vandeweyer *et al.* 2003) examined complications in patients treated with immediate expander reconstruction, with comparison groups for patients treated with, and without adjuvant chemotherapy. There were no statistically significant differences between groups in the rate of implant displacement, implant deflation, breast symmetry (assessed as optimal or satisfactory in approximately 96% of cases in each group), breast volume compared to the preoperative assessment and location of intramammary fold compared to the preoperative assessment.

## **Complications**

There is no high quality evidence on complications following immediate versus delayed reconstruction, so findings should be interpreted with caution.

One systematic review of observational studies suggests that immediate reconstruction may be associated with a higher rate of complications compared to delayed reconstruction (Fischbacher *et al.* 2002). An expert review (Taylor *et al.* 2005) found that capsular contraction occurred at a median rate of 33% (range 2%-73%) in patients treated with immediate expander/implant reconstruction followed by radiotherapy. The median rate of capsular contraction in patients treated with radiotherapy then delayed expander/implant reconstruction was 35% (range 26%-60%). In patients who received autologous tissue reconstruction the rate of flap tissue necrosis/loss had a median value of 44% (range 0%-59%) where reconstruction was immediate and followed later by radiotherapy, and a median value of 15% (range 5%-34%) where reconstruction was delayed until after radiotherapy (Taylor *et al.* 2005). A subsequent systematic review (Javaid *et al.* 2006) found that complications (necrosis, delayed wound healing, fibrosis, capsular contracture) were more frequent in patients treated with immediate reconstruction followed by radiotherapy than in

patients in whom reconstruction was delayed, and also compared to control groups (no radiotherapy).

One retrospective comparative study (Anderson *et al.* 2004) found in univariate analysis that the sequencing of breast reconstruction (immediate or delayed until after adjuvant radiotherapy) was not a statistically significant risk factor for complications. Other factors explored as potential risk factors for complications were smoking history, type of reconstruction, type of bolus used, use of RT boost, sequencing of reconstruction and use of systemic therapy. Of all the factors examined in the univariate analysis, only bolus type was predictive of complications.

One retrospective comparative study (Gouy *et al.* 2005) found that the need for further corrective cosmetic surgery arising from complications within two years of surgery was equal at 50% in patients who received immediate reconstruction and those who received delayed reconstruction. Capsular contracture of Baker grade II-IV occurred in 64% of patients who underwent immediate reconstruction with an implant. In the whole study 96% of patients received radiotherapy.

One retrospective comparative study (Mortenson *et al.* 2004) found the crude rate of complications in a subgroup of patients treated with mastectomy plus immediate reconstruction to be 22%. The mean follow-up in the entire study was 33 months.

One retrospective comparative study (Spear *et al.* 2005) found no statistically significant difference in the crude rate of short-term complications between patients treated with immediate (before radiotherapy) TRAM flap reconstruction (50%) and those in whom TRAM flap reconstruction was delayed until after radiotherapy (57%;  $p=NS$ ). Mean contracture score was higher (representing less contracture) in patients who underwent TRAM after RT (3.81) than in patients who underwent TRAM before RT (2.86),  $p=0.009$ .

One prospective case series (Benediktsson and Perbeck 2006) found the crude rate of capsular contracture (Baker grade III-IV) in patients treated with immediate reconstruction with a subcutaneously located prosthesis to be 21%. The rate was 42% in the subgroup of patients who subsequently received radiotherapy compared to 15% in the subgroup of patients who did not receive radiotherapy ( $p=0.012$ ).

One prospective case series (Drucker-Zertuche and Robles-Vidal 2007) found the crude rate of complications (predominantly short-term) in patients treated with immediate reconstruction to be 26%. This included two cases of symptomatic capsular contracture. The majority of complications (81%) occurred in patients who subsequently received radiotherapy.

One retrospective case series (Ascherman *et al.* 2006) studied complications following immediate reconstruction with tissue expander/implant. The crude rate of major complications leading to implant loss was 9%, and of minor complications not leading to implant loss, 17%. Radiotherapy was associated with major complications (19% where radiotherapy was given compared to 4% where no radiotherapy was given;  $p<0.025$ ) but not with minor complications (22% where radiotherapy was given compared to 13% where no radiotherapy was given;  $p = NS$ ).

One retrospective case series (Cordeiro *et al.* 2004) studied patients treated with immediate tissue expander/implant reconstruction and found the rate of implant removal due to complications to be 7%, and the rate of capsular contracture (Baker grade II-IV) to be 53%. Radiotherapy was associated with implant removal (11% where radiotherapy was given compared to 6% where no radiotherapy was given;  $p < 0.0001$ ) and with capsular contracture (67% where radiotherapy was given compared to 40% where no radiotherapy was given;  $p = 0.006$ ).

One retrospective case series (Henriksen *et al.* 2005) of predominantly delayed implant reconstructions performed with prostheses found the overall crude rate of any adverse event to be 31%, with the incident rate per 1000 patient months being 23%. These data were from initial reconstructions, rather than second procedures (i.e. either planned, or arising from complications).

One retrospective case series (Rey *et al.* 2005) provided data for early and late complications in the first postoperative year in subgroups of patients who underwent immediate reconstruction and either conventional chemotherapy ( $n=67$ ), or high dose chemotherapy ( $n=23$ ). In the larger series of 105 patients, 72% received adjuvant radiotherapy. The crude rate of early complications in patients treated with reconstruction was 2%, and late complications, 22%. Crude rates of capsular contracture were 22% (high dose chemotherapy) and 16% (conventional chemotherapy);  $p=0.51$ .

One retrospective case series (Vandeweyer *et al.* 2003) examined complications in patients treated with immediate expander reconstruction, with and without adjuvant chemotherapy. The crude rate of short term complications in all patients was 13%. Total complications occurred in 25% of patients in the chemotherapy group and in 8% of patients in the control group;  $p = 0.04$ . Complications warranting implant removal occurred in 11% of the chemotherapy group and 2% of the control group;  $p = 0.0084$ . There was no statistically significant difference between groups in the distribution of capsular contracture grade ( $p=1$ ; Fisher's exact test); 70% of patients in the chemotherapy group and 63% of patients in the no chemotherapy group had capsular contracture of grade I.

One retrospective case series (Woerdeman *et al.* 2006) found the crude rate of complications in patients treated with immediate expander/implant reconstruction to be 33%. The crude rate of severe complications leading to implant loss was 14%. In univariate analysis only age and unilateral surgery were statistically significant risk factors for short-term complications. The only statistically significant risk factors for serious complication resulting in loss of implant were being treated by a resident plastic surgeon and a history prior to mastectomy of breast conserving surgery and RT.

One prospective case series (Sandelin *et al.* 2004) found the crude rate of complications occurring within 30 days of surgery following immediate reconstruction to be 11%.

### **Delay to adjuvant therapy**

No reliable evidence was identified on whether immediate breast reconstruction following mastectomy delays the start of adjuvant chemotherapy or radiotherapy. Whilst a minority of observational studies included in an expert review (Taylor & Kumar 2005) indicated that such

delays occur after immediate reconstruction, the review's authors concluded that the evidence was inconclusive.

One expert review (Taylor and Kumar 2005) found that in nine observational studies there was no difference in the time to onset of chemotherapy between patients who underwent mastectomy and immediate reconstruction versus mastectomy alone. However in the same review two observational studies were suggestive of a delay in starting chemotherapy arising from post-operative complications following immediate reconstruction (Taylor and Kumar 2005). A higher quality systematic review (Fischbacher 2002) found that the evidence on whether immediate reconstruction delays chemotherapy is inconclusive.

One retrospective comparative study (Gouy *et al.* 2005) found no statistically significant difference in the mean interval from surgery to starting adjuvant chemotherapy between patients who received immediate reconstruction (26 days) and those who received delayed reconstruction (23 days);  $p=0.11$ . There was also no statistically significant difference in the interval to radiotherapy (87 and 81 days respectively;  $p=0.22$ ). There was also no difference in mean interval between surgery and onset of adjuvant treatment according to the type of immediate reconstruction performed:

One retrospective comparative study (Taylor & Kumar 2005) examined whether immediate breast reconstruction had an impact on chemotherapy in terms of dose given, need for supportive treatment and delays in commencing/continuing chemotherapy. The mean time from surgery to chemotherapy initiation was similar between groups as follows:

Mastectomy: 38 days

Immediate reconstruction: 36 days

The most commonly recorded cause of a delay in starting chemotherapy of > 40 days was incomplete wound healing, which occurred in 41% in patients treated with TRAM reconstruction and 4% of patients treated with mastectomy without reconstruction. The proportion of patients treated with full intended dose of chemotherapy was also similar between groups, as follows:

Mastectomy: 97%

Immediate reconstruction: 95%

One retrospective comparative study (Wilson *et al.* 2004) assessed whether immediate breast reconstruction following mastectomy leads to a delay in the delivery of chemotherapy. The median time from surgery to the start of chemotherapy was similar between groups: 29 (range 17-55) days in the immediate reconstruction group and 28 (range 16-52) days in the mastectomy alone group.

A retrospective case series (Rey *et al.* 2005) studied whether high dose chemotherapy is delayed by immediate breast reconstruction. There was no statistically significant difference in the interval from surgery to the start of high dose chemotherapy between patients treated with immediate reconstruction (54 days) and those treated with mastectomy without reconstruction, (60 days);  $p= 0.13$ .

### **Recurrence/survival**

No reliable evidence was identified to suggest that recurrence or survival differs in patients treated with immediate reconstruction compared to those who receive delayed reconstruction.

In one systematic review (Fischbacher *et al.* 2002) and one expert review (Taylor *et al.* 2005), observational studies reported no difference in recurrence and survival following mastectomy with immediate reconstruction compared to mastectomy with no reconstruction. In the systematic review (Fischbacher *et al.* 2002) one study reported a lower risk of recurrence in women who had immediate reconstruction, but did not adjust for baseline risk. The authors concluded that the evidence was insufficient (Fischbacher *et al.* 2002). One expert review (Taylor *et al.* 2005), summarised the rate of local recurrence in 19 studies of patients treated with mastectomy and immediate reconstruction with a median value of 5% (range 0-15%). The rate of distant metastasis in 16 studies of likewise-treated patients had median value 10.5% (range 2-39%).

Seven subsequently published observational studies report data on recurrence and survival following, in the majority of cases, immediate reconstruction or delayed reconstruction, or both (Table).

Updated 2018

**Table: recurrence and survival outcomes reported in observational studies (published subsequent to reviews by (Fischbacher *et al.* 2002) and (Taylor *et al.* 2005)**

Study & reconstruction timing	Reconstruction type	Follow-up	Recurrence outcome	Survival outcome
(Gouy <i>et al.</i> 2005)  Immediate vs. delayed	Mixed: Implant, Expander, TRAM, Latissimus dorsi	5-year and 10-year outcomes reported	5-year estimated local recurrence-free survival: Immediate reconstruction: 89% Mastectomy alone: 90% Delayed reconstruction: 93%; p=NS	10-year estimated distant disease-free survival: Immediate reconstruction: 48% Mastectomy alone: 43% Delayed reconstruction: 64%; p=0.04
(Drucker-Zertuche & Robles-Vidal 2007)  Immediate	Mixed: TRAM flap, TEIR, Latissimus dorsi flap + implant	Mean 48 months (range 10-92 months)	Crude rates: Distant: 3/105=2.9% Loco-regional + distant: 1/105=1.0%	None
(Sandelin <i>et al.</i> 2004)  Immediate	Mixed: Permanent prosthesis, expander, bilateral free TRAM, free TRAM, pedicled free TRAM	Minimum 5 years	Local recurrence: Crude rate: 13/203 = 6.4%	Deaths due to breast cancer: Crude rate: 31/203 = 15%
Henriksen, 2005 7713 /id}  Delayed	Mixed: implant, or implant + autologous tissue	Initial implantation: mean 23 months, range 3-56 months;  Subsequent implantation: mean 24 months, range 4-52 months.	Local recurrence: 1. Initial implantation: Crude rate: 1.7% Incidence rate per 1000 person-months: 1.1  2. Subsequent implantation: Crude rate 0.3% Incidence rate per 1000 person-months: 0.2	None
(Knottenbelt <i>et</i>	Mixed: Subpectoral	Minimum 60	Local recurrence	Disease-free

Study & reconstruction timing	Reconstruction type	Follow-up	Recurrence outcome	Survival outcome
<i>al.</i> 2004) Immediate	tissue expander, TRAM flap, or permanent implant	months	(crude rate out of all treated breasts at risk): 1/58 = 1.7%  Distant metastasis (crude rate out of all treated breasts at risk): 13/58 = 22.4% (includes 1 patient with local recurrence also)	survival at 5 years: 93%  Deaths with metastatic disease: 9/58 = 15.5%
(Mustonen <i>et al.</i> 2005) Immediate	Mixed, by group: 1. Wide local excision and latissimus dorsi miniflap; 2. Skin sparing mastectomy and TRAM or latissimus dorsi flap; 3. Subcutaneous mastectomy and TRAM or latissimus dorsi flap	Mean 3.6 years.	Recurrences by mastectomy-treated groups: Skin sparing mastectomy and TRAM or latissimus dorsi flap (n=22): Local: 2 Regional: 0 Distant: 3  Subcutaneous mastectomy and TRAM or latissimus dorsi flap (n=34): Local: 3 Regional: 1 Distant: 0  Difference across groups: p=NS	Estimated 5-year overall survival (all patients): 88%  Estimated 5-year disease-free survival (all patients): 80%
(Woerdeman <i>et al.</i> 2006) Immediate	Mixed: permanent implant or tissue expander	Prophylactic mastectomy subgroup: mean 70 months, range 52-91 months.	Prophylactic mastectomy: zero events  Curative intent subgroup: local-regional	Prophylactic mastectomy: zero events  Curative intent subgroup: Distant

Study & reconstruction timing	Reconstruction type	Follow-up	Recurrence outcome	Survival outcome
		Curative intent subgroup: mean 73 months, range 53-171 months	recurrence, crude rate: 2/85=2.4%	metastasis, crude rate: 5/85=5.9%  Estimated actuarial 5-year overall survival rate in patients treated with curative intent: 96%

Updated 2018

### **Effect on type of procedure offered**

Evidence from a single retrospective study from the UK suggests that the use of immediate reconstruction increased over the period 1997-1999, and also reconstruction with autologous tissue. The proportion of patients who receive immediate autologous tissue reconstruction in whom the need for radiotherapy is anticipated changed little over time in this study: from 88% to 100%. However the data may not reflect practice today, nor variation that occurs across centres in the UK.

One retrospective case series (Hussien *et al.* 2004) studied patients treated in the UK who underwent immediate breast reconstruction with either tissue expander or autologous tissue between two time periods; January 1997 to March 1998 and March 1998 to June 1999. The study found that there was an increase in the use of immediate reconstruction, in the later period studied. Also the proportion of patients who underwent immediate reconstruction with autologous tissue alone increased in the second period relative to the first period (49% and 29% respectively,  $p=0.0004$ ). The requirement for RT by treatment period was as follows:

Jan 97-Mar 98: 10 (24%)

Apr 98-Jun 99: 23 (29%)

In the first period autologous immediate reconstruction was performed in all 5 patients for whom RT was expected; 5 patients who unexpectedly received RT had undergone immediate implant reconstruction. In the second period 15/17 patients for whom RT was expected underwent immediate autologous reconstruction; 6 patients who unexpectedly received RT had undergone immediate implant reconstruction.

### **Patient satisfaction**

Evidence from observational studies suggests that in general, patients are satisfied with their reconstructed breasts following either immediate reconstruction, or delayed reconstruction. However some patients are not satisfied with their reconstructions and the impact of this is not further explored by the identified studies (Tykka *et al.* 2002; Ascherman *et al.* 2006; Cordeiro *et al.* 2004; Vandeweyer *et al.* 2003).

A prospective case series study (Tykka *et al.* 2002) evaluated patient satisfaction following delayed breast reconstruction with autologous tissue. Patient satisfaction with general outcome of the operation at 6 months post-operatively was as follows:

Very good: 45%

Quite good: 48%

Quite poor: 5%

Very poor: 0%

The cosmetic outcome at 6 months against patients' preoperative expectations was as follows:

Much better than expected: 17%

Better than expected: 42%

As expected: 27%

Poorer than expected: 8%

Much poorer than expected: 3%

The patient-reported extent to which surgical scarring was a disturbance at 6 months post-operatively was as follows:

Very much: 0%

To some extent: 10%  
Slightly disturbed: 60%  
Not at all: 27%

The most commonly cited benefits of the delayed reconstruction were 'a new breast of one's own', 'no need for external prosthesis' and 'feeling whole'. The most commonly reported drawback of the reconstructions were 'difficult operation' and 'abdominal operation' (Tykka *et al.* 2002).

One retrospective case series (Ascherman *et al.* 2006) measured patients satisfaction following immediate tissue expander/implant reconstruction using a three-point scale: 1=dissatisfied, 2=partially satisfied, 3=fully satisfied. Mean score was 2.4 in patients who in addition received RT compared with 2.7 for patients who received no RT (p=NS).

One retrospective case series (Cordeiro *et al.* 2004) found that following immediate reconstruction tissue expander/implant, the proportion of patients who were satisfied with their reconstructions was 67% who received in addition radiotherapy versus 88% in patients who received no radiotherapy; p=0.004

One retrospective case series study (Vandeweyer *et al.* 2003) found that following immediate expander reconstruction, there was no statistically significant difference in the proportion of patients who were fully satisfied with the cosmetic result between patients who received adjuvant chemotherapy (83%) compared with patients who did not receive chemotherapy (88%; p=NS).

### **Patient preference**

Very little direct evidence for women's preference for immediate versus delayed breast reconstruction was identified. One study with limited applicability is reported below, but it is likely to be of little value in the light of indirect evidence with better applicability e.g. audits of uptake of immediate reconstruction or delayed reconstruction over time.

One prospective comparative study (Belouli *et al.* 2005) assessed the spontaneous (i.e. no prior education on breast cancer) preference of healthy women, half of whom were nurses, for either immediate or delayed breast reconstruction. The sample included no patients with breast cancer. Overall 66% of participants voted for breast reconstruction. Of these 21% voted for immediate reconstruction, 27% for delayed reconstruction and 52% gave no preference. The most common reason for preferring immediate reconstruction was a wish to undergo only one surgical procedure (56%) followed by a wish to avoid mutilation and altered body image (44%). The most common reasons expressed against immediate reconstruction was a fear that it may mask local recurrence (62%) and secondly, a need to come to terms with cancer illness (35%).

## Evidence Tables

Systematic review of combined study designs

Fischbacher . Immediate versus delayed breast reconstruction. STEER. 2[17]. 2002.

### Design

Design: Systematic review of combined study designs (therapy), evidence level: 2-

Country: Various, setting: Secondary care

### Inclusion criteria

Controlled studies that compared immediate versus delayed reconstruction; or studies comparing immediate reconstruction with no reconstruction provided one of the following outcomes were reported:

- i) Psychological outcomes;
- ii) Delays to start of chemotherapy;
- iii) Recurrence and survival.

### Exclusion criteria

Uncontrolled studies;

Comparisons of cosmetic effects following immediate reconstruction versus no reconstruction;

Comparisons of surgical complications following immediate reconstruction versus no reconstruction;

### Population

-

### Interventions

Aim: to summarise evidence on benefits and harms of immediate reconstruction compared with delayed reconstruction.

All studies included patients who underwent either prosthetic or autologous breast reconstruction following mastectomy for breast cancer.

### Outcomes

Psychological measures;

Patient satisfaction;

Cosmesis;

Surgical complications;

Delay to chemotherapy;

Recurrence and survival.

### Follow up

Details inconsistently reported.

## Results

### IMMEDIATE VERSUS DELAYED RECONSTRUCTION

#### Psychological outcomes

Three cohort studies found that immediate reconstruction reduced emotional distress and interference with sexual function and improved self esteem and body image compared with delayed reconstruction.

#### Patient satisfaction

One cohort study reported similar levels of patient satisfaction in immediate reconstruction and delayed reconstruction groups after controlling for confounding factors.

#### Cosmetic effects

Two cohort studies reported that satisfactory cosmetic results were slightly more common in women who had immediate reconstruction than women who had delayed reconstruction. However, the confidence intervals for the differences were wide, included the null hypothesis value of no difference and did not rule out a possible effect in favour of delayed reconstruction.

#### Operative complications

Three cohort studies found that complication rates were similar for immediate and delayed reconstruction. However, the confidence intervals included the null hypothesis value of no difference and were consistent with possibly large advantages for either procedure. The fourth, a larger prospective cohort study, which accounted for confounding factors, found that complications were more common with immediate reconstruction.

### IMMEDIATE VERSUS NO RECONSTRUCTION

#### Psychological outcomes

The randomised controlled trial found that immediate reconstruction reduced psychiatric morbidity at three months compared with no reconstruction (but with expectation of reconstruction at a later date): Absolute risk for score  $\geq 12$  on General Health Questionnaire at 3 months 7% with immediate reconstruction versus 36% with no reconstruction (Absolute risk reduction 29%, 95% CI 7% to 48%). However, this difference was not statistically significant after adjustment for baseline differences in psychological morbidity. The unadjusted difference was much smaller at 12 months: Absolute risk for score  $\geq 12$  on General Health Questionnaire at 12 months 4% with immediate reconstruction versus 10% with no reconstruction (Absolute risk reduction 7%, 95% CI -9% to 23%). There was no evidence for an increased likelihood of psychiatric illness diagnosed by psychiatrist: Absolute risk at 3 months: 7% with immediate reconstruction versus 19% with no reconstruction (Absolute risk reduction 13%, 95% CI -5% to 30%); at 12 months 0% with immediate reconstruction versus 3% with no reconstruction (difference 3%, 95% CI -8% to 17%)

### Delay to chemotherapy

Three cohort studies examined delay in chemotherapy resulting from immediate reconstruction versus no reconstruction. The first study reported a longer delay to the start of chemotherapy with immediate reconstruction than with no reconstruction [median interval to postoperative chemotherapy 35 days (range 5 to 91 days) with immediate reconstruction v 21 days (range 8 to 145 days) with no reconstruction ( $p = 0.05$ )]. The second study reported the opposite [mean interval to postoperative chemotherapy 41 days (range 14 to 131 days) with immediate reconstruction v 53 days (range 1 to 215 days) with no reconstruction ( $p = 0.04$ , Mann-Whitney test)]. The third reported no difference [median interval to postoperative chemotherapy 44 days (range 18 to 82 days) with immediate reconstruction v 45 days (range 11 to 81 days) with no reconstruction]. Time to chemotherapy differed substantially among studies, suggesting that factors other than reconstructive procedure may have contributed to the delay.

### Cancer recurrence and survival

Four cohort studies reported that recurrence and survival were similar for immediate and no reconstruction. One study reported a lower risk of recurrence in women who had immediate reconstruction, but did not adjust for baseline risk. None of the studies provided confidence intervals for the difference.

### AUTHORS' CONCLUSIONS

One randomised controlled trial was identified. The other studies were cohort studies with comparison groups that differed by other characteristics. Studies of this design are intrinsically susceptible to confounding and are therefore inconclusive.

### Psychological outcomes

There is limited evidence from cohort studies and one randomised controlled trial that immediate reconstruction improves psychological outcomes compared with delayed reconstruction.

### Patient satisfaction

One large cohort study found limited evidence that patient satisfaction was similar after immediate and delayed reconstruction.

### Cosmetic effects

There is insufficient evidence about cosmetic effects of immediate versus delayed reconstruction.

### Operative complications

One cohort study that attempted to control for confounding provided weak evidence that complications may be more common with immediate reconstruction.

### Delay to chemotherapy

There is inconclusive evidence about effects of immediate versus delayed reconstruction on delay to start of chemotherapy.

### Cancer recurrence and survival

There is insufficient evidence about effects on recurrence and survival of immediate versus delayed reconstruction.

### General comments

18 primary studies of either prosthesis/expander reconstruction or autologous reconstruction were included, dating to 2002 and representing an estimated minimum of 3000 patients:

Systematic reviews (1)

RCT (1)

Observational studies (referred to as 'cohorts'; most likely to be case series) (16)

Although the time period of the literature studied by this review and that of Javaid et al. (2006) is similar, no primary study appears in both reviews. The review by Javais et al. (2006) was restricted to autologous reconstruction. In contrast to Javais et al. (2006) this review has little emphasis on the relationship between timing of reconstruction and radiotherapy.

### Literature search:

Search date: July 2002. Primary sources: Medline 1966 to date; Embase 1980 to date; Cochrane Library Issue 2, 2002; Clinical Evidence Issue 7; Centre for Reviews and Dissemination, University of York, UK (comprising Database of Abstracts of Reviews of Effectiveness, UK Health Technology Assessment Database, NHS economic evaluation database, UK).

Assessment of study quality is evident and presented narratively. The observational studies are referred to as unreliable and subject to confounding: women treated with immediate reconstruction tended to be younger and differed with regard to tumour stage, adjuvant therapy, smoking and psychological state at the time of the operation. Many studies did not examine these confounding factors. Only four studies controlled for baseline differences between groups compared. One study matched on prognostic factors and one presented results stratified by tumour stage. In no study were outcomes assessed by individuals who were blind to treatment group.

Javaid, Song, Leinster, Dickson & James . Radiation effects on the cosmetic outcomes of immediate and delayed autologous breast reconstruction: an argument about timing. [Review] [21 refs]. Journal of Plastic., Reconstructive.& Aesthetic Surgery: JPRAS. 59[1], 16-26. 2006.

## **Design**

Design: Systematic review of combined study designs (therapy), evidence level: 2-

Country: Various, setting: Secondary care

## **Inclusion criteria**

Primary studies as follows:

>20 subjects;

Of patients who received autologous reconstruction following any type of mastectomy and who received radiotherapy either before or after their reconstruction;

Report cosmetic outcomes;

Included patients with failed previous breast conserving surgery plus RT.

## **Exclusion criteria**

Studies of patients treated with breast conserving surgery without RT;

Studies of patients who received only prosthetic reconstruction.

## **Population**

number of patients = 980.

## **Interventions**

Aim: to review evidence on the optimal timing of RT in relation to autologous reconstruction i.e. to answer the question, 'Should autologous reconstruction be delayed if there is a probability of RT in the post-operative period?'

Patients underwent mastectomy and either:

i) immediate autologous reconstruction followed by RT;

ii) delayed autologous reconstruction after RT.

The type of autologous reconstruction most commonly performed was the TRAM flap.

## **Outcomes**

1. Cosmesis (appearance, volume and symmetry);
2. Immediate complications (e.g. wound complications, infection, fat necrosis, partial or total flap loss);
3. Delayed complications (e.g. fibrosis, contracture).

## **Follow up**

Range of reported means/medians: 18 months-4 years

## Results

### STUDY CHARACTERISTICS

10 studies met the inclusion criteria (with a total of 980 participants), of which only one was prospective. 9/10 studies were retrospective reviews of medical notes and pre/post-operative photographs. No studies performed power calculations or provided confidence intervals of results. Only 5 studies described objective methods for assessment of cosmesis and only one of these studies used a blind, independent assessment to minimise bias.

### RESULTS

Data on the timing, cosmetic outcome and complication rates for autologous breast reconstruction in patients who previously or subsequently undergo breast or chest wall RT are limited.

Two studies in this review which recommend delaying the breast reconstruction until after RT provide strong statistical support in favour of their conclusion:

1) Tran et al. (2003): Late complications in immediate reconstruction group 87.5% vs. 8.6% in delayed reconstruction group;  $p < 0.0001$ .

2) Rogers et al. (2002):

Fat necrosis: 'RT after reconstruction' group: 23% vs. 0% control group (no RT);  $p = 0.006$

Fibrosis: 'RT after reconstruction' group: 56% vs. control group (no RT): 0%;  $p < 0.0001$

Flap contracture: 'RT after reconstruction' group: 16% vs. control group (no RT): 0%;  $p = 0.023$

Three other studies in which RT was given before delayed reconstruction found no statistically significant adverse cosmetic effect although there was a trend for a higher rate of complications where RT preceded reconstruction.

Studies that favoured immediate reconstruction as the cosmetically acceptable option with RT performed afterwards lacked an inter-group comparison and statistical support for their recommendations.

Studies that directly compared immediate reconstruction (with RT later) versus delayed reconstruction (with RT before) suggest that fibrosis and contracture leading to adverse cosmetic outcome is more common if RT is used after reconstruction.

Adverse effects of radiotherapy:

The main adverse effects reported were fat necrosis, delayed wound healing, fibrosis resulting in contracture, loss of volume and distortion of the breast.

Early surgical complications did not appear to vary according to whether preoperative or post-operative RT was given, with the exception of fat necrosis in some studies. However two studies reported a trend towards higher rate of early complications associated with delayed breast

reconstruction compared with immediate reconstruction.

Authors conclude that the available data suggest a case for delayed rather than immediate TRAM reconstruction in patients who need post-operative RT. Where the need for RT is not known before surgery, patients should be counselled about the risks of post-operative RT to the cosmetic result.

### **General comments**

Studies included date up to 2002.

Authors report that the adverse effects of RT following reconstruction with breast prostheses/expanders are well established and are therefore not part of this review.

'Immediate' reconstruction refers to before RT.

Literature search summarised as follows:

Medline, EMBASE, CINAHL, Psych INFO, Cochrane Specialist Register of trials with terms 'breast reconstruction' and 'radiation/radiotherapy'. Within the identified abstracts a search was performed for 'immediate' and 'delayed' reconstruction, 'radiotherapy', 'radiation therapy' and 'autologous reconstruction'.

Study quality appraisal evident, presented narratively. Results tabulated and discussed narratively.

The authors acknowledge that in general the included studies are few, underpowered and retrospective, lacking objective assessment of cosmetic outcomes. There is high heterogeneity with regard to study design, RT dose and results. For these reasons interpret findings with caution.

## Review

Taylor, Horgan & Dodwell . Oncological aspects of breast reconstruction. [Review] [84 refs]. Breast 14[2], 118-130. 2005.

### **Design**

Design: Review (therapy), evidence level: 4

Country: Various, setting: Secondary care

### **Inclusion criteria**

Primary studies of breast reconstruction following mastectomy to treat patients with breast cancer where:

- i) the majority of patients were treated after 1980;
- ii) median/mean follow up period >1 year in the case of assessment of recurrence.

### **Exclusion criteria**

None stated.

### **Population**

-

### **Interventions**

Aim: to review evidence on the impact of breast reconstruction on disease-related outcomes and its interaction with oncological interventions.

Patients were treated according to primary studies; there was much variation but interventions commonly included mastectomy, chemotherapy or radiotherapy and reconstruction (implant and/or autologous; either before or after adjuvant therapy).

### **Outcomes**

Recurrence risk;

Delay in the start of adjuvant therapy;

Interactions between radiotherapy and reconstruction.

### **Follow up**

Mean 57 months; median 49 months (based on a sub-group of 19 primary studies that reported recurrence rates).

In general short follow-up is a feature of the primary studies.

### **Results**

#### **RECURRENCE**

Two observational studies provided direct comparisons of mastectomy and immediate reconstruction compared to mastectomy alone and found, at a follow up of 3 years or more, no difference in recurrence-free survival between the treatment groups.

Further 'single group' observational studies:

Local recurrence after mastectomy and immediate breast reconstruction (19 studies; 2305 patients in total; median follow-up 49 months[range 26-156 months]):

Mean: 5.4%

Median: 5%

Range: 0-15%

Distant recurrence (or, in one study, deaths from disseminated disease) after mastectomy and immediate breast reconstruction (16 studies; 1759 patients in total; median follow-up 49 months[range 26-156 months]):

Mean: 12.5%

Median: 10.5%

Range: 2-39%

Author reports that given the limitations of these studies (see 'comments', their data suggest that there is no obvious increased risk of local/distant recurrence after reconstruction.

#### DELAY IN STARTING ADJUVANT THERAPY

(15 studies; 587 patients in total; reconstruction type: various implant/expander or autologous)

One observational study recorded delays of greater than 1 month in two patients of 23 requiring chemotherapy amongst 46 patients treated with immediate reconstruction. A second study reported that seven out of 28 patients who had immediate TRAM flap reconstruction experienced delayed chemotherapy due to postoperative complications.

Nine other studies that compared time to onset of chemotherapy after immediate reconstruction with control group treated by mastectomy alone revealed no significant difference; chemotherapy commenced on average 41-53 days after operation.

Rate of early postoperative wound complications after immediate reconstruction: 8%-49% (5 studies).

Three observational studies found that in patients who had immediate reconstruction chemotherapy dose was maintained at similar rates to that of patients who underwent mastectomy alone.

#### RADIOTHERAPY AND RECONSTRUCTION

1. RT immediately after mastectomy plus immediate reconstruction with implant or expander (11 small studies; 173 patients in total; median follow-up 31 months [range 19-43 months]):

Rate of capsular contraction:

Mean: 38%

Median: 33%

Range: 2.2%-73% Note: subgroups are so small that they do not permit reliable interpretation.

Cosmesis: (% 'good'/'excellent'): 3 studies report 60%, 7% and 54%, respectively, but subgroups are so small that they do not permit reliable interpretation. In one further study RT was associated with a lower cosmesis score; in one study the mean cosmesis score was 2.99 (scale 1-4); in one study 50% of patients were satisfied with the cosmetic result.

2. Chest wall RT after reconstruction with autologous tissue (predominantly TRAM; 4 studies; 111 patients in total; median follow-up: 28 months [range 19-53 months]):

Rate of flap tissue loss/necrosis:

Mean: 37%

Median: 44%

Range: 0%-59%

Cosmesis: (% 'good'/'excellent'): 2 studies report 90% and 17%, respectively, but subgroups are so small that they do not permit reliable interpretation. In one further study 7/10 patients had a worse cosmetic result after RT.

3. Delayed reconstruction with implant, performed after RT (6 small studies; 116 patients in total; median follow-up 31 months [range 28-46 months]):

Rate of capsular contraction:

Mean: 39%

Median: 35%

Range: 26%-60% Note: subgroups are so small that they do not permit reliable interpretation.

Cosmesis: (% 'good'/'excellent'): 1 study reports 31% and in another study 45% of patients had an 'acceptable' cosmetic result, but subgroups are so small that they do not permit reliable interpretation. In one further study the mean cosmesis score was 2.9 (scale 1-4); in 1 study 50% of patients were satisfied with their cosmetic result.

4. Delayed autologous tissue reconstruction, performed after RT (6 studies; 399 patients in total; median follow-up 29 months [range 24-60 months]):

Rate of flap tissue loss/necrosis:

Mean: 17%

Median: 15%

Range: 5%-34%

Cosmesis: (% 'good'/'excellent'): 1 study reports 64%. In one further study the mean cosmesis score was 2.7 (scale 1-4).

### **General comments**

84 studies were included; identified through a MEDLINE search. Inclusion

criteria are very general and no explicit assessment is made of study quality; hence the grading as level 4 evidence.

Authors report that patients treated with immediate reconstruction tend to be younger patients with poorer prognostic factors, making adjuvant therapy more likely. Also the need for adjuvant therapy is often not realised until after definitive surgery (including after immediate reconstruction).

The authors describe the nature of the included studies, which have the following drawbacks: small size, mostly single institution, retrospective, uncontrolled, short follow-up, high heterogeneity with regard to interventions.

The data on cosmesis are of particularly poor quality: inconsistently reported, methods of assessment unknown, based on very small patient groups, and the direction of the cosmesis scale (1-4) is not reported.

For the above reasons the quality of the evidence is poor and the findings should be interpreted cautiously.

Updated 2018

Prospective comparative study

Belouli, Wyss, Vetter, Meyer & Beer . Immediate or delayed breast reconstruction after mastectomy: What do women really want. European Journal of Plastic.Surgery 28[5], 331-336. 2005.

### **Design**

Design: Prospective comparative study (therapy), evidence level: 3  
Country: Switzerland, setting: Community

### **Inclusion criteria**

200 sampled healthy women, 100 of whom were non-surgical nurses.

### **Exclusion criteria**

Age < 20 years;  
Age > 70 years

### **Population**

number of patients = 200, age range 20 to 69 years.

### **Interventions**

Aim: to assess the preference of healthy women for either immediate or delayed breast reconstruction, and in the case of declining reconstruction, examining reasons why.

Two groups were prospectively defined:

Group 1: Randomly chosen healthy women (n=100)

Group 2: Non-surgical hospital nurses (n=100)

No information was provided about breast reconstruction. Women were interviewed to obtain their spontaneous preference for or against breast reconstruction and the timing: immediate or delayed, and the type: autologous, implant or both.

### **Outcomes**

Preferences expressed re: reconstruction;

Self esteem (Visual analogue scale; range 1-5; 5 representing highest self esteem);

Significance of the breast from an aesthetic viewpoint (Visual analogue scale; range 1-5; 5 representing highest aesthetic significance).

### **Follow up**

Not relevant

### **Results**

Overall 66% of participants voted for breast reconstruction (group 1: 61%; group 2: 71%).

Overall, a preference for reconstructive surgery correlated with younger age (Spearman  $r=0.56$ ,  $p<0.01$ ), higher education (Spearman  $r=0.25$ ,  $p<0.01$ ), higher self esteem (Spearman  $r=0.34$ ,  $p<0.01$ ) and high aesthetic importance of the breast (Spearman  $r=0.62$ ,  $p<0.01$ ).

Overall 21% of participants voted for immediate reconstruction, 27% delayed reconstruction and 52% gave no preference.

The most common reason for preference for immediate reconstruction was a wish to undergo only one surgical procedure (56%) followed by a wish to avoid mutilation and altered body image (44%).

The most common reasons expressed against immediate reconstruction was a fear that it may mask local recurrence (62%) and secondly, a need to come to terms with cancer illness (35%).

For the type of reconstruction, 40% of participants who voted for reconstruction preferred the use of autologous tissue, 14% the use of implants and 23% a combined technique of both methods; 23% could not reach a decision spontaneously.

A preference for autologous tissue reconstruction was due to aversion of foreign bodies (especially silicone) in 87% of participants. Reasons provided for preferring implant reconstruction were confidence of better results (63%), less scarring (21%) and less complex surgery (5%).

### **General comments**

The nurses (group 1) were younger on average (mean age 35 years) than the sample of women (mean age 43 years);  $p<0.01$ , Mann-Whitney test.

100 % of the nurses (group 1) were classified as 'highly educated' compared to 30% of the sample of women ( $p$  NS).

The study provides no details of how participants were sampled, nor any adequate details of why healthy women including 100 nurses were sampled: probably a convenience sample, with unknown applicability to this question.

Only general information is provided re: the interviews: it is not possible to tell whether some responses were open-ended or categorical.

Responses are reportedly spontaneous, with a statement that no information was given. There is probably a differential between the two groups with regard to prior knowledge of breast cancer and surgery. Also spontaneous results may be less valid than if some information had been given e.g. preference between different types of reconstruction. There is high likelihood that context

is lost since no patients with breast cancer were sampled.

Updated 2018

## Retrospective comparative study

Anderson, Hanlon, Fowble, McNeeley & Freedman . Low complication rates are achievable after postmastectomy breast reconstruction and radiation therapy. *Int.J.Radiat.Oncol.Biol.Phys.* 59[4], 1080-1087. 2004.

### Design

Design: Retrospective comparative study (therapy), evidence level: 3  
Country: USA, setting: Secondary care

### Inclusion criteria

85 patients who were treated for breast cancer with modified radical mastectomy, breast reconstruction (immediate or delayed; tissue expander/implant or autologous) and radiotherapy (either before or after reconstruction).

### Exclusion criteria

None reported

### Population

number of patients = 85, age range 29 to 70 years, median age = 45 years.

### Interventions

Aim: to report the complication rate and cosmetic result in patients who receive mastectomy and breast reconstruction and RT, and to identify factors that may be predictive of adverse outcome. Study was performed by a retrospective chart review.

All patients underwent modified radical mastectomy and breast reconstruction with either tissue expander/implant (50 patients) or TRAM flap (35 patients).

70 patients received immediate reconstruction followed by RT (median interval from surgery to RT: 7 months):

TEI: n=44

TRAM: n= 26

15 patients received RT then delayed reconstruction (median interval from RT to reconstruction: 13 months):

TEI: n=6

TRAM: n=9

RT dose: 50-50.4 Gy (plus a 10 Gy scar boost in 4 patients). RT was given with a bolus every-other day, to increase the dose to the surface tissue: a custom wax bolus was used in 44 patients (52%) and a standard bolus was used in 41 patients (48%).

Adjuvant medical therapy:  
78 patients (92%) received chemotherapy;  
55 patients (65%) received tamoxifen.

### **Outcomes**

Complications:

Actuarial incidence of complications dated from either the time of initiation of RT (immediate reconstruction) or from the time of reconstruction (delayed reconstruction), using Kaplan-Meier method; log-rank test.

Major complications: requiring corrective surgery or loss of the reconstruction.

Minor complications: infection, chest wall fibrosis, fat necrosis, contracture.

Cosmesis:

Originally classified using a four category Harvard scale: 'Excellent' (same as opposite breast), 'good' (minimal but identifiable effects of RT visible), 'fair' (significant effects of RT seen on treated breast), and 'poor' (severe tissue sequelae secondary to RT). In this study cosmesis was binary:

'excellent/good' or 'fair/poor'. Differences were examined using Fisher's exact test.

Potentially predictive factors for adverse outcome:

Factors explored were smoking history, type of reconstruction, type of bolus used, use of RT boost, sequencing of reconstruction and use of systemic therapy (using univariate analysis; log-rank test).

### **Follow up**

Median 28 months (range 1-153 months)

### **Results**

Complications:

3-year actuarial rate of complications by reconstruction type:

TEI: 19%

TRAM: 27%;  $p=0.16$ , log-rank test.

3-year actuarial rate of major complications by reconstruction type:

TEI: 5%

TRAM: 0%;  $p=0.21$ , log-rank test.

3-year actuarial rate of minor complications by reconstruction type:

TEI: 14%

TRAM: 27%;  $p=0.04$ , log-rank test.

Predictive factors for complications:

Of all the factors examined in the univariate analysis, only bolus type was predictive of complications. Rate of complications by bolus type:

Custom: 9%

Standard: 24%;  $p=0.05$ , log-rank test.

Cosmesis:

'Excellent/good': 85%

'Fair/poor': 15%

None of the factors examined were predictive of cosmetic outcome.

Sequencing of RT/reconstruction was neither predictive of complications nor cosmetic outcome.

### **General comments**

The aim of the custom wax bolus was to minimise air gaps over the skin, hence increasing homogeneity of dose.

'Delayed' reconstruction (i.e. after RT) is a small sub-group (n=15), of which 9 patients (60%) underwent TRAM reconstruction c.f. immediate reconstruction, where 26/70=37% of patients underwent TRAM reconstruction. Therefore the influence of sequencing of reconstruction and RT may be confounded by reconstruction type. The univariate analyses would not account for any confounding factors.

Updated 2018

Gouy, Rouzier, Missana, Atallah, Youssef & Barreau-Pouhaer . Immediate reconstruction after neoadjuvant chemotherapy: effect on adjuvant treatment starting and survival. Ann.Surg.Oncol. 12[2], 161-166. 2005.

### **Design**

Design: Retrospective comparative study (therapy), evidence level: 3  
Country: France, setting: Secondary care

### **Inclusion criteria**

Patients treated within the years 1985-1995 for invasive breast cancer of tumour stage T2-T4a-c.  
The indication for mastectomy was tumour size  $\geq 3$ cm and bifocal tumours.

Mean age:

Mastectomy: 51 years

Immediate reconstruction: 44 years

Delayed reconstruction: 46 years

Recorded disease characteristics:

Tumour stage:

T2: 123

T3: 101

T4: 37

Clinical lymph node stage:

N0: 103

N1/N2: 148

Grade:

I: 11

II: 157

III: 65

### **Exclusion criteria**

Patients who underwent lumpectomy.

### **Population**

number of patients = 261.

### **Interventions**

Aim: To compare the delay between surgery and adjuvant therapy and also local control and survival, in patients treated with neoadjuvant chemotherapy and mastectomy, with or without reconstruction.

Three treatment groups were defined:

1. Mastectomy (n=181): underwent mastectomy without reconstruction

2. Immediate reconstruction (n=48): underwent mastectomy plus immediate reconstruction as follows:

Implant: 29

Expander: 3

TRAM: 7

Latissimus: 9

3. Delayed reconstruction (n=32) underwent mastectomy plus delayed reconstruction as follows:

Implant: 6

Expander: 1

TRAM: 15

Latissimus: 10

All patients received neoadjuvant anthracycline-based chemotherapy in either three (90 patients) or four (171 patients) cycles, using four regimens.

250 patients received adjuvant RT: 45 Gy.

Tamoxifen was given to all post-menopausal patients and pre-menopausal patients with ER+ tumours.

### **Outcomes**

Interval from reconstruction to commencement of adjuvant therapy;

Local recurrence-free survival and distant disease-free survival;

Need for further cosmetic surgery;

Capsular contracture (assessed using Spear and Baker's classification).

### **Follow up**

Paper reports 5-year and 10-year recurrence outcomes.

### **Results**

Mean interval between surgery and onset of adjuvant treatment (days):

Chemotherapy

Immediate reconstruction: 26

Mastectomy (includes delayed reconstruction): 23; p=0.11

RT

Immediate reconstruction: 87

Mastectomy (includes delayed reconstruction): 81; p=0.22

There was also no difference in mean interval between surgery and onset of adjuvant treatment (days) according to the type of immediate reconstruction

performed:

Chemotherapy

Implant/expander: 25

Autologous: 28; p=0.23

RT

Implant/expander: 88

Autologous: 82; p=0.58

5-year estimated local recurrence-free survival:

Immediate reconstruction: 89%

Mastectomy: 90%

Delayed reconstruction: 93%; p=NS

10-year estimated distant disease-free survival:

Immediate reconstruction: 48%

Mastectomy: 43%

Delayed reconstruction: 64%; p=0.04

Need for further cosmetic surgery (implant removal, flap amelioration) within two years of reconstruction:

Immediate reconstruction: 50%

Delayed reconstruction: 50%

64% of patients who underwent immediate reconstruction with an implant (with or without an autologous flap) developed a capsular contracture (Baker II-IV).

### **General comments**

37/181 = 20% of patients had stage T4 disease (i.e. population outside guideline scope).

The three groups were similar in terms of T stage, nodal status, histology, grade, ER status and chemotherapy regimen (statistically tested), although patients undergoing reconstruction were younger (mean 44 and 46 years; immediate and delayed reconstruction, respectively), than those who did not undergo reconstruction (mean 51 years; p<0.04). Patients who received immediate reconstruction were more likely to have four, rather than three courses of neoadjuvant chemotherapy (p<0.04), whereas clinical response was similar across groups. The immediate reconstruction group tended to receive implant reconstruction (60%) whereas the delayed reconstruction group tended to receive Latissimus dorsi flap reconstruction (p value flap versus implant: <0.001).

No definition is provided of 'delayed' reconstruction, which presumably means after adjuvant therapy.

Authors report that the apparent survival advantage in the delayed reconstruction group is likely to be due to the fact that patients with early metastatic events were not offered a delayed reconstruction.

Updated 2018

Mortenson, Schneider, Khatri, Stevenson, Whetzel, Sommerhaug, Goodnight & Bold . Immediate breast reconstruction after mastectomy increases wound complications: however, initiation of adjuvant chemotherapy is not delayed. Arch.Surg. 139[9], 988-991. 2004.

### **Design**

Design: Retrospective comparative study (therapy), evidence level: 3  
Country: USA, setting: Secondary care

### **Inclusion criteria**

128 women who underwent mastectomy for breast cancer between January 1995 and December 2002

### **Exclusion criteria**

Patients whose reconstructions involved a skin graft;  
Patients receiving chemotherapy for a non-breast cancer at the time of their mastectomy.

### **Population**

number of patients = 128.

### **Interventions**

Aim: to compare wound complications between patients treated with mastectomy versus patients treated with mastectomy plus immediate reconstruction, and to assess whether complications interfered with adjuvant chemotherapy.

Two groups were defined retrospectively:

Mastectomy (n=66)

Mastectomy and immediate breast reconstruction (n=62) with either tissue expander/implant (38/62 = 61%) or autologous tissue (latissimus dorsi or TRAM); including prophylactic antibiotics and closed suction drains. Where used, tissue expansion commenced in the third post-operative week and was completed over 6-8 weeks. This process was interrupted to administer unexpected RT, but was rarely interrupted to administer adjuvant chemotherapy.

### **Outcomes**

Minor complications: defined as any complication requiring antibiotics or debridement.

Major complications: those requiring re-operation, re-admission or delay in chemotherapy (from the scheduled date of commencement and owing to a surgical complication).

## Follow up

Mean 33 months (SD 20.8 months).

## Results

All complications by group n (mastectomies):

Mastectomy: 6/72 = 8.3%

Reconstruction: 17/76 = 22.3%;  $p=0.02$ , Fisher's exact test.

Major complications by group:

Mastectomy: 4/66 = 6%

Reconstruction: 11/62 = 18%

Minor complications by group:

Mastectomy: 2/66 = 3%

Reconstruction: 6/62 = 10%

Mean interval to initiation of chemotherapy (months):

Mastectomy (n=39): 1.54

Reconstruction (n=42): 1.70;  $p=0.43$ , Student's t test

Complications by treatment group in the subgroup of patients who underwent chemotherapy (n=81):

Mastectomy (n=39): 5%

Reconstruction (n=42): 24%;  $p=0.02$  Fisher's exact test

Complications by receipt of chemotherapy:

Chemotherapy: 12/81 = 15%

No chemotherapy: 9/47 = 19%;  $p=0.52$  Fisher's exact test

Complications arising during administration of chemotherapy by treatment group:

Mastectomy (72 unreconstructed mastectomies): 2 (3%)

Reconstruction (76 reconstructed mastectomies): 2 (3%);  $p=0.96$ , Fisher's exact test

## General comments

There are 20 more mastectomies than patients; reported as prophylactic mastectomies; presumably in the contralateral breast: some outcomes are reported for 148 mastectomies rather than 128 patients.

The reconstruction group was significantly younger (mean 48 years) than the mastectomy group (mean 59 years);  $p<0.001$ , Student's t test. Disease stage was equally distributed between groups except for stage III disease, which was more common in the mastectomy group (35%) than the reconstruction group (10%),  $p<0.001$ , Fisher's exact test. Women in the reconstruction group

were more likely to have received prophylactic mastectomy (23%) than those in the mastectomy group (10%);  $p=0.04$ , Fisher's exact test.

Updated 2018

Spear, Ducic, Low & Cuoco . The effect of radiation on pedicled TRAM flap breast reconstruction: outcomes and implications. [Review] [12 refs]. Plastic.& Reconstructive.Surgery 115[1], 84-95. 2005.

## Design

Design: Retrospective comparative study (therapy), evidence level: 3  
Country: USA, setting: Secondary care

## Inclusion criteria

150 patients who underwent 171 TRAM reconstructions within the years 1988 - 1999.

Distribution of active smokers:

1. TRAM only: 18%
2. TRAM after RT: 13%
3. TRAM before RT: 9%

There was no statistically significant difference in smoking history across groups.

Distribution of patients classes as overweight/obese (based on BMI):

1. TRAM only: 47%
2. TRAM after RT: 50%
3. TRAM before RT: 62%

There was no statistically significant difference in BMI group across groups.

25% of procedures were bilateral, with no statistically significant difference in laterality across groups.

## Exclusion criteria

None stated.

## Population

number of patients = 150, mean age = 47 years.

## Interventions

Aim: to compare adverse effects after TRAM flap breast reconstruction. Three groups of patients were defined retrospectively:

1. TRAM only (78 patients; 91 reconstructions)
2. TRAM after RT (38 patients; 42 reconstructions)
3. TRAM before RT(34 patients; 38 reconstructions)

Distribution of vascular delay procedures:

1. TRAM only: 6.6%
2. TRAM after RT: 11.9%; cf TRAM only,  $p=0.0003$
3. TRAM before RT: 10.5%; cf TRAM only,  $p=0.0003$

## Outcomes

Complications:

Infection

Haematoma (requiring surgery/drainage)

Seroma (requiring surgery/drainage)

Delayed wound healing (requiring surgical intervention)

Fat necrosis

Partial flap necrosis (not requiring surgery)

Total flap necrosis (requiring surgery)

Cosmesis (Assessed by 16 blinded, independent individuals and rated for each factor as 1=poor, 2=fair, 3=good and 4=excellent) with three factors:

i) Aesthetic outcome

ii) Symmetry

iii) Contracture

Also: presence/absence of hyperpigmentation

## Follow up

Not reported: outcomes are evaluable in the short term.

## Results

Cosmesis

	Aesthetic result (mean)	Symmetry (mean)	Hyperpigmentation (%)	Contracture (mean)
TRAM alone	3.77	3.72	0/24=0%	3.81
TRAM after RT	3.27	3.27	2/11=18.1%	3.81
TRAM before RT	2.76	2.78	10/23=43.4%	2.86
Statistics				
TRAM vs. TRAM after RT	P=0.021	P=0.03	P=0.09	P=0.03
TRAM vs. TRAM after RT	P=0.0001	P=0.0001	P=0.0002	P=0.0001
TRAM after RT vs. TRAM before RT	P=0.09	P=0.12	P=0.25	P=0.009

There was no statistically significant difference between patients who underwent TRAM after RT and those who underwent TRAM before RT with regard to aesthetic result, symmetry or hyperpigmentation. Mean contracture score was higher in patients who underwent TRAM after RT (3.81) than in

patients who underwent TRAM before RT (2.86),  $p=0.009$ .

Patients who received no RT had generally better cosmetic outcomes than patients in either RT-treated subgroup.

#### Complications

Overall rate of complications (% of no. TRAM flaps):

All patients:  $88/171=51.5\%$

TRAM only:  $45/91 = 49.5\%$

TRAM after RT:  $24/42 = 57.1\%$

TRAM before RT:  $19/38 = 50\%$

There were no statistically significant differences between groups for any of the complications variables.

#### General comments

Provides information on immediate and delayed reconstruction, based on timing prior to/post RT; author's description of 'delay' appears unrelated; concerning preparatory vascular surgery.

Good description of patient subgroups and assessment of outcomes.

Updated 2018

Taylor & Kumar . The effect of immediate breast reconstruction on adjuvant chemotherapy. Breast 14[1], 18-21. 2005.

### **Design**

Design: Retrospective comparative study (therapy), evidence level: 3  
Country: UK, setting: Secondary care

### **Inclusion criteria**

Patients treated for breast cancer by mastectomy, with or without immediate breast reconstruction, and who received chemotherapy, within the years March 1999 and December 2002, identified by the regional tumour registry.

Mean age:

Mastectomy: 52 years

Reconstruction: 43 years

Proportion of patients with disease-positive lymph nodes:

Mastectomy: 78%

Reconstruction: 75%

Proportion of patients with locally advanced disease:

Mastectomy: 47%

Reconstruction: 55%

Mean Nottingham Prognostic Index:

Mastectomy: 5.33

Reconstruction: 4.70

### **Exclusion criteria**

None stated.

### **Population**

number of patients = 93.

### **Interventions**

Aim: to examine whether immediate breast reconstruction had an impact on chemotherapy in terms of dose given, need for supportive treatment and delays in commencing/continuing chemotherapy.

Two groups were defined retrospectively:

1. Reconstruction group (n=44): underwent mastectomy, immediate reconstruction and chemotherapy.

2. Mastectomy group (n=49): underwent mastectomy and chemotherapy.

Reconstruction type:

TRAM: 22 (50%)

Latissimus dorsi: 15 (34%)

Implant/expander: 7 (16%).

### **Outcomes**

Interval from surgery to commencement of chemotherapy;

Delay during chemotherapy;

Dose of chemotherapy given;

Need for medical support during chemotherapy.

### **Follow up**

Not reported: study assesses short-term sequelae following mastectomy, reconstruction and during chemotherapy.

### **Results**

Mean time from surgery to chemotherapy initiation (days):

Mastectomy: 38

Reconstruction (total): 36

TRAM: 43

Latissimus dorsi: 32

Implant/expander: 33

The most commonly recorded cause of a delay in starting chemotherapy of > 40 days was incomplete wound healing, which occurred in 41% in patients treated with TRAM and 4% of patients treated with mastectomy without reconstruction.

Proportion of patients treated with full intended dose of chemotherapy:

Mastectomy: 97%

Reconstruction (total): 95%

TRAM: 93%

Latissimus dorsi: 98%

Implant/expander: 98%

Approximately 10% of patients in each group needed support during chemotherapy with either antibiotics or GCSF.

### **General comments**

Retrospective study of immediate reconstruction based on routinely collected audit data. No statistical analysis provided.

Wilson, Brown, Weiller-Mithoff, George & Doughty . Immediate breast reconstruction does not lead to a delay in the delivery of adjuvant chemotherapy. Eur.J.Surg.Oncol. 30[6], 624-627. 2004.

## **Design**

Design: Retrospective comparative study (therapy), evidence level: 3  
Country: UK, setting: Secondary care

## **Inclusion criteria**

285 patients treated for breast cancer whose treatment included chemotherapy.

## **Exclusion criteria**

Patients who did not receive chemotherapy.

## **Population**

number of patients = 285.

## **Interventions**

Aim: to assess whether immediate breast reconstruction following mastectomy leads to a delay in the delivery of chemotherapy.

Three groups were retrospectively defined:

1. Immediate breast reconstruction group (n=95): underwent skin sparing mastectomy and immediate breast reconstruction and chemotherapy.

Reconstruction was as follows:

Becker implant: 22%

Latissimus dorsi: 51%

Latissimus dorsi + implant: 14%

Free tissue transfer: 13%

2. Mastectomy group (n=95): underwent non-reconstructive mastectomy and chemotherapy.

3. Breast conserving surgery group (n=95): underwent breast conserving surgery and chemotherapy.

## **Outcomes**

Time from surgery to the start of chemotherapy

## **Follow up**

Not reported; extent appears adequate.

## **Results**

Median time (range) to the start of chemotherapy (days) by group:

Immediate reconstruction: 29 (17-55)

Mastectomy: 28 (16-52)

Breast conserving surgery: 26 (20-42)

Median time (range) to the start of chemotherapy (days) by reconstruction type:

Becker implant: 25 (16-31)

Latissimus dorsi: 27.5 (19-41)

Latissimus dorsi + implant: 24 (17-55)

Free tissue transfer: 38 (26-52)

### **General comments**

Study provides data for immediate reconstruction.

Short paper with few details on patient characteristics.

Study does not state directly that patients who received reconstruction underwent mastectomy.

Method of selection of the two non reconstructed groups of patients is not described, except that all patients were treated over the same period.

Cited results for reconstruction are based upon smaller subgroups.

Updated 2018

## Prospective case series

Benediktsson & Perbeck . Capsular contracture around saline-filled and textured subcutaneously-placed implants in irradiated and non-irradiated breast cancer patients: five years of monitoring of a prospective trial. Journal of Plastic., Reconstructive.& Aesthetic Surgery: JPRAS. 59[1], 27-34. 2006.

### Design

Design: Prospective case series (therapy), evidence level: 3  
Country: Sweden, setting: Secondary care

### Inclusion criteria

145 patients with with large (>3cm) or multifocal primary unilateral breast cancer tumours and with a healthy contralateral breast; operated within the years 1991-1994.

### Exclusion criteria

Patients who received secondary RT due to local recurrence in the 5-year follow-up period (n=12);  
Patients who died or who were too ill for review (n=12);  
Patients whose implants were removed due to failure without contracture (n=14).  
This left 107 patients for evaluation.

### Population

number of patients = 107, age range 32 to 75 years, mean age = 54 years.

### Interventions

Aim: to measure the incidence and outcome of capsular contracture in irradiated and non-irradiated breasts after subcutaneous mastectomy and immediate reconstruction with a subcutaneously-located saline-filled prosthesis.

Patients underwent subcutaneous mastectomy and immediate reconstruction with a subcutaneously located prosthesis.

24 patients received RT after reconstruction (dose: 46 Gy in 2 Gy fractions, 5 days a week), and an unspecified number of pre-menopausal patients received chemotherapy.

Prophylactic antibiotics were given, and surgical drains placed at the operation site.

### Outcomes

Extent of capsular contraction assessed by:

1. Applanation tonometry: ratio of breast compressibility at the time of follow-

up relative to the time of surgery; a ratio  $<0.5$  was considered to be indicative of contracture.

2. Modified Baker/Palmer classification based on clinical examination:

B1A-B1B - Good cosmetic result;

B2- Satisfactory;

B3 - B4 - Capsular contraction.

### **Follow up**

Mean 56 months; median 60 months, range 24-60 months.

### **Results**

Rate of capsular contracture (B3-B4):

All patients:  $22/107=20.6\%$

By RT subgroup:

RT:  $10/24 = 41.7\%$

No RT:  $12/83 = 14.5\%$ ;  $p=0.012$

16/22 patients with capsular contracture required re-operation; the remaining 6 patients did not receive further reconstructive surgery either due to choice, or due to advanced disease.

There was good correlation between the two methods of assessment of capsular contracture with mean (standard deviation) applanation tonometry ratio for each Baker/Palmer group as follows:

B1A: 0.798 (0.223)

B1B: 0.635 (0.254)

B2: 0.531 (0.199)

B3: 0.451 (0.070)

B4: 0.250 (0.000)

### **General comments**

Provides data on immediate reconstruction.

Some of the exclusion criteria detract from an evaluation of the efficacy of implant reconstruction.

Drucker-Zertuche & Robles-Vidal . A 7 year experience with immediate breast reconstruction after skin sparing mastectomy for cancer. Eur.J.Surg.Oncol. 33[2], 140-146. 2007.

## **Design**

Design: Prospective case series (therapy), evidence level: 3  
Country: Mexico, setting: Secondary care

## **Inclusion criteria**

105 patients treated for breast cancer within the years 1997-2004, with mastectomy plus immediate reconstruction (autologous, expander/implant or in combination), performed by a single surgeon.

Disease stage:

Stage 0: n=16

Stage I: n=39

Stage IIA: n=28

Stage IIB: n=14

Stage IIIA: n=6

Stage IIIB: n=1

Histology:

Invasive ductal: n=72

Invasive lobular: n=7

DCIS: n=10

Tubular: n=1

81/105 = 77% of patients were pre-menopausal.

## **Exclusion criteria**

None stated.

## **Population**

, age range 22 to 58 years, mean age = 40 years.

## **Interventions**

Aim: to assess the oncologic safety of mastectomy and immediate reconstruction in patients treated for breast cancer.

Primary surgery:

Total mastectomy (n=26)

Total mastectomy plus sentinel node biopsy (n=19)

Modified radical mastectomy (n=60)

Immediate reconstruction:

TRAM flap (n=70)

TEIR (n=29)

Latissimus dorsi flap + implant (n=6)

50 patients received in addition, contralateral breast adjustment.

Adjuvant therapy:

Neoadjuvant chemotherapy: n=30

Concomitant chemotherapy + RT: n=14

Chemotherapy: n=67

RT: n=20

Patients participated in a 30 minute interview to ascertain their satisfaction with their reconstructions, perception of body image and quality of life. In addition cosmetic outcome was assessed by an independent plastic surgeon who did not perform any of the reconstructions.

### **Outcomes**

Local recurrence (defined as biopsy-proven cancer in skin flaps, transposed tissues or chest wall)

Regional recurrence (defined as ipsilateral axillary or supraclavicular nodes)

Distant recurrence (any other site than the above)

Aesthetic outcome (assessed on 8 separate ordinal scales: shape with brassiere, shape without brassiere, contralateral match, inframammary fold, mobility, consistency, overall result, projection)

Complications

Patient satisfaction

### **Follow up**

The interviews were performed for all patients at  $\geq 6$  months following the reconstruction.

Mean follow-up 48 months (range 10-92 months)

### **Results**

Complication rate:

All patients:  $27/105 = 25.7\%$ ; as follows:

Minor complications:

Necrosis of wound margin: n=9;

Fluid collection n= not specified;

Major hematoma: n=6;

Minor fat necrosis: n=7;

Symptomatic capsular contracture: n=2

Major complications:

Total flap necrosis: n=1

Implant exposure: n=2

Abdominal complications:

Abdominal hernia: n=2

22/27 complications were in patients who had received RT, and of these 13/22 were in patients who received expander or implant reconstructions.

Recurrence:

Distant (n=3)

Loco-regional + distant (n=1)

Aesthetic outcome:

There was no difference in overall results between the three types of reconstruction (p=0.324; no further details reported).

Mobility and consistency of reconstructed breast was closer to that of the contralateral breast in patients who received TRAM reconstruction (p=0.015; no further details provided).

For all other aesthetic scales examined, there were no statistically significant differences between reconstruction groups.

Surgeon evaluation:

Excellent: n=39

Good: n=57

Fair: n=6

Poor: n=3

Patient satisfaction:

Extremely satisfactory: n=35

Satisfactory: n=53

Less than satisfactory: n=11

Disappointing: n=6

Patient perception of body image:

Very good: n=31

Good: n=57

Moderately good: n=12

Poor: n=5

Patient reporting of sexual life:

Unchanged: n=95

Deteriorated: n=9

Improved: n=1

Patient reporting of social life:

Unchanged: n=99

Deteriorated: n=0

Improved: n=6

**General comments**

Provides data re: immediate reconstruction.

Study reports details of treatment carefully but provides few details of analysis of results. For many outcomes where a baseline assessment would have been beneficial, it is lacking.

Limited applicability: question does not specify a comparison of outcome by type of reconstruction performed.

Updated 2018

Gendy, Able & Rainsbury . Impact of skin-sparing mastectomy with immediate reconstruction and breast-sparing reconstruction with miniflaps on the outcomes of oncoplastic breast surgery. Br.J.Surg. 90[4], 433-439. 2003.

## **Design**

Design: Prospective case series (therapy), evidence level: 3

Country: UK, setting: Secondary care

## **Inclusion criteria**

Contactable, disease-free patients who underwent either of two procedures (see interventions) within the years 1991-1999. Indications for skin sparing mastectomy with immediate latissimus dorsi myocutaneous flap reconstruction were widespread DCIS, local recurrence following previous breast conserving surgery, prophylaxis and patient preference.

Recorded disease characteristics:

Tumour diameter median 20mm, range 9-90mm.

Tumour grade:

I: 11

II: 21

III: 8

Histology:

Invasive ductal: 31

Invasive lobular: 8

Mixed invasive ductal plus invasive lobular: 1

DCIS: 18

Axillary nodal stage:

N0: 38

N1: 17

Not sampled: 3

## **Exclusion criteria**

Patients who declined to participate.

## **Population**

number of patients = 57, age range 31 to 62 years, mean age = 48 years.

## **Interventions**

Aim: to compare local control, cosmesis, functional disturbance and psychological morbidity in patients with breast cancer treated with two strategies as follows:

1. Skin sparing mastectomy with immediate latissimus dorsi myocutaneous

flap reconstruction (n=57); 12 of whom received adjuvant RT: 50 Gy, 25 fractions over 12 weeks.

2. Partial mastectomy with immediate or delayed latissimus dorsi miniflap reconstruction of the resection defect (n=49); NB no data cited.

### **Outcomes**

1. Cosmesis, assessed by:

- i) Patient-scored visual analogue scale (range 0-100; 100 representing optimal result);
- ii) Photographic assessment by a multi-disciplinary panel of 5 assessors, blinded to procedure: Mean score of the panel members (range 1-5; 1 representing gross unacceptable deformity; 5 representing no deformity)
- iii) Breast retraction assessment (BRA): based upon measurements to assess symmetry between ipsilateral and contralateral breasts; lower score represents less contraction and better symmetry; score >3.5 represents unsatisfactory outcome.

2. Physical disability, assessed by:

- i) Patient-subjective-assessment of physical symptoms in the treated breast, donor site and shoulder, including pain, sensory changes, muscle contraction, restriction in activities;
- ii) Observer-assessed-objective assessment of sensitivity to pain, temperature, touch and vibration of the ipsilateral breast, using the contralateral breast as control.

3. Quality of life, assessed by two psychologists, not involved in patient care, using 3 scales:

- i) Hospital anxiety and depression scale (HADS);
- ii) Rosenberg self-esteem scale (RSE);
- iii) Hopwood body image scale (HBIS).

### **Follow up**

Mean 34 (range 6-65) months.

### **Results**

Skin sparing mastectomy with immediate latissimus dorsi myocutaneous flap reconstruction:

Complication rate:  $8/57 = 14\%$

Skin envelope necrosis (6/8 complications)

Further surgery was required in  $45/57 = 79\%$  of patients

Local recurrence rate:  $1/57 = 1.7\%$  (occured in a patient who did not receive RT).

Cosmesis:

Overall a good cosmetic result was achieved. Median (range) values as follows:

BRA: 2 (0-5.3) NB a marked degree of retraction (BRA > 3.5) was observed in 8 patients.

Panel assessment: 2.9 (1-4.4) NB on this scale a score of 3 represents moderate deformity/difference between breasts.

Patient satisfaction (cosmesis): 72 (3-100)

Patient satisfaction (freedom of dress): 76 (1-100).

Physical disability:

Objective assessment:

Breasts with normal nipple-areola sensation: 2%

Quadrants with normal sensation: median 1 (range 0-4)

Surface area with intact sensation: 35% (range 5-100%)

Subjective assessment:

Breast and nipple-areolar complex feels normal: VAS median 28 (range 0-82)

Breast self-examination 'easy': VAS median 48 (range 1-100)

Shoulder disability restricts some activities: 73%

Anxiety and depression (HADS):

Anxiety level:

Normal (score 0-7): 65%

Mild (score 8-10): 21%

Moderate (score 11-14): 14%

Severe (score 15-21): 0%

Depression level:

Normal (score 0-7): 93%

Mild (score 8-10): 5%

Moderate (score 11-14): 2%

Severe (score 15-21): 0%

Psychological morbidity: mean (range) scores:

Anxiety HADS: 5 (0-14) NB (score range 0-21; low score represents low anxiety)

Depression HADS: 1 (0-10) NB (score range 0-21; low score represents low depression)

Self esteem (RSE): 24 (10-29) NB score range 10-40; low score indicates high self esteem

Body image (HBIS): 5 (0-21) NB score range 0-30; low score represents less disturbance of body image

Concern re: residual cancer: 45 (1-100) NB VAS

### **General comments**

The study compared outcomes following skin sparing mastectomy with immediate latissimus dorsi myocutaneous flap reconstruction versus partial mastectomy with immediate or delayed latissimus dorsi miniflap reconstruction of the resection defect. Our research question does not apply to the latter procedure; no data are cited.

Three of the 57 women had bilateral procedures.

The finding that only 2% of operated breasts had normal nipple-areola sensation is unsurprising since these tissues are excised in skin sparing mastectomy.

Accepting that the main study comparison is not cited, the study benefits from rigorous description of its measurement techniques and its prospective nature. Some value is lost in citing 'single arm' data, but some limited comparison may be possible with other studies.

Updated 2018

Sandelin, Wickman & Billgren . Oncological outcome after immediate breast reconstruction for invasive breast cancer: A long-term study. Breast 13[3], 210-218. 2004.

## **Design**

Design: Prospective case series (therapy), evidence level: 3  
Country: Sweden, setting: Secondary care

## **Inclusion criteria**

203 patients with invasive breast cancer who underwent immediate breast reconstruction.

Tumour stage:

T1: 121

T2: 73

T3: 9

Proportion of patients with involved lymph nodes: 30%

## **Exclusion criteria**

Patients with locally advanced breast cancer or inflammatory breast cancer did not usually undergo immediate reconstruction.

## **Population**

, age range 23 to 70 years, median age = 48 years.

## **Interventions**

Aim: to report disease-related events in a series of patients who received immediate breast reconstruction.

188 patients underwent mastectomy and immediate reconstruction for primary breast cancer.

14 women had surgery (possibly breast conserving surgery) plus immediate reconstruction for recurrent breast cancer.

Reconstruction was performed as follows:

Permanent prosthesis: 22 (11%)

Expander: 168 (83%)

Bilateral free TRAM: 1 (0.5%)

Free TRAM: 3 (1.5%)

Pedicled free TRAM: 9 (4%)

137/203 = 67% of patients underwent contralateral plastic surgery.

21/203 = 10% of patients received neoadjuvant chemotherapy.

60/203 = 30% of patients received chemotherapy.

69/203 = 34% of patients received RT; 46-50 Gy.

108/203 = 53% of patients received hormone therapy.

### **Outcomes**

Postoperative complications

Deaths due to breast cancer

Local recurrence

### **Follow up**

Minimum 5 years

### **Results**

Postoperative complications occurring within 30 days of surgery:

Crude rate: 23/203 = 11%; as follows:

Bleeding requiring re-operation: 5

Implant loss: 3

Flap necrosis: 3

Fat necrosis: 2

Infection: 5

Misc: 5

Deaths due to breast cancer:

Crude rate: 31/203 = 15%

Local recurrence:

Crude rate: 13/203 = 6.4%

### **General comments**

Study provides data on immediate reconstruction.

188/203 = 93% of women underwent mastectomy and immediate reconstruction; the remainder may have received breast conserving surgery i.e. outside the scope of this question.

Tykkä, sko-Seljavaara & Hietanen . Patient satisfaction with delayed breast reconstruction: a prospective study. Ann.Plast.Surg. 49[3], 258-263. 2002.

### **Design**

Design: Prospective case series (), evidence level: 3  
Country: Finland, setting: Secondary care

### **Inclusion criteria**

Patients treated with delayed, autologous tissue breast reconstruction following previous mastectomy between August 1999 and December 1999.

Marital status:

Married/long term relationship: 55 (73%)

Single: 10 (13%)

Divorced: 7 (7%)

Widowed: 3 (4%)

Reconstruction was performed a mean of 3.9 years after mastectomy (range 1.2-16.6 years)

### **Exclusion criteria**

None specified

### **Population**

number of patients = 75, age range 30 to 65 years, mean age = 50 years.

### **Interventions**

Aim: to evaluate patient satisfaction with delayed breast reconstruction with autologous tissue and to examine related factors.

80 patients operated on over a 5-month period were invited to complete questionnaires prior to delayed reconstructive surgery.

Participants were also given questionnaires at 3-month and 6-month post-operative hospital visits.

The questionnaires collected data on socio-demographic variables, general health and the specific outcomes (see below).

Reconstructions performed were as follows:

TRAM: 67 (89%)

Latissimus dorsi 8 (11%)

### **Outcomes**

Patient satisfaction

Proportion of patients reporting pain and problematic scarring

Patient-reported benefits and drawbacks of reconstructive surgery.

### **Follow up**

Patients were assessed prior to reconstructive surgery, and at 3 months and 6 months post-operatively.

### **Results**

Response rate to questionnaires:

Pre-operative: 75/80 = 94%

3 month post-operative: 60/75 = 80%

6 month post-operative: 60/75 = 80%

Patient satisfaction (rating) with general outcome of the operation at 3 months post-operatively:

Very good: 28 (47%)

Quite good: 26 (44%)

Quite poor: 1 (2%)

Very poor: 0 (0%)

Patient satisfaction (rating) with general outcome of the operation at 6 months post-operatively:

Very good: 27 (45%)

Quite good: 29 (48%)

Quite poor: 3 (5%)

Very poor: 0 (0%)

There was no difference in patient satisfaction according to type of reconstruction, waiting time, co-morbidity or any demographic factor.

Outcome at 3 months against patients' preoperative expectations:

Much better than expected: 9 (15%)

Better than expected: 21 (35%)

As expected: 23 (38%)

Poorer than expected: 4 (7%)

Much poorer than expected: 1 (2%)

Outcome at 6 months against patients' preoperative expectations:

Much better than expected: 10 (17%)

Better than expected: 25 (42%)

As expected: 16 (27%)

Poorer than expected: 5 (8%)

Much poorer than expected: 2 (3%)

Proportion of patients reporting pain (shoulder, neck and back):

Pre-operatively: 41 (55%)

3 months post-operatively: 19 (32%);  $p=0.011$

6 months post-operatively: 20 (33%);  $p=0.00097$

Patient-reported extent to which surgical scarring was a disturbance at 6 months post-operatively:

Very much: 0 (0%)

To some extent: 6 (10%)

Slightly disturbed: 36 (60%)

Not at all: 16 (27%)

This variable was negatively correlated with satisfaction at 3 months post-operatively ( $p=0.032$ ) but not statistically significantly so at 6 months ( $p=0.065$ )

Patient responses to questions about the most important benefits of their reconstruction (no. responses):

A new breast of one's own: 31

No need for external prosthesis: 24

Feeling whole: 18

Easier to find clothes: 10

Flat stomach: 7

Improved self esteem: 4

Easier to exercise: 3

One can forget the cancer: 1

Patient responses to questions about the most important drawbacks of their reconstruction (no. responses):

Difficult operation: 17

Abdominal operation: 11

Pain: 11

Long recovery time: 9

Fears, uncertainty: 7

Asymmetrical breasts: 7

Scars: 1

### **General comments**

Provides data on delayed reconstruction.

Some multivariate analysis was performed, but not cited as the authors do not appear to have fully reported which variables were included in the model.

## Retrospective case series

Ascherman, Hanasono, Newman & Hughes . Implant reconstruction in breast cancer patients treated with radiation therapy. *Plastic.& Reconstructive.Surgery* 117[2], 359-365. 2006.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: USA, setting: Secondary care

### **Inclusion criteria**

104 women who underwent mastectomy and TEI reconstruction within the years 1996-2003.

### **Exclusion criteria**

Patients who received mantle RT due to Hodgkins disease

### **Population**

number of patients = 104.

### **Interventions**

Aim: to examine the outcome of breast reconstruction using modern tissue expanders and implants in patients who undergo RT before completion of their reconstructions.

Two patient groups were defined (all patients underwent TEI reconstruction):

#### 1. RT group (n=27)

Patients who underwent mastectomy plus immediate reconstruction plus RT. NB in this group RT either preceded mastectomy due to previous failed lumpectomy (n=8), or took place after mastectomy due to high risk tumours/close margins (n=19).

#### 2. Control group (n=77)

Patients who underwent mastectomy plus immediate reconstruction without RT.

Only 3 reconstructions were described as 'delayed'; all of which were for patients in the control group (range of delay 13 months to 22 years).

### **Outcomes**

i) Complications resulting in removal or replacement of implant (6 parameters: infection, extrusion, port malfunction, capsular contracture, pain, rippling);

ii) Complications not resulting in removal or replacement of the implant (5 parameters: pulmonary embolism, seroma, skin necrosis, cellulitis, pain);

iii) Symmetry (3 point scale: 1=unsatisfactory, 2=satisfactory, 3=optimal);

iv) Patient satisfaction (3 point scale: 1=dissatisfied, 2=partially satisfied, 3=fully satisfied)

### **Follow up**

Not reported.

### **Results**

i) Complications resulting in removal or replacement:

RT group: 5 (18.5%)

Control group: 4 (4.2%);  $p < 0.025$ , Chi square

Within the above, 'extrusion' was the only individual variable that was statistically significantly different between groups:

RT group: 4 (14.8%)

Control group: 0 (0%);  $p < 0.001$ , Chi square

ii) Complications not resulting in removal or replacement of the implant:

RT group: 6 (22.2%)

Control group: 12 (12.5%);  $p$  NS, Chi square

Within the above, no individual variable was statistically significantly different between groups.

iii) Symmetry (mean score)

RT group: 2.1

Control group: 2.6;  $p < 0.01$ , Mann-Whitney U test

iv) Patient satisfaction (mean score)

RT group: 2.4

Control group: 2.7;  $p$  NS, Mann-Whitney U test

Association between smoking, diabetes and chemotherapy with complications (univariate analysis); complication rate shown:

Smokers: 2/14=14%

Non-smokers: 24/90=26%;  $p$  NS, Chi square test

Diabetic: 2/6=33%

Non-diabetic: 24/98=24%;  $p$  NS, Chi square test

Chemotherapy: 18/55=33%

No chemotherapy: 8/49=16%;  $p < 0.01$ , Chi square test

There was no statistically significant difference in the rate of complications, symmetry or patient satisfaction according to timing of RT (before mastectomy vs. after implant/expander insertion but before implant exchange/port removal); no data provided.

### **General comments**

Study evaluates predominantly immediate reconstruction (97.6%).

In 19 patients reconstruction was bilateral, thus some analyses are for a total of 123 reconstructed breasts, making results imprecise for outcomes where non-independence of the two breasts applies.

Patients in the RT group were more likely to receive chemotherapy than those in the control group (85% and 43% respectively;  $p < 0.001$ , Chi square test) and were more likely to receive 'Mentor' devices (as opposed to 'McGhan' devices) than the control group (26% and 9% respectively;  $p < 0.025$ , Chi square test).

The RT group is likely to consist of poorer-prognosis patients owing to the need for RT and in most cases, chemotherapy. Chemotherapy had a demonstrated association with complications.

Analyses were univariate

Updated 2018

Cordeiro, Pusic, Disa, McCormick & VanZee . Irradiation after immediate tissue expander/implant breast reconstruction: outcomes, complications, aesthetic results, and satisfaction among 156 patients. *Plastic.& Reconstructive.Surgery* 113[3], 877-881. 2004.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: USA, setting: Secondary care

### **Inclusion criteria**

Patients treated between 1995 and 2001 with mastectomy, immediate TEIR and subsequent RT.

### **Exclusion criteria**

Patients who previously received RT

### **Population**

number of patients = 623, mean age = 48 years.

### **Interventions**

Aim: to evaluate surgical complications, aesthetic results and patient satisfaction in patients who received mastectomy with immediate tissue expander/implant reconstruction (TEIR).

Two groups were retrospectively defined:

1. TEIR + RT group (n=81): were treated as follows:

- i) Mastectomy plus immediate TEIR;
- ii) Tissue expansion during adjuvant chemotherapy, commencing 10-14 days from surgery;
- iii) Exchange of expander for permanent implant at approximately 4 weeks after completion of chemotherapy;
- iv) Chest wall RT beginning 4 weeks after exchange.

2. TEIR alone group (n=542): patients were treated as above but with no RT.

RT included 50 Gy in 25-28 fractions to the chest wall, implant and supraclavicular fossa, plus a 5mm bolus over the chest wall

### **Outcomes**

Complications (including capsular contracture, assessed on a Spear/Baker scale of 1-4; 1 representing no contracture and 2-4 representing increasing degrees of contracture);

Aesthetic result: assessed as poor, fair, good or excellent;

Patient satisfaction.

### **Follow up**

TEIR + RT group: mean 33 months;  
TEIR alone group: mean 34 months.

### Results

Rate of removal of implants:

TEIR + RT group:  $9/81 = 11\%$

TEIR alone group:  $33/542 = 6\%$ ;  $p < 0.0001$ , Fisher's exact test.

Reasons for implant removal included infection, implant exposure, implant leakage, recurrent cancer and capsular contracture.

Rate of any capsular contracture (grade 2-4):

TEIR + RT group:  $46/68 = 67.6\%$

TEIR alone group:  $30/75 = 40\%$ ;  $p = 0.006$ , Fisher's exact test.

Proportion of patients with 'good' or 'excellent' aesthetic result:

TEIR + RT group:  $53/66 = 80.3\%$

TEIR alone group:  $66/75 = 88.0\%$ ;  $p = 0.0006$ , Mann-Whitney test.

Proportion of patients who were satisfied with their reconstructions:

TEIR + RT group:  $67\%$

TEIR alone group:  $88\%$ ;  $p = 0.004$ , Fisher's exact test.

### General comments

Most outcomes are reported for a subgroup of patients in the RT group with > 1 year of follow-up and a randomly selected subgroup of patients who received no RT:

TEIR + RT group:  $n = 68$

TEIR alone group:  $n = 75$

Contracture and aesthetic result were assessed by an independent observer and the operating surgeon.

Henriksen, Fryzek, Holmich, McLaughlin, Krag, Karlsen, Kjoller, Olsen & Friis . Reconstructive breast implantation after mastectomy for breast cancer: clinical outcomes in a nationwide prospective cohort study. Arch.Surg. 140[12], 1152-1159. 2005.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Denmark, setting: Secondary care

### **Inclusion criteria**

A retrospective review of a large, routinely compiled patient database identified 574 patients treated with mastectomy for breast cancer, followed by breast reconstruction.

Either initial implantation or subsequent implantation procedures were included with data presented as follows:

Initial implantation: 484 implants in 407 patients

Subsequent implantation: 417 implants in 302 patients.

49% of subsequent implantations were planned second stage events; the remainder occurring due to patient request e.g. different size (20%) or due to clinical complications (64%).

Mean age (initial implantation): 50 years, range 21-78 years;

Mean age (subsequent implantation): 51 years, range 24-78 years.

Tumour dissemination:

Local: 65.1%

Regional: 26.9%

Distant: 1.2%

Unspecified: 6.8%

Histology:

Invasive ductal: 66.9%

DCIS: 6.8%

Lobular, invasive: 13.7%

LCIS: 0.2%

Others: 12.4%

### **Exclusion criteria**

Patients who underwent solely autologous reconstruction.

### **Population**

number of patients = 574.

### **Interventions**

Aim: to report on the clinical course following post-mastectomy breast reconstruction in 574 patients with breast cancer.

Patients underwent mastectomy and reconstruction as follows:

Immediate: 7%

Delayed; with implant: 88%

Delayed; with implant + autologous tissue (3%)

Delayed; with other procedure e.g. liposuction (2%)

### **Outcomes**

Total adverse events occurring within 2 years of the reconstruction (and of the individually listed adverse events, those cited are wound infection, capsular contracture [Baker grade], skin necrosis, local recurrence).

Proportion of the above events that prompted further surgery.

### **Follow up**

Initial implantation: mean 23 months, range 3-56 months;

Subsequent implantation: mean 24 months, range 4-52 months.

### **Results**

Wound infection

Initial implantation:

No (%): 29 (7.1)

Incidence rate per 1000 person-months: 4.8

Proportion requiring surgery: 44.8%

Subsequent implantation:

No (%): 13 (4.3)

Incidence rate per 1000 person-months: 2.9

Proportion requiring surgery: 23.1%

Capsular contracture; Baker Grade II:

Initial implantation:

No (%): 35 (8.6)

Incidence rate per 1000 person-months: 5.7

Proportion requiring surgery: 80%

Subsequent implantation:

No (%): 15 (5)

Incidence rate per 1000 person-months: 3.2

Proportion requiring surgery: 60%

Severe capsular contracture; Baker grade III-IV:

Initial implantation:

No (%): 17 (4.2)

Incidence rate per 1000 person-months: 2.7

Proportion requiring surgery: 94.1%

Subsequent implantation:

No (%): 20 (6.6)

Incidence rate per 1000 person-months: 4.3

Proportion requiring surgery: 80%

**Skin necrosis:**

**Initial implantation:**

No (%): 5 (1.2)

Incidence rate per 1000 person-months: 0.8

Proportion requiring surgery: 20%

**Subsequent implantation:**

No (%): 3 (1)

Incidence rate per 1000 person-months: 0.6

Proportion requiring surgery: 33.3%

**Local recurrence:**

**Initial implantation:**

No (%): 7 (1.7)

Incidence rate per 1000 person-months: 1.1

Proportion requiring surgery: 28.6%

**Subsequent implantation:**

No (%): 1 (0.3)

Incidence rate per 1000 person-months: 0.2

Proportion requiring surgery: 100%

**Any adverse event:**

**Initial implantation:**

No (%): 125 (30.7)

Incidence rate per 1000 person-months: 22.5

Proportion requiring surgery: 21.1%

**Subsequent implantation:**

No (%): 108 (35.8)

Incidence rate per 1000 person-months: 29.7

Proportion requiring surgery: 20.5%

**General comments**

Data in this paper appear to be compiled from different samples/sources, the majority of the data (88%) refer to delayed reconstruction, with implant.

All cited data refer to n (patients).

Hussien, Salah, Malyon & Wieler-Mithoff . The effect of radiotherapy on the use of immediate breast reconstruction. Eur.J.Surg.Oncol. 30[5], 490-494. 2004.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: UK, setting: Secondary care

### **Inclusion criteria**

121 patients treated with mastectomy and immediate breast reconstruction between January 1997 and June 1999.

### **Exclusion criteria**

None stated.

### **Population**

number of patients = 121.

### **Interventions**

Aim: to evaluate the effect of RT on the choice of immediate breast reconstruction technique in view of the increased number of breast cancer patients receiving adjuvant RT.

Two groups were retrospectively defined according to the period of treatment, the contemporary indications for RT being as follows:

1. January 1997 to March 1998 (n=42): inadequate excision margins, >4 involved lymph nodes, T3-T4 tumour;
2. March 1998 to June 1999 (n=79): criteria widened to include medial tumours, Grade III tumours of stage T1-T2 and presence of lympho-vascular invasion

Case notes were reviewed and all patients were sent a questionnaire.

### **Outcomes**

Patterns of use of different types of immediate reconstruction;

Relationship between use of RT and type of immediate reconstruction performed.

### **Follow up**

Not relevant.

### **Results**

Questionnaire response rate was 100%.

Group 2 was significantly larger than group 1 (79 versus 42 patients respectively;  $p=0.008$ ), representing an increase in the use of immediate reconstruction, in the later period studied.

Type of immediate reconstruction performed: n (patients); Jan 97 to Mar 98:

Tissue expander: 18

Latissimus dorsi + implant: 12

Latissimus dorsi: 2

Free flap (DIEP): 10

Type of immediate reconstruction performed: n (patients); Apr 98 to Jun 99:

Tissue expander: 24

Latissimus dorsi + implant: 16

Latissimus dorsi: 26

Free flap (DIEP): 13

The increase in the proportion of patients who underwent immediate reconstruction with autologous tissue alone increased in the second period relative to the first period (49% and 29% respectively,  $p=0.0004$ )

Requirement for RT by treatment period:

Jan 97-Mar 98: 10 (24%)

Apr 98-Jun 99: 23 (29%)

Of patients receiving RT, proportion for whom RT was expected at time of reconstruction by treatment period:

Jan 97-Mar 98:  $5/10 = 50\%$

Apr 98-Jun 99:  $17/23 = 74\%$

In the first period autologous immediate reconstruction was performed in all 5 patients for whom RT was expected; 5 patients who unexpectedly received RT had undergone immediate implant reconstruction.

In the second period 15/17 patients for whom RT was expected underwent immediate autologous reconstruction; 6 patients who unexpectedly received RT had undergone immediate implant reconstruction.

### **General comments**

Provides data on immediate reconstruction only.

Criteria for expecting RT are probably based upon triple assessment information.

The role of the patient questionnaire is not described; presumably to augment data from case notes; possible recall bias.

Knottenbelt, Spauwen & Wobbles . The oncological implications of immediate breast reconstruction. Eur.J.Surg.Oncol. 30[8], 829-833. 2004.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: The Netherlands, setting: Secondary care

### **Inclusion criteria**

54 patients who underwent immediate reconstruction of the breast following mastectomy for breast cancer, who were treated between Jan 1993 and Dec 1996:

Premenopausal: 39  
Postmenopausal: 13  
Not known: 2

Stage:  
pT1-T2, N0: 32 (35 breasts)  
pT1-T2, N1: 14 (15 breasts)  
pT3-T4, N0: 2  
pT3-T4, N1: 6

Four patients had bilateral breast cancer, making a total of 58 reconstructions.

### **Exclusion criteria**

None stated.

### **Population**

number of patients = 54, age range 32 to 70 years, mean age = 46 years.

### **Interventions**

Aim: to assess whether the presence of a breast prosthesis interferes with the detection and management of recurrent disease, and whether recurrence and survival differ from that seen in patients treated with mastectomy alone.

All patients underwent modified radical mastectomy with immediate reconstruction as follows:

Subpectoral tissue expander (55 reconstructions)  
TRAM flap (1 reconstruction)  
Permanent implant (2 reconstructions)

Adjuvant therapy:

RT to the axilla and/or chest wall (n=15)

Systemic chemotherapy (n=14)

Chemotherapy + RT (n=8)

Post menopausal women with positive lymph nodes received tamoxifen (n not

specified).

### **Outcomes**

Cosmesis (assessed by the plastic surgeon and surgical oncologist as excellent, good, fair or poor).

Disease-related events.

### **Follow up**

Minimum 60 months.

### **Results**

Cosmesis:

Excellent/good: 11 patients

4 patients developed severe contractures or encapsulation requiring corrective surgery (no further data).

Local recurrence (crude rate out of all treated breasts at risk):

1/58 = 1.7%

Distant metastasis (crude rate out of all treated breasts at risk):

13/58 = 22.4% (includes 1 patient with local recurrence also)

Deaths with metastatic disease:

9/58 = 15.5%

Disease-free survival at 5 years: 93%

### **General comments**

Cosmesis is not a primary study outcome; a description of assessment is provided but only partial results.

No methods are reported to derive the figure for disease-free survival at 5 years of 93%; may be an actuarial estimate.

Mustonen, Kataja, Berg, Pietilainen & Papp . Recurrences after immediate reconstruction in breast cancer. Scandinavian Journal of Surgery: SJS 94[1], 21-24. 2005.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Finland, setting: Secondary care

### **Inclusion criteria**

Patients treated with immediate breast reconstruction within the years 1998-2001.

Mean ages in groups 1, 2 and 3 were 52, 47 and 47 years, respectively.

### **Exclusion criteria**

None stated.

### **Population**

number of patients = 79.

### **Interventions**

Aim: to measure local-regional and distant recurrence of breast cancer in patients treated with immediate breast reconstruction as follows:

1. Wide local excision and latissimus dorsi miniflap (n=23);
2. Skin sparing mastectomy and TRAM or latissimus dorsi flap (n=22);
3. Subcutaneous mastectomy and TRAM or latissimus dorsi flap (n=34);

Patients in the first group (breast conserving surgery) received RT; 50 Gy.

Patients with disease-positive lymph nodes or tumours >20mm in size received chemotherapy; patients with ER+ or PR+ tumours received hormone therapy.

### **Outcomes**

Local, regional and distant recurrence;

Disease-free and overall survival, estimated by Kaplan-Meier method.

### **Follow up**

Mean 3.6 years.

### **Results**

Estimated 5-year overall survival (all patients): 88%

Estimated 5-year disease-free survival (all patients): 80%

Recurrences by mastectomy-treated groups:

Skin sparing mastectomy and TRAM or latissimus dorsi flap (n=22):

Local: 2

Regional: 0

Distant: 3

Subcutaneous mastectomy and TRAM or latissimus dorsi flap (n=34):

Local: 3

Regional: 1

Distant: 0

There was no statistically significant difference in recurrence at any site between the treatment groups.

### **General comments**

Study provides data on immediate reconstruction.

The group treated with wide local excision and latissimus dorsi miniflap (n=23) do not meet the criteria for this question, therefore applicability of this study is 71%.

Updated 2018

Rey, Martinelli, Petit, Youssef, De, Rietjens, Garusi & Giraldo . Immediate breast reconstruction and high-dose chemotherapy. Ann.Plast.Surg. 55[3], 250-254. 2005.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Switzerland, setting: Secondary care

### **Inclusion criteria**

105 patients treated with mastectomy between 1999 and 2002.

Mean age (years):

Group 1: 44

Group 2: 46

Group 3: 50

### **Exclusion criteria**

Patients who received autologous tissue reconstruction.

### **Population**

number of patients = 105.

### **Interventions**

Aim: to evaluate whether high dose chemotherapy is delayed by immediate breast reconstruction.

All patients underwent total mastectomy plus axillary clearance. Three groups were defined retrospectively according to additional treatment as follows:

1. Immediate reconstruction plus high dose chemotherapy (n=23);
2. High dose chemotherapy without reconstruction (n=15);
3. Immediate reconstruction with conventional dose chemotherapy (n=67).

Reconstruction type was as follows:

Prosthesis: 80%

Expander: 20%

Reconstruction was performed always before chemotherapy, but in the case of expanders, these were exchanged for permanent implants after the conclusion of chemotherapy.

64% of patients receiving reconstruction had in addition, plastic surgery to the contralateral breast.

72% of patients received RT.

### **Outcomes**

**Complications:**

Local infection;

Capsular contracture (Baker 3 or 4);

Necrosis, warranting surgical removal;

Delay from surgery to high dose chemotherapy.

NB complications were recorded as 'early' if occurring before chemotherapy and 'late' if occurring after commencement of chemotherapy.

**Follow up**

Group 1: mean 12 months

Group 2: mean 13 months

Group 3: mean 13 months

**Results**

Early Complications:

	Group		
	Reconstruction + high dose chemo	Reconstruction + conventional chemo	High dose chemo; no reconstruction
Local infection	0	2 (2.9%)	0
Local necrosis	0	0	0
Interval: surgery to high dose chemotherapy (days)	54		60

There was no statistically significant difference in the interval from surgery to the start of high dose chemotherapy between group 1 (immediate reconstruction, 54 days) and group 2 (mastectomy, 60 days); p= 0.13.

Late complications:

	Group		
	Reconstruction + high dose chemo	Reconstruction + conventional chemo	High dose chemo; no reconstruction
Capsular contracture	5 (22%)	11 (16%)	
Local infection	3 (13%)	0	0
Local necrosis	1 (4.3%)	0	0

The local infection rate was statistically significantly higher for patients who

received high dose chemotherapy after reconstruction (13%) than patients who received conventional dose chemotherapy after reconstruction (0%),  $p = 0.014$ . There was no statistically significant difference in capsular contracture rates between these two groups (22% versus 16%;  $p=0.51$ ).

### **General comments**

Study provides data for immediate reconstruction.

The three treatment groups were visibly similar in terms of length of hospital stay, follow-up, TNM stage and receipt of RT. The only difference was in the use of neoadjuvant chemotherapy, which was 60% in patients who received high dose chemotherapy without reconstruction, 13% in patients who received immediate reconstruction plus high dose chemotherapy and 10% in patients who received immediate reconstruction and conventional chemotherapy. The reconstruction technique was similar in both reconstructed groups (differences not tested statistically).

The need for chemotherapy at all, or at which dose, was never known at the time of commencing definitive surgery.

Re: observed rates of capsular contracture: the majority had received RT: 4/5 patients with contracture in group 1 and 10/11 patients with contracture in group 2. However, there was no statistically significant difference in the rate of capsular contraction when subgroup analysis was performed between patients given RT and those not given RT for:

Group 1 (immediate reconstruction plus high dose chemotherapy);  $p = 1$ ;

Group 2 (high dose chemotherapy without reconstruction);  $p=0.5$ .

Vandeweyer, Deraemaeker, Nogaret & Hertens . Immediate breast reconstruction with implants and adjuvant chemotherapy: a good option? Acta Chir Belg. 103[1], 98-101. 2003.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Belgium, setting: Secondary care

### **Inclusion criteria**

91 patients treated for breast cancer with mastectomy plus immediate expander reconstruction between January 1990 and December 1997.

In 11 Of 91 patients (12.1%) mastectomy was performed due to disease recurrence

Mean age (range)

Chemotherapy group: 44 (29-66) years

Control group: 51 (29-77) years

Histology

Chemotherapy group:

Invasive ductal: 85.7%

DCIS: 0%

Invasive lobular: 14.3%

LCIS: 0%

No chemotherapy group:

Invasive ductal: 53%

DCIS: 36.4%

Invasive lobular: 7.6%

LCIS: 3%

### **Exclusion criteria**

Patients who underwent reconstruction with only autologous tissue.

### **Population**

number of patients = 91.

### **Interventions**

Aim: to examine complications and disease related events in patients treated for breast cancer with mastectomy and immediate reconstruction; and the effect of adjuvant therapy.

All patients underwent mastectomy (modified radical or simple) with immediate reconstruction, and with plastic surgery to the contralateral breast.

The expander implants were expanded on the 3rd, 6th and 9th post-operative days.

Two groups were defined retrospectively:

1. Chemotherapy group (n=27): patients received adjuvant chemotherapy (total 28 implants);

2. Control group (n=66): patients did not receive adjuvant chemotherapy

No patients received RT.

### **Outcomes**

Complications (short term: prior to administration of chemotherapy e.g. haematoma, cutaneous necrosis, infection; total, and those warranting implant removal);

Cosmetic outcome;

Patient satisfaction;

### **Follow up**

Mean 44 months (range 13-93 months); equal between groups.

### **Results**

Complications (crude rate; short-term; prior to administration of chemotherapy):

All patients: 12/91 = 13%

Total:

Chemotherapy group: 7/28 = 25%

Control group: 5/66 = 7.6%; p = 0.04, Fisher's exact test.

Complications warranting implant removal:

Chemotherapy group: 3/28 = 10.7%

Control group: 1/66 = 1.5%; p = 0.0084, Fisher's exact test.

Cosmetic outcome:

Capsular contracture (assessed as grade I-IV):

There was no statistically significant difference between groups in the distribution of capsular contracture grade (p=1; Fisher's exact test); 70% of patients in the chemotherapy group and 63% of patients in the no chemotherapy group had capsular contracture of grade I.

There were no statistically significant differences between groups in the rate of implant displacement, implant deflation, breast symmetry (assessed as optimal or satisfactory in approximately 96% of cases in each group), breast volume of preoperative assessment, location of intramammary fold of preoperative assessment.

**Patient satisfaction:**

There was no statistically significant difference in patient satisfaction between groups ( $p=1$ ; Fisher's exact test); in the chemotherapy group 83% of patients were fully satisfied, compared with 88% of patients who did not receive chemotherapy.

**General comments**

Study provides data on immediate breast reconstruction.

Treatment groups originate from indications based upon TNM stage. Patients in the chemotherapy group appear to have more advanced stage than those in the no chemotherapy group; respective proportions with pN1 disease 82% and 4.5% , but with a bias since not all patients in the no chemotherapy group underwent axillary staging surgery.

Scale for capsular contracture not described - Grade 1 may represent little or no contracture.

Other factors possibly explain the observed differences in short term ( occurring before administration of chemotherapy) complication rates between groups e.g. definitive surgery.

Updated 2018

Woerdeman, Hage, Smeulders, Rutgers & van der Horst . Skin-sparing mastectomy and immediate breast reconstruction by use of implants: an assessment of risk factors for complications and cancer control in 120 patients. *Plastic.& Reconstructive.Surgery* 118[2], 321-330. 2006.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: The Netherlands, setting: Secondary care

### **Inclusion criteria**

120 patients who underwent skin-sparing mastectomy and immediate implant reconstruction (total 174 reconstructions) between July 1996 and June 2000.

54 (45%) patients underwent bilateral mastectomy and reconstruction

33/120 = 28% of patients were smokers.

16/120 = 13% of patients had an adverse general health factor (listed as rheumatoid arthritis, plumonary disease, previous oncologic (non breast cancer) treatment, diabetes mellitus, cardiovascular disease, alcohol abuse, multiple sclerosis, cowden disease).

10/120=8% of patients (10 breasts) had been treated previously with breast conserving surgery and RT

### **Exclusion criteria**

None reported

### **Population**

number of patients = 120.

### **Interventions**

Aim: to examine patient-related and breast-related risk factors for complications following skin sparing mastectomy with immediate implant reconstruction.

Immediate reconstruction was performed with either a permanent implant (18 breasts) or a tissue expander (156 breasts), with expansion commenced two weeks after surgery and repeated fortnightly, with insertion of a final implant at a mean of 8 months (range 1-22 months) from surgery.

All patients were treated with prophylactic antibiotics during the peri-opertaive period.

Adjuvant therapy (n patients):  
RT: 5

Chemotherapy: 3

Hormone therapy: 9

Combined: 5

Adjuvant therapy was never commenced within the first 6 post-operative weeks, nor delayed due to the immediate reconstruction.

## Outcomes

Recurrence

Survival

De novo breast cancer in patients who received prophylactic mastectomy

Short term post-operative complications (seroma, haematoma, infection, wound dehiscence, ischaemia - occurring within 6 weeks of surgery), also classed as 'severe' if the implant was lost and otherwise, 'mild'.

Potential risk factors modelled in univariate/multivariate analysis for complications:

### 1. 'Patient-related' factors

Age, general health risk factors (rheumatoid arthritis, pulmonary disease, previous oncologic [non breast cancer] treatment, diabetes mellitus, cardiovascular disease, alcohol abuse, multiple sclerosis, cowden disease), smoking, body mass index and unilateral vs. bilateral surgery.

### 2. 'Breast-related' factors

Experience of the general surgeon and plastic surgeon (staff vs. resident), indication (curative vs. prophylactic), implant type (implant vs. expander), duration of antibiotic use, axillary surgery and previous RT.

## Follow up

Minimum 4 years;

Subgroup of patients treated with prophylactic mastectomy: mean 70 months, range 52-91 months.

Subgroup of patients treated with curative intent: mean 73 months, range 53-171 months.

## Results

Complications

Crude rates:

All complications: 40/120 = 33% (patients)

Mild complications: 23/120 = 19% (patients)

Severe complications: 17/120 = 14% (patients)

Patient related factors:

In univariate analysis only age and unilateral surgery were statistically significant risk factors for short-term complications. :

Univariate analysis: patient-related risk factors for short term complications

Factor	OR	95% CI	p
Age (>44 years)	2.23	1.01-4.88	0.05
BMI (>25kg/m <sup>2</sup> )	0.74	0.32-1.69	0.48
Smoking	2.22	0.97-5.12	0.06
General health factors	2.25	0.78-6.53	0.14
Unilateral surgery	2.57	1.15-5.88	0.02

In multivariate analysis there was no statistically significant interaction between age and laterality of surgery.

Breast-related factors:

In univariate analysis no characteristic statistically significantly predicted short term complications.

Univariate analysis: breast-related risk factors for short term complications

Factor	OR	95% CI	p
Prophylactic surgery	1.23	0.62-3.41	0.56
Resident general surgeon	1.25	0.61-2.55	0.55
Resident plastic surgeon	2.21	0.90-5.44	0.09
Definitive prosthesis	1.73	0.63-4.75	0.29
Single dose antibiotics	0.74	0.38-1.44	0.38
Axillary dissection	2.01	0.98-4.12	0.06
Separate incision for axillary dissection	2.35	0.75-7.40	0.14
Previous breast conserving surgery + RT	2.73	0.75-9.87	0.13

Risk factors for loss of implant:

Patient-related factors:

Univariate analysis: patient-related risk factors for severe complications leading to loss of implant

Factor	OR	95% CI	p
Age (>44 years)	2.27	0.78-6.60	0.13
BMI (>25kg/m <sup>2</sup> )	0.75	0.23-2.48	0.64
Smoking	0.82	0.25-2.74	0.75
General health factors	0.85	0.18-4.11	0.84
Unilateral surgery	3.00	0.93-10.0	0.06

Breast related factors:

Univariate analysis: breast-related risk factors for severe complications leading to loss of implant

Factor	OR	95% CI	p
Prophylactic surgery	0.63	0.24-1.64	0.34
Resident general surgeon	1.13	0.40-3.15	0.82
Resident plastic surgeon	5.07	1.75-14.7	0.003
Definitive prosthesis	1.02	0.22-4.83	0.98
Single dose antibiotics	0.85	0.33-2.20	0.73
Axillary dissection	0.99	0.34-2.93	0.99
Separate incision for axillary dissection	1.54	0.32-7.54	0.59
Previous breast conserving surgery + RT	6.62	1.68-26.1	0.007

The only statistically significant risk factors for serious complication resulting in loss of implant were being treated by a resident plastic surgeon and a history prior to mastectomy of breast conserving surgery and RT.

Influence of short term surgical complications on subsequent implant loss (univariate analysis):

Univariate analysis: short term surgical complications as risk factors for severe complications leading to loss of implant

Factor	OR	95% CI	p
Infection	257	42.9-1520	<0.001
Skin problem	9.76	2.86-33.3	<0.001

Seroma	4.28	1.42-12.9	0.01

Recurrence and deaths due to breast cancer:

No recurrence or deaths due to breast cancer occurred in any of the 35 patients treated with prophylactic mastectomy.

In the 85 patients treated with curative intent, 2 patients experienced a local-regional recurrence and 5 patients a distant metastasis. Five of these patients died; the estimated actuarial 5-year overall survival rate in patients treated with curative intent: 96%.

### General comments

Whilst some multivariate analyses were performed, little reporting is made of them in the paper. Most of the findings on risk factors come from univariate analyses that do not account for the combined effects of different factors. In addition two separate groups of factors were considered ('patient-related' and

'breast-related'), which the authors point out, are theoretical and cannot be considered conjointly.

Many results are reported for numbers of treated breasts; this means that data points from patients treated bilaterally are not independent.

The finding that short term complications were strongly predictive of complications leading to implant loss is not surprising; short-term complications and long term complications as events may be measuring the same thing.

Data from the subgroup of 35 patients (29% of the series) treated with prophylactic mastectomy have limited applicability to this question.

Updated 2018

## Chapter 4 – Post-operative and adjuvant therapy planning

### ***4.1 Does progesterone receptor status add further, useful information to that of oestrogen receptor status in patients with invasive breast cancer?***

#### **Short summary**

Four retrospective studies addressed the relative contribution of progesterone receptor (PR) status to the choice and outcomes of endocrine therapy. Ponzzone *et al.* (2006) examined the effects of various endocrine therapies. Two moderate quality cohort studies compared tamoxifen with a non-intervention control (Dowsett *et al.*, 2006 and Stendahl *et al.*, 2006) and a third study re-examined tissue from a trial which had compared tamoxifen with anastrozole versus both in combination (Dowsett *et al.*, 2008). All groups used immunohistochemistry to visualise the presence of hormone receptors but the criteria used to assign negative and positive status was not consistent.

Positive hormone receptor status (either estrogen or progesterone) was associated with significantly longer relapse-free survival compared with negative receptor expression. Weak evidence suggested that the ER+ve/PR-ve sub-group experienced a significant relapse-free survival benefit with tamoxifen therapy compared with controls whilst those with ER-ve status had a poorer relapse-free survival (Dowsett *et al.*, 2006).

Low levels of either ER or PR correlated with a shorter time to recurrence but hormone status did not predict the superiority of anastrozole over tamoxifen that had been found in a large multi-centre RCT (Dowsett *et al.*, 2008).

Tamoxifen therapy was significantly better than control treatment with respect to RFS when either ER or PR were labelled in > 75% of cells at which point PR was also independently associated with favourable overall survival (Stendahl *et al.*, 2006).

Compared with the other three sub-groups, ER-positive/PR-negative status was initially associated with superior prognosis with respect to disease-free survival but after 8 years this advantage was lost and the prognosis was reversed (Ponzzone *et al.* (2006).

There was no strong evidence to support PR being predictive of a response to endocrine therapy despite being independently prognostic for relapse-free survival and/or overall survival. The benefits of PR status appeared to change with time and with the degree of cellular expression. There were no prospective studies comparing the response to a specific endocrine therapy of ER/PR sub-groups and no evidence with regard to treatment decisions based on hormone receptor status.

## PICO question

POPULATION	INTERVENTION	COMPARISON	OUTCOME
Patients with invasive breast cancer	PR testing by Immunohistochemistry (IHC)	ER testing alone by IHC	<ul style="list-style-type: none"><li>• Change in treatment decision e.g. to give endocrine therapy</li><li>• Choice of systemic treatments e.g. endocrine therapy, chemotherapy</li><li>• Response to hormone treatment for ER+/PR+ versus ER+/PR- groups</li></ul>

The search strategy developed from this PICO table and used to search the literature for this question can be found in Appendix A

## Evidence summary

With the direction that papers should be included for appraisal only if endocrine status had been determined by immunohistochemistry, three studies were identified for this topic: one large (n=972) retrospective case series and two moderate quality retrospective cohort studies (total n=1,313). The assignment to positive or negative endocrine status i.e. cut-off point, was not consistent in the three papers. There were no prospective studies comparing the response to a specific endocrine therapy of ER/PR sub-groups and no evidence with regard to treatment decisions.

Dowsett *et al.* (2006) reported the results from a retrospective study of histological material from two large RCTs (NATO and CRC), both of which had compared the use of tamoxifen (TAM) versus no adjuvant treatment for 2 years in post-menopausal women with early breast cancer (pre-menopausal women were acceptable in one trial providing they were node +ve). Archived histological samples from these trials were processed by immunohistochemistry for endocrine status and assessed by operators blinded to the original treatment allocation. Relapse-free survival (RFS) was analysed with respect to endocrine receptor sub-group (ER and PR) status. Assignment of endocrine status involved both signal intensity and the number of labelled cells – this method may be non-standard (for comparison purposes the percentage of ER +ve/PR +ve samples was ~53% of the total).

Comparing positive with negative status, both ER and PR were individually strongly associated with prognosis. By multivariate analysis of RFS, only data for ER -ve status correlated with a lack of significant benefit for tamoxifen compared with the 'no adjuvant therapy' option. When data were analysed for the four ER/PR combinations, ER +ve/PR -ve produced the only relative risk that was significantly in favour of tamoxifen (although the P value was not given).

Stendahl *et al.* (2006) presented a similar retrospective study using archived histological samples from a previous RCT which had compared TAM with a control for 2 years in pre-menopausal women (or post-menopausal if <50 years) with stage II invasive breast cancer. Tumour tissue was re-sampled, prepared for micro-array and labelled for ER and PR status. Quantification of the labelling allowed sub-grouping on the basis of the percentage of cells stained i.e. 0-10%, 11-50%, 51-74% and >75%. The outcomes of interest were RFS and overall survival (OS) and data were presented as separate Kaplan Meier plots for ER and PR and for each of the % expression sub-groups.

It was clear for ER data that the plotted RFS curves for TAM and control treated subjects diverged, starting from the point where ER concentration >10% (regarded in some studies as defining ER +ve) and increasing thereafter. However, the P value presented with each plot did not reach significance until ER >75%. The authors disregarded the P values in reporting this outcome, emphasising the divergence from ER >10% onwards and expressed their opinion that ER was a poor prognostic factor for the response to TAM compared with controls.

The RFS curves for PR showed a different pattern, but with a similar statistical outcome. The survival curves of TAM and control did not diverge visibly until PR expression >75% such that high levels of PR expression might predict an advantage of TAM therapy when compared with control treatment. This PR +ve sub-group comprised 37% of the total study population. These results were similar for PR regardless of ER status and multivariate analyses confirmed a strong reduction in risk of relapse for women with tumours expressing a high level of PR (RR = 48 (95%CI: 0.26-0.88) P = 0.018) and for prolonged OS (RR = 0.52 (95%CI: 0.28-0.99) P = 0.048). The authors concluded that women with PR expression in >75% cells responded favourably to TAM with respect to RFS and OS, regardless of ER status, and that fractionation studies would be preferable to using dichotomous outcomes in the prediction of those patients who would most benefit from TAM therapy.

Ponzone *et al.* (2006) presented data from a large retrospective study of patients who had received endocrine therapy and for whom sufficient clinical and pathological data were available with adequate follow-up. ER and PR status had been determined by immunohistochemistry and the threshold for positive status was 1% labelled cells. The main outcome of interest was disease-free survival (DFS) in relation to endocrine status. The endocrine therapy with which study

participants had been treated varied greatly and included TAM, aromatase inhibitors and GnRH agonists. Many women had also received chemotherapy. Data were not analysed by treatment type.

Multivariate analysis indicated that PR –ve status was a highly significant prognostic factor for DFS in response to therapy for women with tumours of ER +ve status (HR = 2.3 (95%CI: 1.3-3.4) P = 0.002) and this was confirmed by multivariate analysis. However, after 8 years the survival curves for PR +ve and PR –ve showed a cross-over effect meaning that after this time had elapsed PR –ve status was no longer advantageous and instead conferred a poorer prognosis. Women with ER –ve status were not included in these data analyses. This paper presented only very weak evidence in favour of determining PR status in ER +ve tumours in order to identify sub-groups which might gain greater benefit from (unspecified) endocrine therapy.

#### Updated evidence summary

One study updated the evidence on the relative contribution of progesterone receptor (PR) to the choice and outcomes of endocrine therapy. The authors of a retrospective case series (Dowsett *et al.*, 2008) processed archived tissue from the Arimidex, Tamoxifen Alone or in Combination (ATAC) trial to determine endocrine status. The results were correlated with trial outcomes to identify potential prognostic factors in the response to therapy. Low levels of either endocrine receptor, ER or PR, matched to a shorter time to recurrence, results that were similar regardless of treatment assignment. Whilst the ATAC trial had demonstrated a superior efficacy for ATA compared with TAM this advantage was not reflected by endocrine status in the post-trial study.

## Evidence Tables

Ponzzone <i>et al.</i> (2006)
<b>Design:</b> Retrospective case series (prognosis). Evidence level: 3 <b>Country:</b> Italy
<b>Inclusion criteria:</b> Patients who had received endocrine therapy and for whom clinical & pathological data were available Adequate follow-up Written informed consent
<b>Exclusion criteria:</b> N/A
<b>Population:</b> Number of patients = 972, median age = 60.5 years, range: 20-90
<b>Interventions:</b> <b>Interventions:</b> All patients had received endocrine therapy: Tamoxifen for 5 years = 74.6% Tamoxifen + GnRH analogs (2 years) (pre-menopausal) = 13% Aromatase inhibitors for 5 years if TAM contra-indicated (post-menopausal) = 12.3% Chemotherapy (if node +ve or high risk) then endocrine therapy = 39.3%  NB. Chemotherapy: CMF, FEC/FAC or anthracyclines with taxanes.
<b>Outcomes:</b> To verify the influence of PR and Her2 status on ER +ve breast cancer and determine the association of endocrine status with the response to adjuvant endocrine therapy.  Primary outcome: Disease-free survival (from date of surgery to progression) (DFS).
<b>Follow up:</b> Median follow-up = 35 months (range: 1-205 months)
<b>Results:</b> Distribution of endocrine status determined by IHC: ER +ve: Median % = 70.5; Mean % = 67.2 PR +ve: Median % = 50; Mean % = 41.3  ER +ve/ PR +ve = 76% ER +ve/ PR -ve = 18% ER -ve/ PR +ve = 3.5% ER -ve/ PR -ve = 2.4%  Distribution of Her2 status: Median % Her2 +ve = 0 Mean % = 11.9

Her2 +ve status occurred in ER +ve/ PR -ve tumours = 39%  
Her2 +ve status occurred in ER +ve/ PR +ve tumours = 17.7% P=0.000

DFS (univariate analysis of predictive factors) in women with ER +ve status:  
PR status: 0% (-ve) vs  $\geq 1\%$  (+ve) cellular expression: HR = 2.3 (95%CI: 1.3-3.4) P = 0.002  
HER2 status  $\geq 40\%$ (+ve) vs  $< 40\%$  (-ve) cellular expression: HR = 1.9 (95%CI: 1.0-3.5) P = 0.03

DFS (multivariate Cox analysis of prognostic factors):  
PR status: lack of expression: HR = 2.3 (95%CI: 1.3-4.0) P = 0.003 (favouring PR -ve status)  
Her2 status: overexpression: HR = 2.0 (95%CI: 1.0-3.9) P = 0.05 ('borderline')  
Prognostic significance of Her2 only for ER +ve/ PR -ve tumours: HR = 2.4 (95%CI: 1.1-5.3) P = 0.04

**General comments:**

This paper describes a large retrospective study of data collected from 972 women, consecutively treated for primary breast cancer and who had been given endocrine therapy between January 1988 and January 2005 at a single Italian centre.

ER and PR status were determined by IHC (no methodology details given) and if  $\geq 1\%$  cells were positively stained the sample was classed as endocrine +ve. Similarly, Her2 overexpression was assessed by IHC using CB11 or Hercept. Overexpression cut-off was 40% of cells. Finding relationships between endocrine and Her2 status in the response to endocrine therapy was the primary outcome of interest and was conducted using data from women with ER +ve status only (~74%).

A significant effect of PR -ve status as an initial protective factor for early relapse was shown but a cross-over effect occurred at 96 months which meant that, after that time, PR -ve status indicated a poorer prognosis compared with PR +ve. Her2 status continued to be associated with a poor prognosis throughout as the data did not show a significant cross-over effect at any time.

The data analysis takes no account of the, admittedly small, number of ER -ve patients (~6%).

The authors concluded that knowledge of PR status could help to identify which sub-set of women with ER +ve tumours might derive the most benefit from endocrine therapy.

This is a reasonable quality but, nonetheless, retrospective analysis without a comparative control group. The results provide only limited evidence.

ER +ve and/or PR +ve: RR = 0.75 (95%CI: 0.62-0.90) no P value.

**General comments:**

This paper described a study in which archived histological samples from 2 large RCTs were processed for IHC to label biomarkers including ER and PR. Endocrine status was assessed by persons blinded to treatment allocation.

ER and PR were visualised using 1D5 and 1A6 antisera respectively. Antigen retrieval was also used to optimise signal (0.01M citrate buffer at 60°C). In some cases, rather than preparing sections from archived tissue blocks, pre-mounted slides were used (these may have been up to 20 years old). Negative and positive controls and double operator quality control were employed. Receptor status was graded using both staining intensity and number of cells. For the data analysis, ER sections which were either weakly or strongly stained were considered +ve. It is not clear how this method of quantification accords with that employed by other studies.

Data were analysed by ER and PR response separately and together. By univariate analysis, ER and PR status were clearly strong prognostic indicators but, by multivariate analysis, there was no statistical difference in ER +ve, ER -ve, PR +ve or ER -ve individually in the response to tamoxifen treatment compared with no adjuvant therapy (all confidence intervals overlapped, although the RR value for ER -ve was actually non-significant as the confidence interval included '1'). When ER and PR status were combined only the ER +ve/ PR -ve sub-group was associated with a significant advantage to tamoxifen (RR = 0.70 95%CI: 0.49-0.99, no P value given) but, taken together the four sub-groups were not significantly different from one another.

The authors claimed the possibility of a substantial benefit for tamoxifen in women in the ER -ve/ PR +ve group but they base this assertion on a point estimate for RR where the confidence interval of this figure clearly crosses the line of no effect and hence is of no significance. Nonetheless the authors concluded that, in the event of proven ER -ve status, a PR test might be warranted. This sub-group comprises a low percentage of the population of women with breast cancer.

The reporting of these results appears to be somewhat biased within the paper since the authors often refer to 'trends' and 'suggestions' of difference which the statistics do not support. However, the results were well reported and therefore open to a fair interpretation by the reader.

Stendahl <i>et al.</i> (2006)
<b>Design:</b> Retrospective cohort study. Evidence level: 2+ <b>Country:</b> Sweden
<b>Inclusion criteria:</b> Participants in a RCT of tamoxifen (TAM) vs control (2 years) who were: Pre-menopausal women or, if post-menopausal, <50 years With stage II invasive breast cancer
<b>Exclusion criteria:</b> N/A
<b>Population:</b> Number of patients = 500
<b>Interventions:</b> 0.6mm core tumour samples were taken from archived histological samples using H&E stained sections as guidance. Samples were immunostained for ER and PR using tissue micro-array with 6F11 and clone 16 antisera for quantification of ER and PR respectively. Positive nuclei were sub-grouped into fractions (0-10%, 11-50%, 51-74%, >75% and unknown).
<b>Outcomes:</b> From the original RCT: Overall survival (OS) and recurrence-free survival (RFS). Recurrence excluded contralateral breast cancer.
<b>Follow up:</b> Median follow-up = 13.9 years
<b>Results:</b> Distribution of labelled sub-groups, if counting >10% cells labelled as '+ve' (n=500 patients): ER -ve/ PR +ve = 130 (26% of patients) ER -ve/ PR -ve = 13 (2.6% of patients) ER +ve/ PR +ve = 274 (54.8% of patients) ER +ve/ PR -ve = 30 (6% of patients) ER unknown/ PR -ve = 3 (0.6% of patients) ER unknown/ PR +ve = 7 (1.4% of patients) ER -ve/ PR unknown = 8 (1.6% of patients) ER +ve/ PR unknown = 20 (4% of patients) Endocrine status unknown = 15 (3% of patients)  NB. PR +ve expression of >75% cells (i.e. highly expressed) occurred in 168 (37%) of patients.  Authors stated that the benefit of TAM vs no treatment became 'apparent' from the point at which ER were expressed in >10% cells and that this benefit increased as ER expression increased hence ER +ve status was predictive for a benefit with TAM compared with controls. However, no relative risk (RR) evaluation was presented and the

P value of the difference between curves on the Kaplan Meier graph for RFS showed significance only when ER >75% of cells (P=0.03) even though the gap between the 'TAM' and 'no treatment' curves diverged more as ER positivity increased.

Authors stated that the benefit of TAM vs no treatment when gauged by PR expression in tumour material, regardless of ER status, was not apparent until PR was labelled in >75% cells at which point RR for RFS = 0.41 (95%CI: 0.24-0.69) P = 0.001 and RR for OS = 0.46 (95%CI: 0.26-0.83).

Further analysis revealed similar results for PR >75% regardless of ER status and a multivariate analysis of outcomes when PR >75% gave a RR for RFS = 0.48 (95%CI: 0.26-0.88) P = 0.018 and for OS = 0.52 (95%CI: 0.28-0.99) P = 0.048

**General comments:**

This paper presents the results from a post-RCT study in which archived histological samples were processed for ER and PR sub-group status using tissue micro-array. Survival outcomes in response to two years tamoxifen therapy vs no treatment were then analysed by endocrine sub-group. Note that staining intensity did not form part of the endocrine status assessment.

Fractionation of the ER/PR labelling allowed predictive sub-groups to be identified for example, where previously PR >10% may not have demonstrated independent prognostic strength in determining survival outcomes, PR >75% was clearly advantageous to both RFS and OS, regardless of the ER status.

The authors stated that, whatever the cut-off value for ER status, survival outcomes were not improved by TAM compared with no treatment unless PR was highly expressed but in tumours highly expressing PR, ER status alone did not predict outcome. The purpose of their study was to show that fractionation of endocrine receptor status could provide more useful information in making treatment decisions than dichotomised outcomes only.

Whilst the study was of good intention there was a lack of statistics to support some evidence statements and appeared to be contradiction in the reporting of the significance, or otherwise, of ER status. There were no details of patient demographics.

Dowsett *et al.* (2008)

**Design:** Retrospective case series (prognosis). Evidence level: 3

**Country:** Multi-national

**Inclusion criteria:**

Postmenopausal women with histologically proven operable invasive breast cancer  
Completion of primary treatment.

Assignment to either the anastrozole (ANA) or tamoxifen (TAM) arms of the Arimidex, Tamoxifen Alone or in Combination (ATAC) trial

**Exclusion criteria:**

Assignment to the combined arm of ANA + TAM in the ATAC trial

Know to have had endocrine –ve tissue

**Population:**

Number of patients = 9366 (original trial) of which tissue from 1856 women was successfully stained and combined with patient outcomes data. Median age = 63 years.

**Interventions:**

Original ATAC trial consisted of three treatment arms: ANA at 1 mg vs TAM at 20 mg vs combined treatment with ANA + TAM. The combined arm was closed after a median follow-up of 33 months having shown no greater efficacy than TAM alone.

Archived tissue was collected from two centres but processed in only one for endocrine receptor (ER and PR) status and Her2 status using standard immunocytochemistry.

**Outcomes:**

To identify molecular characteristics of tumours that might indicate a benefit of ANA vs TAM. Correlating endocrine status to time to relapse (TTR).

**Follow up:**

Median follow-up of original study = 68 months.

**Results:**

1782 patients were ER +ve and/or PR +ve (78.5% were PR +ve).

TTR for ANA vs TAM in original ATAC group (n=5216): HR = 0.74 (95%CI: 0.64-0.87) (P = 0.0002) for endocrine +ve tumours

TTR for ANA vs TAM in post-study group (n=1856): HR = 0.69 (95%CI: 0.53-0.91) (P = 0.008) for endocrine +ve tumours.

Recurrence was slightly lower for both treatment arms in the post-study group than in the original ATAC group.

Relationship between ER status and TTR for ANA and TAM patients:

TAM: P = 0.078 (NSD)

ANA: P = 0.0009

Relationship between PR status and TTR for ANA and TAM patients:

TAM: P = 0.0012

ANA: P < 0.0001

After 5 years of treatment with ANA, 2.6%, 5.1%, 8.3% and 13.2% of survivors were found in the highest, second highest, third highest and lowest PR +ve quartiles respectively (P < 0.0001).

By central analysis:

TTR for ANA vs TAM in post-study group: HR = 0.72 (95%CI: 0.52-1.01) for ER +ve/PR +ve tumours

TTR for ANA vs TAM in post-study group: HR = 0.68 (95%CI: 0.40-1.17) for ER +ve/PR –ve tumours (NSD).

Univariate analyses:

ANA arm (n=857):

ER status: HR = 0.83 (95%CI: 0.73-0.95) (P = 0.004)

PR status: HR = 0.89 (95%CI: 0.84-0.94) (P < 0.0001)

TAM arm (n=829):

ER status: HR = 0.90 (95%CI: 0.81-1.00) (P = 0.057) (NSD)

PR status: HR = 0.92 (95%CI: 0.87-0.97) (P = 0.001)

Multivariate analyses:

ANA arm:

ER status: HR = 0.89 (95%CI: 0.79-1.01) (P = 0.07) (NSD)

PR status: HR = 0.92 (95%CI: 0.87-0.99) (P = 0.016)

TAM arm:

ER status: HR = 0.94 (95%CI: 0.84-1.04) (P = 0.2) (NSD)

PR status: HR = 0.93 (95%CI: 0.88-0.99) (P = 0.014)

**General comments:**

This paper presents the findings from a retrospective exercise using tissue from a large multi-centre trial comparing ANA with TAM therapy for women with early stage breast cancer. Archived specimens were centrally processed for endocrine (and Her2) status, the results of which were compared with patient outcome data to identify possible prognostic factors.

Assessment of endocrine status from stained sections was performed by personnel blind to any other factor. ER was quantified using an H-score (percentage of cells weakly stained plus 2x the number of cells moderately stained plus x3 the number of cells strongly stained where a positive score was >1). PR was scored simply as percentage of cells stained where > 10% was regarded as positive.

The populations in the original ATAC trial and in this smaller post-trial group were similar in most respects except that in this study more women had node negative tumours and fewer women had received adjuvant chemotherapy.

Univariate analysis showed that both ER and PR status were strong prognostic factors for TTR where low receptor expression was associated with shorter TTR. These analyses were not affected by treatment choice between ANA and TAM. Multivariate analyses, which included nodal status, tumour size and grade, produced P values for ER status of 0.023 (ANA) and 0.32 (TAM) and for PR status of 0.09 (ANA) and 0.032 (TAM).

The authors comment on the apparently contradictory result from the main ATAC trial in which a greater relative benefit of ANA vs TAM was conferred on patients with ER +ve/PR -ve status compared with ER +ve/PR +ve whereas this study shows no significant difference between these groups. They suggest firstly that the ATAC analysis was unplanned but that also the present analysis comprised smaller sub-groups. Hence the results remain contradictory. It would not be possible to determine if the relationship

between endocrine status and TTR occurs naturally or is influenced by therapy.

Several authors disclosed potential conflicts of interest.

## **4.2 What are the indications for adjuvant chemotherapy in patients with early invasive breast cancer?**

Adjuvant! On-line: review of evidence concerning its validity, and other considerations relating to its use in the NHS

A report by Jonathan Gribbin & Robyn Dewis

### **Introduction**

The Guideline Development Group (GDG) for early and locally advanced breast cancer proposed a piece of work to assess the validity of Adjuvant! On-line as a tool to assist with clinical decisions, about adjuvant therapy, in patients with early invasive breast cancer. This document summarises the methodology used to assess this, and the key findings including a description of the Adjuvant! product, the methods used to develop it, and commercial issues associated with recommending its use.

Adjuvant! can be accessed at [www.adjuvantonline.com](http://www.adjuvantonline.com)<sup>1</sup>. It is a tool for assessing the risks of an individual patient developing recurrent disease and/or dying within 10 years, when receiving specific treatment (on the basis of well validated factors such as age, menopausal status, oestrogen receptor (ER) status, number of involved axillary nodes etc.). Doctor and patient can use the tool together to decide on the most appropriate adjuvant treatment regimen (chemotherapy, hormone therapy, or none). Adjuvant! is a decision aid and does not direct towards a specific treatment regimen.

This appraisal has been proposed as an alternative to a question that had been framed in the PICO question 'What are the indications for adjuvant chemotherapy in patients with early invasive breast cancer?'. The GDG agreed that this PICO question covered huge topic areas and would need to be addressed using a very long list of search terms which the group were unable to specify satisfactorily.

Noting that Adjuvant! is already in use in the UK and is designed to incorporate the Oxford Overview meta-analyses, an alternative, pragmatic approach was proposed, namely of undertaking an appraisal of evidence about the validity of Adjuvant!. Two SpR/SpTs providing support to the GDG were asked to undertake this appraisal by reviewing what is known about the tool. The following represents their understanding of the research question, and the approach they took in addressing it.

### **Research question**

The primary purpose of the appraisal was to summarise and critique what is known about Adjuvant!, and its validity as a tool for supporting clinical decisions about adjuvant chemotherapy, in UK patients, with early invasive breast cancer. Where it exists, evidence regarding its usefulness is also included.

This is a narrative report incorporating a formally referenced review of the published literature, together with other information provided by Adjuvant!. It addresses:

- A description of Adjuvant!: its intended purpose and use

- Current usage in the NHS
- Methodology underpinning Adjuvant!, including how it was developed and how it is updated.
- Any caveats/issues/known shortcomings highlighted to Adjuvant! users
- An appraisal of published evidence about Adjuvant!'s validity
- An appraisal of any published evidence regarding its usefulness
- General assumptions/issues/uncertainties in applying this tool based on USA data to NHS patients
- Commercial considerations – implications for Adjuvant!'s validity and/or practical use
- Licensing considerations – implications for unrestricted access to Adjuvant!
- Any other practical considerations relating to Adjuvant!'s use in the NHS.

*Specific questions raised by GDG members that were included within scope*

1. To what extent does the SEER database on which the tool is based consider adverse reactions?
2. What is the applicability of the USA data in the SEER database to UK patients in the NHS?
3. What commercial relationships underpin the design and maintenance of the system?
4. Are there any current/future licensing considerations for NHS users?
5. What are the key practical considerations relating to its use?

*Excluded from scope*

The decision about which chemotherapy or hormone therapy regimen to recommend are separate questions, which fall outside the scope of this appraisal. This appraisal focuses on the validity of the Adjuvant! tool itself.

This approach highlights issues relating to major assumptions inherent in the methodology which are apparent from a consideration of Adjuvant!'s methodology and the published literature. However, it does not provide a systematic, exhaustive breakdown of all the individual factors, algorithms and statistical models on which the Adjuvant! model may be based (except where these are appraised in the published literature). Similarly, this relatively short piece of work is not intended to be a critical appraisal of the Oxford Overviews (whose meta-analyses are fundamental to Adjuvant!).

**Search strategy**

*Sources*

The Ovid search engine was used to interrogate MEDLINE database (1950 to October 2007) and EMBASE. A subsequent search was also made against SIGLE for relevant grey literature.

*Search parameters*

A pilot search experimented with a number of synonyms for Adjuvant!. The final definitive search was executed using the following search criteria and the above source.

**Table 1 Parameters and logic used in the automated search**

Search	Criteria applied	Date run	Result
--------	------------------	----------	--------

1	Breast neoplasm\$ or breast cancer\$ And (decision making or computer assisted or computer\$ or decision support or decision support systems or software or decision support techniques) And (adjuvant\$)	15/10/07	615 papers
---	---	----------	------------

#### *Further screening & supplementary information*

The results of the automated search were manually screened, by reading the abstracts, in order to identify relevant articles and to exclude all other papers that were not reporting research into Adjuvant! or similar decision support tools.

Adjuvant Inc. was invited to respond directly to specific questions that the literature does not address. These responses are incorporated in the findings.

#### *Search results*

Executing the automated search strategy resulted in the identification of 615 papers satisfying the search parameters. Manual screening of abstracts resulted in the exclusion of all but 9 of these papers<sup>2-10</sup>. Excluded papers included studies of specific treatments, risk communication and other methods of displaying outcomes e.g. prognostic tables.

## **Findings**

#### *Adjuvant! Online tool*

The purpose of Adjuvant!<sup>1</sup> is to assist health professionals and patients with early stage breast cancer discuss the risks and benefits of adjuvant therapy after surgery. It does this by presenting estimates of the risk of cancer-related mortality or relapse, which can be used in consultations. It is intended to be operated and interpreted by oncologists and suitably qualified health professionals. It is not intended to replace clinical judgement and is not designed to be used by patients.

#### *Conceptual design*

The concept behind Adjuvant! is that the quality of decision-making about adjuvant therapy is enhanced in consultations where clinicians can communicate to patients the net benefit of various adjuvant therapies<sup>3</sup>. Therefore Adjuvant! is designed to:

- 1) Estimate the 'baseline' risk of mortality or relapse for patients without adjuvant therapy
- 2) Estimate the proportion of negative events that given therapies are known to prevent
- 3) Apply this effect to the baseline risk so that direct comparisons can be made of the estimated risks of mortality or relapse between treatments and with no treatment.

#### *User functionality*

The current version of Adjuvant! is version 8. User functionality comprises facilities to:

- 1) Enter patient information including age, co-morbidities plus tumour information including size, oestrogen receptor status and number of involved nodes. This is

- used to estimate risk at 10 years of breast cancer related death or relapse without additional therapy.
- 2) Display information about the efficacy of different therapy options, with the option of overriding the estimated efficacies.
  - 3) Derive estimates of risk at 10 years of breast cancer related death or relapse for the treatments selected by the user.
  - 4) Print results, access on-line help and links to sources of evidence.

Underlying this user functionality there are tables and algorithms, which aim to encapsulate evidence of effectiveness according to the Oxford Overviews. These are maintained by Adjuvant! Inc. User access to these is limited to that described above.

User access to Adjuvant! is controlled via a logon screen requiring a username and password. Registration for a username and password is open to users willing to sign a license agreement. In doing so they agree that they are a suitably qualified medical professional. There is no additional authentication of this at registration.

#### *Technological implementation*

Users access Adjuvant via a desktop browser with an Internet connection to [www.adjuvantonline.com](http://www.adjuvantonline.com). User functionality is implemented in a Java-based program which is only present for the duration of the user's session. Some functionality also requires Adobe Acrobat and/or a printer. The server functionality runs under a Unix operating system. No patient identifiers are entered into Adjuvant!, thereby avoiding any risk or concern relating to patient confidentiality.

Further evaluation of the physical implementation is beyond the scope of this study.

There are also versions of Adjuvant designed to run on Palmtop or PocketPC. These are also beyond the scope of this study.

#### *Control and licensing*

Adjuvant! is owned by a US-based company called Adjuvant Inc. Adjuvant Inc. and all IP rights in the Adjuvant! tool are owned by Dr Ravdin, who has created and developed the tool over a period of more than 10 years. Dr Ravdin's stated motivation is academic; the venture has not been for the purpose of realising financial profit<sup>11</sup>.

Over the years, funding has been secured from government, industry and research foundations. None of these sources of funding exercise editorial purview over the content of releases. Adjuvant! carries no advertising and there are no other sources of revenue.

Licenses to use Adjuvant! are free of charge. Dr Ravdin states they will remain free of charge indefinitely; there is no plan to charge a license fee either now or in the long term<sup>11</sup>.

#### *Maintenance and development*

Maintenance of functionality in the current version of the tool is undertaken by Adjuvant! Inc., which secures part-time or occasional assistance from a small group of relevant specialists.

Help files are updated to reflect the current literature. The user functionality and underlying methodology is updated less frequently; recent versions of the tool have incorporated only minor changes.

The direction and timing of these developments is determined by Dr Ravdin, according to the publication of new evidence, requests from users, and the availability of personnel to implement the changes. In the past, new versions have been released around the time of major research meetings, e.g. ASCO, San Antonio Breast Cancer Symposium.

Currently efforts are focussed on developing the next major release of Adjuvant!, which will incorporate recent trial evidence relating to human epithelial growth factor receptor (HER2) and trastuzumab. Beyond this, there is no formally documented plan describing the development path for the product.

Users are not required to undertake any maintenance.

#### *Current usage in the NHS*

Dr Ravdin reports that there were 2,978 registered active users in the UK as at July 2007 (which represents about 7% of the total registered user base of more than 42,000). This is based on information supplied at registration which is not authenticated.

Estimates of frequency of usage are derived from the number of Adjuvant! sessions that ran in a given period of time. In the first six months of 2007 the Adjuvant! platform delivered 110,800 user sessions. Based on the crude assumption that frequency of usage is the same across all users, this represents an estimated 8,000 user sessions in the same period for users registered in the UK. It is not possible to determine how many of these sessions supported actual consultations with NHS patients.

A survey of usage amongst oncologists in the UK is planned but will not report before July 2008 at the earliest<sup>12</sup>.

#### *Underlying Methodology - derivation of baseline risk estimate*

##### Population

The data used for the baseline risk estimate was derived from the SEER database (Surveillance, Epidemiology and End Results Program in the USA)<sup>13</sup>. Adjuvant! was based upon database 9 which covered 14% of the US population<sup>14</sup>. Detailed information was not available on the breakdown for the SEER 9 population but studies have assessed its similarity to the US population:

1. The SEER population is similar to the US population in terms of age and sex distribution. The US population has larger percentage of the population in the under 55 age groups and fewer in the over 55 age groups, when compared to the population of England and Wales<sup>15</sup>.
2. The SEER population over represents certain ethnic groups, e.g. Native American/Hawaiian and some South East Asian groups compared to the US population. This is related to the States that are included in the database e.g. Alaska and Hawaii<sup>13</sup>.
3. The ethnic mix of the US population differs from that of England and Wales. Only broad categories can be considered due to differences in categorising ethnicity, but broadly speaking in the US there are lower percentages of white and mixed races, with higher percentages of Black and Other Races<sup>13</sup>.
4. Socioeconomic data in the SEER database is of poor quality.

5. Date and cause of death are recorded. Date of death is considered robust, however cause of death is of poor quality<sup>14</sup>.

As survival is analysed in terms of age group the differences in the age of the population is unlikely to affect the generaliseability of the data. The difference in ethnicity, however, is likely to affect this. The incidence of breast cancer is highest in the white population, but mortality is highest in the black population. A program based on this data, that does not take ethnicity into account, will tend to overestimate survival in the black population and underestimate in the white. It is difficult to assess what effect this would have on other ethnic groups or to know if survival differs in these ethnic groups in the United Kingdom.

### Selection

Ravdin et al<sup>3</sup> selected a population from the SEER database for the development of Adjuvant!. Women who met the following criteria were included in the calculations of baseline risk:

1. Had invasive, unilateral and non-inflammatory breast cancer
2. Had received definitive surgery and axillary staging with at least 6 lymph nodes
3. Had data on tumour size, number of nodes sampled and the number of positive nodes.

Women were specifically excluded from the calculations of baseline risk for the following reasons:

1. Those aged under 35 years.  
This group of young women were observed to have a worse prognosis than the other age groups. (A correction applied to allow for this group of women is described below.)
2. Those aged over 59 years. This group of women was believed to be healthier and have better access to health care. Analysis of this group revealed that women with breast cancer appeared to have better survival than the general US population of the same age.

### Survival

The SEER data were then used to calculate survival. This was observed survival for 5 years that was then extrapolated to 10 years, as the data were insufficient to cover this period. Relative survival was used, which makes an adjustment for age specific death rates from other causes. This survival estimate is based upon the tumour size, the number of positive nodes and the oestrogen receptor status of the tumour. There are some assumptions made in calculating survival for Adjuvant!.

1. Impact of ER status. There were data issues around ER status that led to estimates inconsistent with what would be expected from the literature. For this reason a relative risk of 1.3 was applied to predict survival in ER positive and negative individuals (based on evidence from long-term studies of node negative patients).
2. The effect of stage of tumour and adjuvant therapy received. An assumption was made that a percentage of the population would have received adjuvant therapy. In order to find the 'base line risk', the survival without the use of adjuvant therapy, it was assumed that at stage one the adjuvant therapy would have improved outcomes by 15% and at all other stages by 30%.
3. Constant Hazard. Survival calculations assume that the risk of death/recurrence remain constant throughout the study period considered.

### Relapse

The SEER database does not hold information on relapse of disease. An assumption is made that, on average, individuals survive for three years after relapse of breast cancer in order to calculate the risk of relapse.

### Other issues with UK US comparisons

Other differences between the US and UK population were also considered. There is a lack of universal access to health care in the US, which may affect the survival of certain groups within the US. However, individuals' data were only entered into the study when they had received initial surgery and staging and so should not affect applicability to the UK population. There are also differences in attitudes towards healthcare between the two countries, e.g. the UK population tend to choose less radical surgery than the US population<sup>16</sup>. Although this may lead to differences in decisions made when using the tool it does not affect its validity for the UK.

### Estimating negative outcomes averted

Adjuvant! applies an estimation of negative outcomes averted to the baseline survival to give an estimation of survival following one or more adjuvant therapies<sup>3</sup>. Estimation of negative outcomes averted is quantified in terms of the proportion risk reduction (PRR), i.e. the proportion of the baseline risk, which is reduced by each therapy.

PRR for specific therapies are derived from the Overviews. They are incorporated into Adjuvant! to derive estimates of breast cancer-specific mortality. To avoid the possibility of gross error in estimating the breast cancer specific mortality of over 70 year olds (in which group most mortality is probably non-breast cancer-specific), Adjuvant! applies the PRR for 50-69 years for women 70 years or older. When the operator is using the tool to model outcomes for patients over 70 years of age, Adjuvant! warns the user about the possible effect of this simplifying assumption.

To model the relative value of various chemotherapy regimen Adjuvant! groups treatments into three distinct "generations", based on their perceived efficacy and toxicity. Prompts appear on screen at relevant points in the user session with details of the basis on which this grouping has been done. The prompts also outline the key inferences that Adjuvant! makes to estimate relative efficacy (e.g. of a third generation regimen compared to none) and points the user to further information contained in the Help files.

### Applying calculation to previous baseline

The Oxford Overviews report the results of clinical trials. Few trials for cancer therapy consider the effect of one treatment against placebo/no treatment. The majority report the risk reduction of using one treatment over another. According to Ravdin<sup>3</sup>, the Overviews suggest that treatment effects are independent of other treatment used. Adjuvant! uses this assumption, through the following formula, to calculate the proportionate risk reduction achieved by the use of a specific adjuvant therapy:

$$\text{PRR combined therapy} = 1 - [(1 - \text{PRR therapy 1}) \times (1 - \text{PRR therapy 2})]$$

### Validation

Since Ravdin et al's 2001 paper describing the tool and its methodology, there have been two further published studies that assess the validity of the Adjuvant! tool. The tool is currently being compared against two further European registers<sup>11</sup>.

#### Prospective population-based validation

Olivotto et al<sup>8</sup> set out to independently validate Adjuvant! by comparing the observed 10 year outcome of each of 4083 patients with stage 1 and 2 breast cancer on a British Columbian register with the outcome predicted by Adjuvant!.

Taking the cohort as a whole, they found a high degree of agreement between the predicted and observed overall survival and breast cancer specific survival. They also analysed the differences between observed and predicted outcomes for specific subgroups which in most cases were within 2% or not significantly different (at  $P > 0.05$ ).

For patients younger than 35 years of age or with lymphatic or vascular invasion (LVI) Adjuvant! over-estimated the survival. After the operators applied their judgement to adjust for LVI using the prognostic factor impact calculator tool within Adjuvant! (PFIC), the 10 year predictions were no longer significantly different.

The strength of this study is that it provides validation of Adjuvant! predictions using an external reference population. The strength of evidence it provides in this assessment is limited by the following factors:

- The study was undertaken on version 5 of Adjuvant!
- It is implicit that the operators were very familiar with the tool, and may have included its author. It is not clear whether an "average" operator would achieve the same level of agreement when making adjustments using the prognostic factor impact calculator (PFIC).

In summary, the study provides independent validation of an earlier version Adjuvant!. For women aged 30 to 59 years of age whose adverse prognostic factors are automatically accounted for within the tool, Adjuvant! provides reliable predictions of the benefits of adjuvant therapy. The reliability of predictions for other groups depends in part on the knowledge and judgement of the operator in making adjustments using the PFIC.

It should be noted that more recent versions of Adjuvant! incorporate an adjustment to "correct" the overestimation of survival for young ER positive patients<sup>11</sup>.

#### Clinician-based validation

Loprinzi et al<sup>4</sup> describe the development of an algorithm to calculate 10-year outcomes for breast cancer patients. As part of this, they asked 11 US oncologists for their estimates of 10-year disease-free survival. The mean of these estimates were compared to predictions generated by Adjuvant!. The degree of correlation was not measured formally; the graphical representation of the correlation suggests a reasonable degree of agreement.

These published data provides weak evidence for the validity of Adjuvant!. However, the fact that the predictions of oncologists vary supports the rationale that there is a need for a tool, which provides evidence-based predictions in an understandable format.

#### Impact and usefulness

The purpose of Adjuvant! is to provide predictions of risk that support dialogue between clinician and patient about the most appropriate adjuvant therapies for that patient. There is little published literature evaluating the impact of Adjuvant! on these interactions, nor on the degree to which clinicians correctly handle the tool or what meaning patients ascribe to the predictions. A USA study<sup>7</sup> of the effects on treatment choices of Adjuvant! compared to a well presented information pamphlets did not find statistically significant differences between the groups. After adjusting for disease-related and socio-demographic confounders, they found that those who used Adjuvant! were less likely to choose adjuvant treatment (OR 0.32 95%CI 0.12-0.84). This is broadly consistent with the findings of an apparently related study<sup>9</sup>.

A study of 102 treatment management decisions in a Hong Kong oncology centre<sup>10</sup> found that clinicians changed their decision in 13 instances after taking into consideration the predictions made by Adjuvant!. Based on analysis of this decision-making, Adjuvant!'s impact was attributed to: the distinction it makes between the marginal benefits of intervention compared to prognosis per se, the deeper consideration of therapeutic goals and costs for individuals which it enables, a comparison of the relative benefits of different treatments, the quantification of iatrogenic risks. The study found that treatment decisions continued to be strongly influenced by factors *omitted* from the version of Adjuvant used in the study (e.g. lymphovascular invasion and HER2 expression). Clinicians in this study tended to ignore the adjustments to risk recommended by the programme on the basis of low tumour grade when these adjustments were perceived to conflict with other indicators such as node-positivity. Clinicians' attitudes to the utility of Adjuvant were varied but the study authors formed the impression that, in the context of case discussions, the tool enabled groups to achieve consensus more quickly.

There is a body of literature concerning the impact of *other* decision tools on a range of patient-clinician interactions. For example, a systematic review<sup>17</sup> of 17 RCTs did not show a consistent impact on patient knowledge and satisfaction. More recently, there has been at least one trial to evaluate the effect of a decision support tool on the knowledge and satisfaction of breast cancer patients in particular<sup>18</sup>. A full review of this literature is beyond the scope of this assessment.

## Summary/Conclusions

The predictions made by Adjuvant! are based on a published methodology, which has been updated periodically as evidence of treatment effectiveness and data on risk factors becomes available.

Help files and published descriptions of the tool make clear some of the assumptions and limitations that underpin the methodology. The impact of these individual assumptions is difficult to assess, and beyond the scope of this paper. Adjuvant! deals with key uncertainties by alerting the user to them at relevant points.

Survival estimates are derived from a US population. Quantifying the impact on survival of socio-economic background and of ethnic differences between the US and UK populations is difficult.

The strongest evidence of Adjuvant's validity for the UK is derived from comparisons between its predictions and observed outcomes using a Canadian population. This study found its predictions to be reliable for most groups. Since that study, an adjustment has been applied to 'correct' the predictions made for a subset of younger patients.

Further validation is under way using European populations. Dr Ravdin would welcome similar validation against a UK population.

Weaker evidence for its validity includes comparisons of its predictions with the predictions of clinicians. The development path for Adjuvant! appears to be consistent with a product which intends to remain evidence-based.

Dr Ravdin's stated intention is that license to use Adjuvant! will remain free of charge. This together with its web-based design means that the cost to users of using Adjuvant! should remain very low.

There are only two trials assessing the impact of Adjuvant! in doctor-patient interactions. These indicate that in a USA setting patients considering adjuvant treatment were less likely to select adjuvant treatment if their consultation involved use of Adjuvant! instead of an information pamphlet. A third study of 102 clinician decisions about patient management found that using Adjuvant! resulted in a change of decision in 13 cases, and that clinicians' views of the tool's utility were varied.

### ***4.3 What is the optimal time interval from completion of definitive surgery to commencement of adjuvant therapy?***

#### **Short Summary**

There is a moderate volume of evidence to address the sequencing of adjuvant therapies, including several randomised trials. Non-randomised, retrospective studies of the interval between surgery and adjuvant therapy were also available.

#### **Sequencing Of Adjuvant Therapies**

*Concurrent adjuvant chemotherapy/radiotherapy versus chemotherapy followed by radiotherapy:* There is high quality evidence from randomised controlled trials (RCTs) (Hickey *et al.* 2006; Calais *et al.* 2005; Toledano *et al.* 2007) that suggest there is no advantage arising from concurrent adjuvant chemotherapy/radiotherapy versus sequential chemotherapy followed by radiotherapy in terms of local recurrence, distant metastases and overall survival. RCT evidence on acute toxicity for this comparison is not consistent, since there is no difference with regard to some toxic effects, whereas other toxic effects are more common following either concurrent therapy, or sequential therapy. RCT evidence suggests that late toxic effects are more common following concurrent therapy than sequential therapy and that in the subgroup of lymph node-positive patients local recurrence-free survival is higher following concurrent therapy than sequential therapy.

*Radiotherapy followed by chemotherapy versus chemotherapy followed by radiotherapy:* Further RCT evidence (Hickey *et al.* 2006; Huang *et al.* 2003) suggests there is no advantage arising from radiotherapy followed by chemotherapy versus chemotherapy followed by radiotherapy in terms of distant metastases and overall survival. RCT evidence is suggestive of a higher rate of neutropenic sepsis in patients who receive radiotherapy before chemotherapy but with no difference for other toxicity outcomes. One meta-analysis of data from observational studies suggests that loco-regional recurrence is higher where chemotherapy precedes radiotherapy, compared to radiotherapy then chemotherapy.

*Early versus late chemotherapy:* RCT evidence from the International Breast Cancer Study Group (1997) suggests there is no difference in 5-year disease-free survival or overall survival arising from early chemotherapy given over the first three months following surgery versus delayed chemotherapy given between 9 and 15 months following surgery.

#### **Interval Between Surgery And Start Of Adjuvant Therapy**

*Interval from surgery to radiotherapy:* There is considerable high quality evidence that addresses this clinical issue (Huang *et al.* 2003; Whelan *et al.* 2003; Hershman *et al.* 2006a). Evidence from a meta-analysis of data from

observational studies suggests that locoregional recurrence is more likely if radiotherapy is delayed more than 8 weeks following surgery. Other observational studies do not consistently indicate that a longer interval to start of radiotherapy is associated with greater likelihood of locoregional recurrence, but these studies consider different lengths of interval. Evidence from a meta-analysis of data from observational studies suggests there is no difference in the rate of distant metastases arising from an interval to radiotherapy of 8 weeks or more, compared to an interval of less than 8 weeks. Authors of a Canadian guideline based upon a systematic review conclude that evidence does not support definition of an optimal interval between surgery and radiotherapy (Whelan *et al.* 2003).. One retrospective cohort study (Hershman *et al.* 2006a) suggests that in elderly patients who receive radiotherapy and no chemotherapy, higher mortality is observed where radiotherapy is given 3 months or more following surgery, compared to within 3 months of surgery. In the same study numerous demographic and tumour-related variables were also associated with mortality outcomes, making interpretation difficult.

Other observational studies found that disease free and overall survival were not adversely affected by increasing delay to the start of radiotherapy in the first three months after surgery (Benchalal *et al.* 2005; Jobsen *et al.* 2006; Mikeljevic *et al.* 2004). A large UK cohort study of 7800 women found that overall survival was adversely affected only in those whose radiotherapy was delayed for at least 5 to 6 months after surgery (Mikeljevic *et al.* 2004).

*Interval from surgery to chemotherapy:* One retrospective cohort study (Hershman *et al.* 2006b) suggests that in elderly patients who receive chemotherapy with no radiotherapy prior to chemotherapy, higher mortality is observed where chemotherapy is given 3 months or more following surgery, compared to within 3 months of surgery. In the same study numerous demographic and tumour-related variables were also associated with mortality outcomes, making interpretation difficult.

Other cohort studies found increasing delay to the start of adjuvant chemotherapy in the first 3 months after surgery was not associated with poorer disease free or overall survival (Cold *et al.* 2005; Colleoni *et al.* 2000; Lohrisch *et al.* 2006; Sanchez *et al.* 2007; Shannon *et al.* 2003). Colleoni *et al.* (2000) reported that disease free survival was adversely affected by delays of three or more weeks in the sub-group of women with ER-negative disease. Another study reported that disease free and overall survival were adversely affected only when the start of chemotherapy was delayed until at least three to six months after surgery (Lohrisch *et al.* 2006).

### Evidence Summary

There is a moderate volume of evidence to address the sequencing of adjuvant therapies, including several randomised trials. Non-randomised, retrospective studies of the interval between surgery and adjuvant therapy are also available.

Published randomised trials compare different *sequences* of adjuvant therapies following surgery, three of which have been summarised in a high quality Cochrane systematic review (Hickey *et al.* 2006). Although not stated originally in the PICO formatted research question, the GDG communicated that outcome data following different sequencing strategies are of interest and for this reason, are reported here.

Only non-randomised studies exist of the effect of the *interval* between definitive surgery and start of adjuvant treatment on important outcomes (e.g. recurrence, survival). However numerous large, retrospective studies addressed this issue so an arbitrary inclusion threshold of studies with at least 1000 patients was used.

The RCT findings are consistent. The findings of the cited observational studies are inconsistent and should be interpreted with caution. In particular where meta-analyses have been performed using data from observational studies (i.e. Huang *et al.* 2003) there is the risk that confounding and bias in the primary studies contribute to a precise, but spurious pooled estimate. Authors of a Canadian clinical guideline supported by a systematic review (without meta-analysis) report that for some outcomes the evidence is inadequate to support treatment decisions (Whelan *et al.* 2003).

The SECRAB trial is in progress, comparing a sequential schedule of chemotherapy followed by radiotherapy with a synchronous schedule of radiotherapy administered during the chemotherapy regimen, but no data from this trial are available yet.

Since the Cochrane Review of randomised studies by Hickey *et al.* 2006 (Hickey *et al.* 2006) evaluates the effect of sequencing of adjuvant RT relative to adjuvant CT, further primary non-randomised studies of sequencing were excluded.

However data from some such studies was included in two systematic reviews that are cited here (Huang *et al.* 2003; Whelan *et al.* 2003)

## **SEQUENCING OF ADJUVANT THERAPIES**

### **1. Concurrent adjuvant chemotherapy/radiotherapy versus chemotherapy followed by radiotherapy**

In a meta-analysis of data from two RCTs (Arcangeli 2006; Calais 2004), the Cochrane review (Hickey *et al.* 2006) found no statistically significant difference between concurrent chemotherapy/radiotherapy versus chemotherapy followed by radiotherapy in terms of ipsilateral local recurrence [OR (concurrent:sequential) 1.30; 95% CI 0.45 to 3.77;  $p=0.63$ ] and distant metastases [OR (concurrent:sequential) 1.43 95% CI 0.86 to 2.37,  $p=0.16$ ]. Only one included trial (Arcangeli 2006) reported overall survival, which did not statistically significantly differ at 5 years follow-up, being 94.7% in the concurrent arm and 93.9% in the sequential arm.

In the Cochrane systematic review (Hickey *et al.* 2006) one included RCT (Arcangeli 2006) reported that acute toxicity was “mild” in both randomised arms. The other trial (Calais 2004) found no statistically significant difference between randomised arms for fever (OR 1.27, 95% CI 0.79 to 2.03,  $p=NS$ ), cardiac complications (OR 1.73, 95% CI 0.50 to 5.96,  $p=NS$ ), neutrophil toxicity (OR 0.89, 95% CI 0.63 to 1.27,  $p=NS$ ) or platelet toxicity (OR 0.89, 95% CI 0.39 to 2.06,  $p=NS$ ). However, oesophageal toxicity (OR 1.44, 95% CI 1.03 to 2.02,  $p=0.03$ ), haematological toxicity (OR 1.43, 95% CI 1.01 to 2.03,  $p=0.04$ ) and skin toxicity (OR 1.46, 95% CI 1.00-2.14),  $p=0.05$ ) were significantly lower with sequential therapy. Nausea and vomiting was significantly less common with concurrent therapy (OR 0.70, 95% CI 0.50 to 0.98,  $p=0.04$ ). In both trials and in both randomised arms, all women received 80% or more of the prescribed chemotherapy (judged by Hickey *et al.* 2006 to be a sensible arbitrary threshold). All patients in both randomised groups in the Arcangeli 2006 trial received 100% of their planned radiotherapy, and there was no significant difference in the total dose delivered in both groups of the RCT by Calais 2004 (Hickey *et al.* 2006).

An abstract paper updated the data from the Calais 2004 trial with longer follow-up (Calais *et al.* 2005). At a median 6.7 years follow-up there remained no differences between the two arms in rates of overall survival, disease-free survival or loco-regional control. In the subgroup of node-positive patients the survival rate without local and regional failure was significantly higher in the concurrent therapy arm ( $p<0.035$ ). The incidence of late toxic effects (subcutaneous fibrosis, telengectasia, skin pigmentation, and breast atrophy) was higher in the concurrent arm than in the sequential arm.

Subsequent to the Cochrane Review (Hickey *et al.* 2006) another RCT compared concurrent chemotherapy/radiotherapy with sequential chemotherapy followed by

radiotherapy (Toledano *et al.* 2007). There were no statistically significant differences between the sequential therapy group and the concurrent therapy group in 5-year rates of disease-free survival (80% and 80% respectively;  $p=0.83$ , Log-rank test), recurrence-free survival (92% and 95% respectively;  $p=0.76$ , Log-rank test) and overall survival (90% and 91% respectively;  $p=0.76$ , Log-rank test). There was also no difference in local recurrence-free survival in the node-negative subgroup of patients between the sequential therapy group (93%) and the concurrent therapy group (93%;  $p=0.81$ , Log-rank test). However in the node-positive subgroup local recurrence-free survival was statistically significantly worse in the sequential therapy group (91%) compared to the concurrent therapy group (97%;  $p=0.02$ , Log-rank test; HR 0.61, 95% CI 0.38-0.93).

This trial reported acute toxicities. Oesophagitis was more frequent in the concurrent arm than the sequential arm (115 v 89 respectively;  $p = .04$ ). Nausea/vomiting was significantly higher in the sequential treatment arm than the concurrent treatment arm (235 v 248 respectively;  $p = .008$ ), whereas anaemia was significantly more frequent in the concurrent arm than the sequential treatment arm (111 v 81 respectively;  $p = .02$ ) (Toledano *et al.* 2007).

This trial also reported late toxicities attributed to radiotherapy in a non-intention-to-treat analysis of a sample of randomised patients (Toledano *et al.* 2006). At a median follow-up of 6.7 years Subcutaneous fibrosis, telangectasia, skin pigmentation, and breast atrophy occurred at higher rates in the concurrent arm than in the sequential arm. Twenty patients experienced Grade 2 or higher subcutaneous fibrosis in concurrent arm versus 5 patients in the sequential arm ( $p = 0.003$ ). Twenty-five patients and 7 patients showed Grade 2 or higher telangectasia in the concurrent arm and the sequential arm, respectively ( $p = 0.001$ ). Forty-four patients and 20 patients showed Grade 2 or higher breast atrophy in the concurrent arm and the sequential arm, respectively ( $p = 0.0006$ ). Thirty patients experienced Grade 3 or higher skin pigmentation in the concurrent arm versus 15 patients in the sequential arm ( $p = 0.02$ ). No statistical difference was observed between the 2 arms concerning Grade 2 or higher breast oedema, arm lymphoedema or Grade 2 or higher pain (Toledano *et al.* 2006).

A Canadian clinical guideline underpinned by a systematic review of mixed study designs (predominantly from non-randomised studies) addressed strategies for breast radiotherapy after breast-conserving surgery for early breast cancer (Whelan *et al.* 2003). The authors identified no evidence to confirm that concurrent adjuvant chemotherapy and radiotherapy results in a better outcome, whilst evidence suggested that concurrent treatment results in an increased chance of toxic effects.

## **2. Radiotherapy followed by chemotherapy versus chemotherapy followed by radiotherapy**

Data from one RCT (Bellon 2005) cited in the Cochrane systematic review (Hickey *et al.* 2006) found no statistically significant difference arising from radiotherapy followed by chemotherapy versus chemotherapy followed by radiotherapy in terms of distant metastases [HR (RT first:CT first) 0.82, 95% CI 0.49 to 1.36, p=0.44] and overall survival [HR (RT first:CT first) 0.85, 95% CI 0.51 to 1.40, p=0.52].

In the Cochrane systematic review (Hickey *et al.* 2006) one included RCT (Bellon 2005) found that radiotherapy before chemotherapy was associated with statistically significantly more neutropenic sepsis than chemotherapy before radiotherapy [OR (RT first: CT first) 2.96, 95% CI 1.26 to 6.98, p=0.02]. There was no significant difference in outcome between randomised arms for skin toxicity [OR (RT first: CT first) 1.48, 95% CI 0.68 to 3.26, p=NS], subcutaneous toxicity [OR (RT first: CT first) 2.05, 95% CI 0.50 to 8.40, p=NS], pneumonitis [OR (RT first: CT first) 11.47, 95% CI 0.63 to 209.7, p=NS], lymphoedema [OR (RT first: CT first) 0.11, 95% CI 0.01 to 2.02, p=NS] and brachial plexopathy [OR (RT first: CT first) 3.02, 95% CI 0.12 to 74.98, p=NS]. Owing to the small number of events, many of the results had wide confidence intervals.

A systematic review of mostly observational studies (Huang *et al.* 2003) performed a meta-analysis using data from 11 studies (one RCT) comparing adjuvant chemotherapy followed by radiotherapy versus adjuvant radiotherapy followed by chemotherapy. Loco-regional recurrence at 5 years follow-up had OR (CT first: RT first) 2.28 (95% CI, 1.45 to 3.57), corresponding to a statistically significant increase in the 5-year LRR from 6.0% in the RT first group to 16.0% in the chemotherapy-first group.

### **3. Early versus late chemotherapy**

An RCT with 2x2 factorial design (International Breast Cancer Study Group 1997) permits comparison of early CMF chemotherapy (i.e. months 1, 2 and 3 following surgery) versus delayed CMF chemotherapy (i.e. months 9, 12 and 15 following surgery). All patients received tamoxifen and patients who received breast conserving surgery received radiotherapy; given after early chemotherapy or before late chemotherapy, with randomisation stratified according to whether radiotherapy was given. 5-year disease-free survival was 64% in the early chemotherapy group and 59% in the delayed chemotherapy group. 5-year overall survival was equal at 74% in both groups. Differences in survival were not statistically significant across the four analysis groups, which also included patients treated with adjuvant tamoxifen alone, and patients treated with both early and late chemotherapy. The rate of toxicity of grade 3 or worse was 9.7% in the early chemotherapy group and 7.6% in the delayed chemotherapy group.

## **INTERVAL BETWEEN SURGERY AND COMMENCEMENT OF ADJUVANT THERAPY**

### **Interval from surgery to radiotherapy**

A systematic review of mostly observational studies examined the relationship between the interval from surgery to starting radiotherapy and local control (Huang *et al.* 2003). In a meta-analysis of data from eight studies locoregional recurrence was more frequent when radiotherapy was delayed: OR (interval>8 weeks:interval ≤8 weeks) 1.62 (95% CI, 1.21 to 2.16); corresponding to an increase in the 5-year rate of loco-regional recurrence from 5.8% in those patients treated within 8 weeks to 9.1% in those patients treated between 9 and 16 weeks after surgery.

Two further studies cited by Huang *et al.* 2003 used different definitions of delay and were not included in the meta-analysis. One study showed a statistically significantly higher risk of local recurrence for patients who waited for RT for more than 80 days after lumpectomy ( $P < .05$ ) whereas the other study reported no significant difference in any recurrence between patients treated with postoperative RT within 4 weeks after surgery and those treated more than 4 weeks after surgery ( $P = 0.44$ ) (Huang *et al.* 2003).

The systematic review by Huang *et al.* 2003 also performed a meta-analysis for the odds of distant metastases comparing women receiving postoperative RT more than 8 weeks after surgery and those women treated within 8 weeks after surgery. There was no statistically significant difference: OR (interval>8 weeks:interval ≤8 weeks) 1.22 (95% CI, 0.94 to 1.59). Two further included studies were not included in the meta-analyses, but both found no association between delay and the rate of distant metastasis (Huang *et al.* 2003).

A Canadian clinical guideline underpinned by a systematic review of mixed study designs addressed strategies for breast radiotherapy after breast-conserving surgery for early breast cancer (Whelan *et al.* 2003). The authors concluded that the evidence reviewed was inadequate to define an optimal interval between breast-conserving surgery and the start of radiotherapy.

A retrospective cohort study examined the effect upon survival of the interval between surgery and radiotherapy in 13,907 patients of age 65 years or older who received radiotherapy within one year of diagnosis and who did not receive chemotherapy (Hershman *et al.* 2006a). Overall survival and breast cancer-specific survival were similar in patients who received RT within 1 month, 2 months, or 3 months after surgery (no data shown). In a multivariate analysis, overall mortality rates were higher among women who delayed RT 3 months or more after surgery relative to women who received RT within 3 months of surgery (HR 1.61; 95% CI, 1.42–1.82), as were cancer-specific mortality rates (HR 2.14; 95% CI, 1.79–2.57). This analysis adjusted for the effect upon survival of numerous demographic and tumour-related variables. However numerous variables were also found to be statistically significantly associated in isolation with survival outcomes: patient age, disease stage, hormone receptor status,

tumour grade, comorbidity score, marital status, type of hospital and socioeconomic status (Hershman *et al.* 2006a).

Other observational studies found that disease free and overall survival were not adversely affected by increasing delay to the start of radiotherapy in the first three months after surgery (Benchalal *et al.* 2005; Jobsen *et al.* 2006; Mikeljevic *et al.* 2004). Survival analyses were adjusted for known prognostic factors. A large UK cohort study of 7800 women found that overall survival was adversely affected only in those whose radiotherapy was delayed for at least five to six months after surgery (Mikeljevic *et al.* 2004). In the cohort analysed by Jobsen *et al.* (2006), delayed radiotherapy was associated with a reduction in the risk of cancer death, although radiotherapy delay appeared to be confounded with year of treatment in their cohort.

### **Interval from surgery to adjuvant chemotherapy**

Similar to the study described above by Hershman *et al.* 2006, the same team of authors examined the effect upon survival of the interval between surgery and chemotherapy in a retrospectively studied cohort of 5003 women of age 65 years and older, who received chemotherapy within 1 year of their diagnosis of breast cancer, but who did not receive radiotherapy prior to chemotherapy (Hershman *et al.* 2006b). Breast cancer specific survival was similar in patients who received chemotherapy within 1 month, 2 months, or within 3 months following surgery. Overall survival also did not differ among patients who started treatment in any of these time intervals (full data not shown). In a multivariate analysis, the breast cancer specific mortality rate was higher among women who delayed chemotherapy 3 months or more following surgery (HR >3 months :<1 month 1.69, 95% CI 1.31–2.19), as was the overall mortality rate (HR >3 months :<1 month 1.46, 95% CI 1.21–1.75). This analysis adjusted for the effect upon survival of numerous demographic and tumour-related variables. However several variables were also found to be statistically significantly associated in isolation with survival outcomes, including advanced age, African American race, residence in a non-metropolitan location, estrogen receptor negative tumors, poorly differentiated tumors, increased number of comorbidities, being unmarried, and undergoing radiotherapy ( $p < 0.05$  in all cases).

Other cohort studies found increasing delay to the start of adjuvant chemotherapy in the first three months after surgery was not associated with poorer disease free or overall survival (Cold *et al.* 2005; Colleoni *et al.* 2000; Lohrisch *et al.* 2006; Sanchez *et al.* 2007; Shannon *et al.* 2003). Three of the studies used comparable stratification of chemotherapy delay (Cold *et al.* 2005; Colleoni *et al.* 2000; Shannon *et al.* 2002). Colleoni *et al.* (2000) reported that disease free survival was adversely affected by delays of three or more weeks in the sub-group of women with ER-negative disease. Another study reported that disease free and overall survival were adversely affected only when the start of chemotherapy was delayed until at least three to six months after surgery

(Lohrisch *et al.* 2006). However the start of chemotherapy was delayed for three to six months in only four percent of the cohort.

## Evidence Tables

Hickey, Francis & Lehman . Sequencing of chemotherapy and radiation therapy for early breast cancer. Cochrane Database of Systematic Reviews 2006 Issue 4. Chichester (UK), John Wiley & Sons, Ltd.
<b>Design</b>
Systematic review of RCTs. Country of origin: various Evidence grade: 1+
<b>Inclusion criteria</b>
Aim: To determine the effects of different sequencing of radiotherapy and chemotherapy for women with early stage breast cancer who have been treated surgically.  <b>Types of studies</b> Randomised trials evaluating different ways of sequencing radiotherapy and chemotherapy were eligible. The comparison between different sequences had to be unconfounded (i.e. the randomised groups differed only in relation to the sequencing of the two treatments). Trials incorporating the use of other adjuvant treatments, such as monoclonal antibodies or hormonal therapy, were eligible if these other treatments were applied in both groups in the randomised trial. Published and unpublished studies were eligible.
<b>Exclusion criteria</b>
Women who had previously received adjuvant therapy for breast cancer were not eligible.
<b>Population</b>
N=1097  <b>Types of participants</b> Women with surgically treated, histologically confirmed early stage breast cancer who required both adjuvant chemotherapy and radiotherapy were included. Early breast cancer included tumours classified as UICC stage T1-3N0-1M0. Surgery could comprise mastectomy, lumpectomy, wide local excision or quadrantectomy, with or without axillary dissection, axillary sampling or sentinel node biopsy.
<b>Interventions</b>
The following comparisons were eligible: 1) Adjuvant radiotherapy followed by adjuvant chemotherapy versus adjuvant chemotherapy followed by adjuvant radiotherapy; 2) Adjuvant chemotherapy followed by adjuvant radiotherapy versus a 'sandwich technique' (when one or more courses of chemotherapy are followed by radiotherapy, which is followed by further chemotherapy); 3) Adjuvant chemotherapy followed by adjuvant radiotherapy versus concurrent adjuvant

chemotherapy and radiotherapy.

Chemotherapy regimens included those delivered at standard doses (i.e. not high dose), and could include drugs such as cyclophosphamide, 5-fluorouracil, anthracyclines, taxanes and other agents.

Radiotherapy had to be delivered to the breast or chest wall, including or not including the supraclavicular fossa and axilla. Standard fractionation (1.8 to 3.0 Gy per fraction) had to be used, delivering a total of 40 to 61 Gy at the reference point. It could include a boost (using electrons, interstitial therapy or external beam) or new techniques.

## **Outcomes**

### **Primary outcomes**

- Local recurrence in the ipsilateral breast
- Cause-specific mortality

### **Secondary outcomes**

- Overall survival
- Distant metastases (in isolation or at the same time as local recurrence)
- Relapse-free survival
- Subsequent mastectomy
- Harms, including acute and late effects of radiotherapy, chemotherapy-related toxicity
- Ability to deliver the prescribed dose of chemotherapy; ability to deliver the prescribed dose of radiotherapy
- Costs
- Quality of life
- Patient preference

The authors set an arbitrary threshold of 80% when assessing the ability to deliver the prescribed dose of chemotherapy or radiotherapy, as acceptable.

Local recurrence included recurrence in the ipsilateral breast, the skin and parenchyma.

## **Follow up**

Median values for three included RCTs:  
Arcangeli 2006: 65 months  
Bellon 2005: 135 months (range 17-196 months)  
Calais 2004: 36 months

## **Results**

### **1. Concurrent treatment versus chemotherapy followed by radiotherapy**

Two trials; n=853; (Arcangeli 2006;Calais 2004)

NB: OR < 1 indicates a beneficial effect of concurrent treatment compared with sequential treatment

Local recurrence (ipsilateral):

OR concurrent therapy vs. chemotherapy followed by radiotherapy 1.30 (95% CI 0.45 to 3.77, p=0.63).

Overall survival:

Arcangeli 2006 reported the overall survival in concurrent and sequential groups at 5 years as being 94.7% and 93.9% respectively, with a non-significant hazard ratio (HR).

Distant metastases:

OR 1.43 (95% CI 0.86 to 2.37, p=0.16).

Harms and toxicity:

The Arcangeli 2006 report includes the comment that acute toxicity was “mild in both groups, with infrequent moist desquamation in limited areas”.

The other trial (Calais 2004); n=647; reported harms and toxicity in detail. No significant difference was found between the treatment groups for fever (OR 1.27, 95% CI 0.79 to 2.03, p=NS), cardiac complications (OR 1.73, 95% CI 0.50 to 5.96, p= NS), neutrophil toxicity (OR 0.89, 95% CI 0.63 to 1.27, p= NS) or platelet toxicity (OR 0.89, 95% CI 0.39 to 2.06, p=NS). However, oesophageal toxicity (OR 1.44, 95% CI 1.03 to 2.02, p=0.03), haematological toxicity (OR 1.43, 95% CI 1.01 to 2.03, p = 0.04) and skin toxicity (OR 1.46, 95% CI 1.00-2.14), p=0.05) were significantly lower with sequential therapy. Nausea and vomiting was significantly less common with concurrent therapy (OR 0.70, 95% CI 0.50 to 0.98, p= 0.04).

Ability to deliver the prescribed chemotherapy dose (compliance):

The arbitrary threshold of the delivery of at least 80% of the prescribed chemotherapy was achieved for all women in both trials.

Ability to deliver the prescribed radiotherapy dose (compliance):

All patients in both randomised groups in the Arcangeli 2006 trial received 100% of their planned radiotherapy, and there was no significant difference in the total dose delivered in both groups of Calais 2004.

## **2. Radiotherapy followed by chemotherapy versus chemotherapy followed by radiotherapy**

One trial, n=244, (Bellon 2005).

NB: an OR or HR of less than 1.0 favours the group allocated to receive radiotherapy first.

Overall survival:

HR 0.85 (95% CI 0.51 to 1.40, p=0.52)

Distant Metastases:

HR 0.82 (CI 0.49 to 1.36, p=0.44)

Harms and toxicity:

Radiotherapy before chemotherapy was associated with significantly more neutropenic sepsis (OR 2.96, CI 1.26 to 6.98, p=0.02). There was no significant difference in outcome between randomised arms for skin toxicity (OR 1.48, 95% CI 0.68 to 3.26, p=NS), subcutaneous toxicity (OR 2.05, 95% CI 0.50 to 8.40, p=NS), pneumonitis (OR 11.47, 95% CI 0.63 to 209.7, p=NS), lymphoedema (OR 0.11, 95% CI 0.01 to 2.02, p=NS) and brachial plexopathy (OR 3.02, 95% CI 0.12 to 74.98, p=NS). Owing to the small number of events, many of the effects had wide CIs.

### **Authors' conclusions**

Evidence from three well conducted randomised trials indicates that local control and survival is similar for concurrent chemotherapy and radiotherapy, radiotherapy followed by chemotherapy, and chemotherapy followed by radiotherapy for women with early breast cancer when the radiotherapy is commenced within seven months after surgery.

### **General comments**

#### **Literature search methods**

Cochrane Breast Cancer Group Specialized Register (10 March 2005) and CENTRAL (Issue 4 2005), MEDLINE (1996 to 2005), CINAHL, Current Contents (1998 to June 2005) and Science Citation Index. Search strategy for searching MEDLINE detailed.

#### **Study selection**

Three authors selected studies independently on the basis of title/abstract and resolved differences by discussion. Studies were selected with their results masked.

#### **Data extraction**

Two authors extracted data and resolved differences by discussion.

#### **Quality assessment**

Study quality assessment was performed considering allocation concealment (graded as B – unclear) in all three trials; intention to-treat analysis and extent of follow-up (arbitrary threshold of 80% of patients accounted for). Blinding was not feasible and so was not considered to be relevant.

#### **Heterogeneity of results**

No significant heterogeneity was detected for any outcomes analysed.

#### **Other factors**

Data were not available for many outcomes; the included trials are anticipated to publish further results. Specifically, the authors note that the review cannot answer questions on the basis of the evidence that is currently available regarding:

1. Harms, costs, patient preferences and quality of life;
2. The impact of newer chemotherapy regimens and biological agents;
3. The impact of new modes of radiotherapy;
4. Concurrent administration of modern chemotherapy and radiotherapy.

The authors advise that caution be employed in interpreting these results due to:

1. The low event rate for some endpoints such as local recurrence; low statistical power;
2. Inclusion of patients with positive margins in the RCT by Bellon 2005
3. Inadequate follow-up for survival outcomes.

Huang, Barbera, Brouwers, Browman & Mackillop . Does delay in starting treatment affect the outcomes of radiotherapy: a systematic review (DARE structured abstract). Journal of Clinical Oncology 21, 555-563. 2003.
<b>Design</b>
Systematic review of mixed study design Country of origin: USA Evidence grade: 2-
<b>Inclusion criteria</b>
All studies in any language that examined the relationship between delay in RT and the outcomes of treatment.  Specifically, studies in which: <ul style="list-style-type: none"> <li>• All patients were treated with RT;</li> <li>• The delay in initiating RT was defined and described;</li> <li>• Relevant outcomes were reported quantitatively.</li> </ul>
<b>Exclusion criteria</b>
Two studies that commented on the relationship between delay and outcomes without presenting any analytic results were excluded.
<b>Population</b>
N=9896 Patients with breast cancer treated with RT after definitive surgery.
<b>Interventions</b>
Radiotherapy
<b>Outcomes</b>
Local control; Distant metastasis; Survival NB: few studies reported distant metastasis or survival  Results were meta-analysed to produce pooled odds ratios (OR) of outcome in the delayed group versus the nondelayed group. Heterogeneity of results was assessed, and when present, exploratory analyses were performed to examine the effects of age, disease stage, residual tumour, length of follow-up and study quality.
<b>Follow up</b>
Meta-analysis performed on the basis of 5-year follow-up where available
<b>Results</b>

21 studies of patients with breast cancer were included (n=9876).  
10 studies examined the effect of RT delay (n=7401; after lumpectomy in nine studies and lumpectomy or mastectomy in one study).  
12 studies examined sequencing of RT relative to other therapies (n=2495).

### **1. Relationship between interval to starting RT and local control in breast cancer**

Loco-regional recurrence:

Eight (of ten, see above) studies compared local control between patients who were treated more than 8 weeks after surgery and those treated within 8 weeks of surgery. In each of these studies, delay in starting postoperative RT was associated with an increase in LRR at 5 years (although not always statistically significantly so, since some of the 95% CIs for the reported ORs for LRR included the null hypothesis value of 1). The pooled random-effects OR from the meta-analysis was 1.62 (95% CI, 1.21 to 2.16), corresponding to an increase in the 5-year LRR from 5.8% in those patients treated within 8 weeks to 9.1% in those patients treated between 9 and 16 weeks after surgery. There was no significant heterogeneity among the eight studies ( $p=0.66$ ).

The relationship between delay and the risk of local recurrence remained significant when one low-quality study was excluded (OR 1.60, 95% CI, 1.20 to 2.14).

The remaining two studies used different definitions of delay and could not be included in the meta-analysis. One study showed a significantly higher risk of local recurrence for patients who waited for RT for more than 80 days after lumpectomy ( $P < .05$ ).

The other study reported no significant difference in any recurrence between patients treated with postoperative RT within 4 weeks after surgery and those treated more than 4 weeks after surgery ( $P =0.44$ ).

Other outcomes:

The association between delay in RT and the rate of distant metastasis was reported in five studies. Three compared the rate of distant metastasis between women receiving postoperative RT more than 8 weeks after surgery and those women treated within 8 weeks after surgery. On the basis of analyses of these three studies, the pooled random-effects OR was 1.22 (95% CI, 0.94 to 1.59).

The other two studies did not report their results in a way that permitted their inclusion in the meta-analyses, but both reported that there was no statistically significant association between delay and the rate of distant metastasis.

None of these studies reported the relationship between delay and survival.

### **2. Relationship between sequencing of RT with systemic chemotherapy and local control in breast cancer**

Locoregional recurrence:

12 studies provided data (primary surgery as follows: lumpectomy in 10 studies, mastectomy in one study, and not specified in one study).

One report provided insufficient information for inclusion in the combined analysis. It

showed no significant association between delay in RT and local control (P=0.92) or distant failure (P=0.41).

The remaining 11 studies involved 1,927 patients. One study was a RCT and the others were observational cases series. The pooled random-effects OR from the combined analysis of these 11 studies was 2.28 (95% CI, 1.45 to 3.57), corresponding to an increase in the 5-year LRR from 6.0% in the RT first group to 16.0% in the chemotherapy-first group.

When five low-quality studies were excluded from the analysis, the association between delayed RT and increased local failure remained statistically significant (OR 2.38, 95% CI, 1.29 to 4.40). There was no significant heterogeneity between the results of these studies (P=0.70).

Other outcomes:

Several studies of the sequencing of RT and chemotherapy reported rates of distant metastasis, but these were not analysed because the timing of chemotherapy was considered to be a more important determinant of systemic recurrence rates than the timing of RT.

### **General comments**

Well-conducted systematic review, but most data originate from observational studies, therefore the results should be interpreted with caution.

### **Search Strategy**

MEDLINE and CANCELIT from 1975 to June 2001, using the following text words or Medical Subject Headings (MESH) terms: delay, waiting times, waiting lists, neoplasm, clinical outcome, radiation treatment, radiotherapy, sequence, interval, local control, relapse, recurrence rate, metastasis, quality of life, and survival.

The electronic searches were supplemented by manual searches of studies presented in the American Society for Therapeutic Radiology and Oncology conferences and the annual meeting of the Royal College of Physicians and Surgeons of Canada. Additional reports from the reference lists of key articles were identified.

### **Data extraction**

The following data were extracted independently by two reviewers using a proforma: year of publication; demographic characteristics of the patients (age, sex); characteristics of the disease (primary site, stage or size of tumor, histology, grade, nodal status, and estrogen receptor status in breast cancer); type of surgery and status of surgical margins; definition of delay and number of patients at each level of delay; details of RT (dose, fractionation, overall time); details of any systemic therapy and its timing in relation to RT; median follow-up; and outcomes (rates of local recurrence rate [LRR], metastasis, and survival).

### **Quality Assessment**

Most of the relevant studies were retrospective observational studies.

A quality scale was designed to distinguish between observational studies with greater or lesser potential for bias. The nine-point scale was constructed to measure the extent to

which each study provided the information necessary either to ensure that the delayed and control groups were similar or to control for differences between them in our analysis. The following factors were considered:

1. Demographic characteristics (age and sex)
2. Disease-related factors (tumor stage or size, histology or tumor grade, and status of surgical margin)
3. Intervention-related factors (RT dose and fractionation, surgical procedure, and chemotherapy regimen)
4. Completeness of follow-up.

The scale ranges from 0 to 9, with higher scores indicating higher quality. All eligible studies were independently assessed by two investigators. Intraclass correlation coefficient ( $r_i$ ) was 0.95 (95% confidence interval [CI], 0.91 to 0.97). Any discrepancies were reconciled before data entry. Studies with scores  $\geq 5$  are referred to below as high-quality studies, and studies with scores  $< 5$  are referred to as low-quality studies.

### **Analysis**

Studies of the sequencing of RT and chemotherapy were analysed separately from pure RT studies. Studies were categorised into two or three groups on the basis of duration of delay. To enable us to include as many studies as possible in the meta-analysis, the data were dichotomised using the cutoff points of 8 weeks. In three studies the definition of delay differed from the norm (Benk et al. 1999; Nixon et al. 1994; Yock 2000). These studies were not included in the meta-analysis, but their data are presented separately.

Whelan, Olivotto, Levine & Health Canada 's Steering Committee on Clinical Practice Guidelines for the Care and Treatment of Breast Cancer. Clinical practice guidelines for the care and treatment of breast cancer: breast radiotherapy after breast-conserving surgery (summary of the 2003 update). CMAJ Canadian Medical Association Journal Available at <a href="http://www.cmaj.ca/cgi/data/158/3/DC1/21">http://www.cmaj.ca/cgi/data/158/3/DC1/21</a> . 2003.
<b>Design</b>
Guideline (appraised here as a systematic review of mixed study designs) Country of origin: Canada Evidence grade: 2-
<b>Inclusion criteria</b>
Specific criteria for selection of studies are not reported, although these may be reported in the original guideline of 1997, which this updates.
<b>Exclusion criteria</b>
Not reported.
<b>Population</b>
Patients with breast cancer who receive RT following breast conserving surgery.
<b>Interventions</b>
Aim: To help physicians and their patients arrive at optimal strategies for breast radiation therapy after breast-conserving surgery (BCS) for early breast cancer.
<b>Outcomes</b>
Local control Survival Quality of life Adverse effects Cosmetic results
<b>Follow up</b>
Variably reported; not summarised.
<b>Results</b>
<b>1. Interval between surgery and adjuvant RT.</b>  The guideline/systematic review authors concluded that the optimal interval between BCS and the start of irradiation has not been defined on the basis of the following studies:  One observational study of 436 patients found that patients who began radiation therapy more than 7 weeks after BCS appeared to be at greater risk of recurrence than patients receiving treatment earlier (14% v. 5%). However, the demonstrated effect of the interval between radiation therapy and surgery was not statistically significant when other relevant

factors were considered in a multivariate analysis (Clarke et al. 1985; level V evidence).

In a study involving 653 patients with node-negative breast cancer who received a dose of 60 Gy or greater to the primary tumour site, when risk factors were controlled, there was no difference in the recurrence rates associated with intervals ranging from 4 to 8 weeks between surgery and radiation therapy (Nixon et al. 1994; level V evidence).

There are a number of conflicting reports regarding the risk of recurrence following delay in radiation therapy after lumpectomy:

A review was conducted of 508 cases of patients with stage I or II breast cancer treated with breast irradiation after lumpectomy (Slotman et al. 1994; level V evidence). At a median follow-up of 5.7 years, the rate of local recurrence was 1.7% among patients who started radiation within 7 weeks after surgery and 5.6% among those with a longer interval ( $p < 0.05$ ). In a Cox proportional-hazard analysis, the interval between surgery and radiation remained predictive of local recurrence ( $p = 0.003$ ).

A review was performed of 1962 cases of women at low risk for recurrence who did not receive chemotherapy (Froud et al. 2000; level V evidence). At a median follow-up of 5.9 years, they found no difference in ipsilateral breast recurrence for intervals between surgery and radiation therapy of 0–20 weeks. However, the risk of distant recurrence was significantly higher with intervals of more than 12 weeks between surgery and the start of radiation therapy.

## **2. Sequencing of chemotherapy and breast RT**

On the basis of the studies shown below, the authors conclude that the optimal sequencing of chemotherapy and RT is not clearly defined and that there is no evidence that concurrent treatment results in a better outcome, whilst concurrent treatment results in an increased chance of toxic effects, especially with anthracycline-containing regimens.

The 2001 update of a study by Recht and associates reported the results for 244 patients treated with lumpectomy who were randomly assigned to receive radiation therapy before or after chemotherapy. The median follow-up was 11.3 years. There was no statistically significant difference in time to any failure, time to distant metastases or time to death between the two groups. The recurrence rates by site of first failure were also similar between the two groups (local recurrence 15% v. 13%, respectively; distant recurrence 26% v. 32%, respectively) (level II evidence). This study was relatively underpowered to detect differences in failure patterns.

The timing of radiation therapy has been considered in other studies, with inconsistent results (level V evidence) (Antoniades et al. 1993; Buchholz et al. 1993; Buzdar et al. 1993; Hartsell et al. 1992; Recht et al. 1991).

In several trials designed to evaluate adjuvant chemotherapy regimens after BCS, radiation

therapy was delayed until chemotherapy was completed, without any apparent increase in local recurrence (level I evidence) (Fisher et al. 1990; Levine et al. 1998; Wallgren et al. 1996, Gore et al. 1987).

Several case series have shown that when chemotherapy and radiation therapy are given concurrently, the potential for increased acute and late adverse effects of radiation therapy, including a worse cosmetic outcome, is increased, especially when anthracycline-based regimens are used (level III evidence; Gore et al. 1987, Hoogenraad et al. 1992; Abner et al. 1991).

### **General comments**

Canadian guideline, underpinned by a systematic review of mixed study designs.

### **Literature search**

A literature search was performed using MEDLINE from 1966 to October 2001 and CANCERLIT from 1983 to September 2001. A nonsystematic review of the literature was continued through April 2002. Search terms included the following: "breast neoplasms," "segmental mastectomy," "lumpectomy," "breast conservation," "radiotherapy," "irradiation," "clinical trials," "practice guidelines" and "meta-analysis." Bibliographies from recently published reviews were scanned and relevant articles retrieved.

### **Study quality assessment**

The quality of the evidence was categorised into 5 levels based upon: Sackett DL. Rules of evidence and clinical recommendations on the use of antithrombotic agents. Chest 1989;95(Suppl):2S-4S.

International Breast Cancer Study Group . Effectiveness of adjuvant chemotherapy in combination with tamoxifen for node-positive postmenopausal breast cancer patients. International Breast Cancer Study Group. Journal of Clinical Oncology 15[4], 1385-1394. 1997.

### **Design**

RCT (2 x 2 factorial comparison)  
Country of origin: International  
Evidence grade: 1+

### **Inclusion criteria**

Post-menopausal patients with node-positive, unilateral breast cancer

### **Exclusion criteria**

31 patients from non-compliant institutions;  
21 patients who were ineligible due to advanced stage (8), stage N0 (2), medically unfit for randomisation (1), previous cancer (3), bilateral breast cancer (1), unclear resection margins (3), pre-menopausal status (4) and randomisation 12 weeks after surgery (1).

### **Population**

N=1266 in total; N=610 in arm B + arm C from which data are applicable to this question.  
Stage: T1a-T3a, pN1, M0  
Median age 60 years (range 35-84 years).

### **Interventions**

Aim: to study the use of tamoxifen (T) with and without cyclophosphamide, methotrexate and fluorouracil (CMF) chemotherapy, and also the optimal sequencing of CMF when used with T.

All patients received primary surgery: total mastectomy or BCS (breast RT mandatory in cases of BCS). All patients received axillary dissection. Breast RT was given after the end of the first phase of chemotherapy, where applicable (see below).

Patients were randomly allocated to one of four adjuvant treatment plans:

Group A (n=306): T  
Group B (n=302): T + early CMF  
Group C (n=308): T + delayed CMF  
Group D (n=296): T + early CMF + delayed CMF

Adjuvant therapy started within 6 weeks of surgery.

Tamoxifen was given for 5 years, or until relapse, whichever occurred first.

Early CMF was 3 cycles, repeated every 28 days i.e. months 1, 2 and 3 following surgery.

Delayed CMF was 3 cycles, given on months 9, 12 and 15 following surgery.

<b>Outcomes</b>
Disease-free survival Overall survival
<b>Follow up</b>
Outcomes reported at a median follow-up of 60 months.
<b>Results</b>
<p><b>Recurrence and survival outcomes</b></p> <p>5-year disease-free survival: Group B: T + early CMF: 64% Group C: T + delayed CMF: 59%</p> <p>5-year overall survival: Group B: T + early CMF: 74% Group C: T + delayed CMF: 74%</p> <p><b>Compliance with chemotherapy (grouped data for patients in all three chemotherapy arms)</b></p> <p>95% of patients in the early CMF groups (B and D) received some chemotherapy for at least 3 courses. 14% of patients assigned to delayed chemotherapy did not receive it due to relapse (5%), refusal (7%) or other reasons (2%).</p> <p><b>Rate of toxicity of grade 3 or worse (by individual chemotherapy-including randomised group)</b></p> <p>Group B: T + early CMF: 9.7% Group C: T + delayed CMF: 7.6% Group D: T + early CMF + delayed CMF: 17.1%</p>
<b>General comments</b>
<ul style="list-style-type: none"> <li>• Randomisation was stratified according to:</li> <li>• Participating institution;</li> <li>• Type of surgery (mastectomy vs. BCS + RT);</li> <li>• ER status (positive vs. negative).</li> </ul> <p>Randomisation process described. Power calculation performed, with planned sample size: 1200 patients to give 80% power to detect an 8% difference in disease-free survival. Treatment groups were balanced for age, race, type of primary surgery, number of positive nodes and tumour size.</p> <p>Only arms B and C are relevant subgroups for this question. Most analyses in this study are not relevant to this question due to confounding by treatment according to group A (no chemotherapy) and group D (additional cycles of chemotherapy).</p>

Analysis appears to be by intention-to-treat (not reported). Blinding of subjects not feasible; and not feasible in all instances for investigators.

Calais, Serin, Fourquet, Bosset & Favre . Randomized study comparing adjuvant radiotherapy (RT) with concomitant chemotherapy (CT) versus sequential treatment after conservative surgery for patients with stages I and II breast carcinoma: Long-term results. International Journal of Radiation Oncology Biology Physics 63[2], S53. 2005.
<b>Design</b>
RCT Country of origin: Evidence grade: 1+
<b>Inclusion criteria</b>
716 patients with breast cancer treated between February 1996 and April 2000.
<b>Exclusion criteria</b>
Not reported
<b>Population</b>
N=716
<b>Interventions</b>
All patients received conservative surgery with axillary dissection and were randomly allocated to two treatment arms as follows: 1. Arm A: sequential treatment with chemotherapy (CT) first followed by radiotherapy (RT) started 3 to 5 weeks after the final cycle of CT. 2. Arm B: CT administered concurrently with RT.  Chemotherapy was based upon mitoxantrone, 5-fluorouracil and cyclophosphamide, 6 cycles were delivered with 21 days interval.  RT regimen was 50 Gy to the breast in 5 weeks with 10 to 20 Gy boost added to the tumour bed with electrons or brachytherapy. The subclavicular area was irradiated when axillary dissection was positive.
<b>Outcomes</b>
Time to initiation of RT Treatment compliance Overall survival Disease-free survival Loco-regional control Late toxic effects
<b>Follow up</b>
Median 6.7 years (data included in the Cochrane Review by Hickey et al. 2006 had a follow-up period of 3 years).
<b>Results</b>

**Time to initiation of RT**

Mean time to initiation of RT was 170 days in arm A and 39 days in arm B ( $p < 0.0001$ ).

**Treatment compliance**

RT compliance was similar in the 2 randomised arms in respect of total dose, treatment duration and treatment interruption. Compliance to CT was also comparable between arms. CT mean relative dose intensity was 94% in arm A and 92% in arm B. Oesophagitis of grade  $>1$

was seen at a higher rate in arm B than in arm A (23% versus 7%, respectively).

Haematologic toxicity was also higher in arm B in respect of neutrophil count and haemoglobin level. The incidence of other acute toxic effects including skin toxicity was similar in the 2 arms. Two patients developed acute leukemia (one in each arm).

**Disease related events**

No differences were observed between the two arms in rates of overall survival, disease-free survival or loco-regional control.

For node-positive patients the survival rate without local and regional failure was significantly higher in arm B ( $p < 0.035$ ). Other prognostic factors for disease-free survival were tumour grade, hormone receptor status, tumour margin status and in situ component.

**Late toxicity**

The incidence of late toxic effects (subcutaneous fibrosis, telengectasia, skin pigmentation, and breast atrophy) was higher in arm B than in arm A.

**General comments**

Conference abstract: trial included in the Cochrane Review by Hickey et al. 2006, but with shorter follow-up.

The 2 arms were equally balanced regarding to age, stage, performance status, histology, hormonal receptors, tumour margins, in situ component and axillary status.

Randomisation was stratified according to axillary status.

1. Toledano, Azria, Garaud, Fourquet, Serin, Bosset, Miny-Buffet, Favre, Le & Calais . Phase III trial of concurrent or sequential adjuvant chemoradiotherapy after conservative surgery for early-stage breast cancer: final results of the ARCOSEIN trial. *Journal of clinical oncology : official journal of the American Society of Clinical Oncology* 25[4], 405-410. 2007.

2. Toledano, Garaud, Serin, Fourquet, Bosset, Breteau, Body, Azria, Le & Calais . Concurrent administration of adjuvant chemotherapy and radiotherapy after breast-conserving surgery enhances late toxicities: long-term results of the ARCOSEIN multicenter randomized study. *International Journal of Radiation Oncology, Biology, Physics* 65[2], 324-332. 2006.

### **Design**

RCT  
 Country of origin: France  
 Evidence grade: 1 +

### **Inclusion criteria**

716 patients with stages I and II breast cancer treated between February 1996 and April 2000 Surgical margins had to be negative before randomisation.

### **Exclusion criteria**

Patients who received prior ipsilateral breast/axillary RT, ipsilateral breast reconstruction, augmentation/reduction mammoplasty, or those with synchronous bilateral breast tumors were excluded.  
 21 patients were excluded from the analysis after randomisation due to ineligibility

### **Population**

N=716

Hormone receptor status:  
 ER+ or PR+: 462 (69%)  
 ER- and PR-: 205 (31%)

Menopausal status:  
 Menopausal: 287 (41%)  
 Premenopausal: 401 (58%)  
 Unknown 7 (1%)

NB Late toxicity data are based upon the following selected patient subgroup: of 571 patients who were alive without recurrence, 297 patients treated at the five largest institutions were invited to attend for assessment of late toxicity and cosmesis. 72% of these were assessed for these outcomes (n=214).

### **Interventions**

Aim: to compare sequential CT followed by RT versus CT administered concurrently with RT.

All patients underwent complete gross excision and axillary dissection. Adjuvant treatment began within 6 weeks after surgery. Patients were randomised as follows:

1. Sequential CT-RT group (n=358): RT started 3 to 5 weeks after the last cycle of CT.
2. Concurrent CT-RT group (n=358) In the concurrent arm, RT started the day of the first CT cycle.

RT was delivered to the breast and, when indicated, to the regional lymphatics. The RT breast dose was 50 Gy in 2-Gy fractions, with a 10 to 20 Gy boost to the tumor bed at the discretion of each participating center. Lymph node RT was given at a total dose of 50 Gy in 25 Gy fractions in node-positive patients and in the case of central or medial tumor locations. RT to the internal mammary chain was left at the discretion of local RT guidelines. RT was interrupted if grade 3 cutaneous toxicity occurred.

The CT regimen consisted of mitoxantrone, fluorouracil and cyclophosphamide in six courses of 21 days each. CT was interrupted or stopped if haematologic side effects reached a specified threshold. No dose reductions were planned.

Post or perimenopausal women with ER+ or PR+ tumours received tamoxifen, which was started during or after RT at the discretion of the treating physician.

## Outcomes

Disease free survival (time from randomisation to the first treatment failure or death without recurrence)  
Adverse effects  
Cosmetic results  
Overall survival

### **Further details of assessment of outcomes for late toxicity (subgroup analysis, n=214; 2<sup>nd</sup> reference):**

Late effects were assessed as a single event at the most recent follow-up visit (median follow-up 6.7 years) using the LENT-SOMA scale (which is scored upon an assessment of pain, arm/breast lymphoedema, fibrosis, telangiectasia, atrophy, retraction, ulceration, pigmentation).

General frequency definitions for LENT-SOMA assessment were as follows:

- Occasional = monthly
- Intermittent = weekly
- Persistent = daily
- Refractory = constantly

Other LENT-SOMA definitions/assessments were as follows:

- Pigmentation: 5-points scoring system (excellent, good, moderate, poor, very poor).
- Breast oedema: permanent swelling with an increased volume of the treated breast, either asymptomatic (without pain or any consequences) or symptomatic.
- Fibrosis: detected by palpation of the treated breast in comparison with the untreated side.
- Arm oedema: difference in circumference of the ipsilateral and controlateral arm 15 cm above and 10cm below the olecranon
- Management of arm oedema, the patient's statements were taken into account, even if no differences in circumference could be measured.
- Intensive physiotherapy: weekly therapy.
- Breast retraction and atrophy: volume loss caused by RT or RT and surgery
- Cardiac event: myocardial infarction or congestive heart failure.
- Radiation pneumonitis: cough, fever, and shortness of breath that occurred 2 to 9 months after the completion of RT.

## **Follow up**

Median 60 months

For subgroup analysis of late effects (n=214): median 6.7 years (range 4.3-9 years)

## **Results**

### **1. Recurrence and survival**

5-year disease-free survival (all patients)

Sequential group: 80%

Concurrent group: 80%; p=0.83, Log-rank test

5-year overall survival (all patients)

Sequential group: 90%

Concurrent group: 91%, p=0.76, Log-rank test

5-year local recurrence free survival (all patients)

Sequential group: 92%

Concurrent group: 95%; p=0.76, Log-rank test

Local recurrence-free survival in the node negative subgroup (n=305)

Sequential group: 93%

Concurrent group: 93%, p=0.81, Log-rank test

Local recurrence-free survival in the node positive subgroup (n=389)

Sequential group: 91%

Concurrent group: 97%, p=0.02, Log-rank test; HR 0.61, 95% CI 0.38-0.93

### **2. Adverse effects**

**a) Acute effects**

Acute locoregional toxicities were moderate in both arms. Oesophagitis was more frequent in the concurrent arm (115 v 89; P = .04). Acute systemic symptoms also were mild in both arms. Nausea/vomiting was significantly higher in the sequential treatment arm (248 v 235; P = .008), whereas anaemia was significantly more frequent in the concurrent arm (111 v 81; P = .02).

**b) Late toxicity (subgroup analysis, n=214; 2<sup>nd</sup> reference):**

Subcutaneous fibrosis, telangiectasia, skin pigmentation, and breast atrophy occurred at higher rates in the concurrent arm than in the sequential arm. Twenty patients experienced Grade 2 or higher subcutaneous fibrosis in concurrent arm versus 5 patients in the sequential arm (p = 0.003; see table below).

Twenty-five patients and 7 patients showed Grade 2 or higher telangiectasia in the concurrent arm and the sequential arm, respectively (p = 0.001; see table below).

Forty-four patients and 20 patients showed Grade 2 or higher breast atrophy in the concurrent arm and the sequential arm, respectively (p = 0.0006; see table below).

Thirty patients experienced Grade 3 or higher skin pigmentation in the concurrent arm versus 15 patients in the sequential arm (p = 0.02; no data shown).

No statistical difference was observed between the 2 arms concerning Grade 2 or higher breast oedema or arm lymphoedema (see table below).

A trend toward increased Grade 2 or higher pain was seen in the concurrent arm, but this was not statistically significant (p = 0.07; see table below).

No deaths due to late toxicity, ulceration or severe cardiac or pulmonary events were observed in any patient in either group.

**Table: Radiotherapy late effects of the cutaneous and subcutaneous tissue scored by LENT-SOMA scale [n(patients)]**

Effect	Grade 0		Grade 1		Grade 2		Grade 3		Grade 4	
	A	B	A	B	A	B	A	B	A	B
Atrophy	44	34	43	29	10	25	10	17	0	2
Telangiectasia	82	58	18	24	2	8	5	17	-	-
Fibrosis	64	54	38	33	5	14	0	6	-	-
Breast oedema	99	100	8	6	0	1	0	0	-	-
Pain	73	56	21	27	10	17	3	5	0	2
Lymphoedema	86	80	18	25	2	0	1	2	0	0
Managed pain	102	96	3	6	2	4	0	0	0	1
Managed lymphedema	99	102	0	0	2	1	6	4	0	0

**Effect of length of follow-up in late-toxicity evaluation: rates of late toxicities (pain, breast edema, fibrosis, atrophy, lymphedema, telangiectases Grade 1 or higher or pigmentation Grade 2 or higher) as a function of interval between randomisation and clinical assessment.**

Before 5 years follow-up, there was no statistically significant difference in late toxicity between randomised arms. From the six year follow-up point the difference in rate of late toxicities became statistically significant (see table below).

Arm	Extent of follow-up (years)				
	<5	<6	<7	<8	<9
Concurrent arm	5/7	27/40	37/60	58/90	68/107
Sequential arm	4/9	13/34	27/63	36/87	44/107
p (by Chi square)	0.34	0.01	0.04	0.003	0.01

**General comments**

Power calculation performed to derive a target sample of 680 participants. Randomisation was stratified for participating center and axillary node status.

The main baseline characteristics of the two groups were similar. Involved tumor margins were found more in the sequential arm (36 v 20; P = .03), whereas margin invasion with ductal carcinoma in situ was seen more in the concurrent arm (28 v 44; P = .08).

There was no difference between the two arms in terms of type of surgery, mainly tumorectomy and quadrantectomy. The median CT dose was similar in the two arms. RT treatment was interrupted in 123 patients overall, for varying reasons, without a difference between the two arms.

Loss to follow-up: n=13 (10 patients in the sequential arm and 3 in the concurrent arm).

Authors do not report concealment of allocation nor blinding, which would not be feasible for the primary outcomes. However assessment of late toxicity was made by a radiation oncologist who was blinded to treatment allocation.

The analysis of late toxicity outcomes is not an intention-to-treat analysis. For this assessment the LENT-SOMA instrument was applied in 40 patients initially by 2 physician staff members to synchronise the objective grading to optimise the interobserver reliability.

Hershman, Wang, McBride, Jacobson, Grann & Neugut . Delay of adjuvant chemotherapy initiation following breast cancer surgery among elderly women. Breast Cancer Research and Treatment 99[3], 313-321. 2006.
<b>Design</b>
Retrospective cohort study Country of origin: USA Evidence grade: 2-
<b>Inclusion criteria</b>
5003 women identified from the Surveillance, Epidemiology and End-Results (SEER) & Medicare databases, of age 65 years and older, who were diagnosed with Stage I or II breast cancer from 1991 to 1999, and who received CT within 1 year of their diagnosis of breast cancer, but who did not receive RT prior to CT.
<b>Exclusion criteria</b>
<ul style="list-style-type: none"> <li>• Women who did not participate in Medicare;</li> <li>• Women treated with adjuvant RT prior to CT;</li> <li>• Women who had a prior cancer diagnosed before age 65, a prior breast cancer or other cancer, end-stage renal disease, or a diagnosis without histologic confirmation.</li> </ul>
<b>Population</b>
N=5003
<b>Interventions</b>
<p>Aim: to investigate factors that may contribute to delay in the receipt of adjuvant CT, and the effect of timeliness in the initiation of CT on overall survival among elderly women who did not receive prior RT.</p> <p>The interval from the date of the last surgical procedure within 6 months after the breast cancer diagnosis to the date of first CT was analysed as a categorical variable, with analysis groups arising as follows:</p> <ul style="list-style-type: none"> <li>• &lt;1 month (n=2361; 47%)</li> <li>• ≥1 to &lt;2 months (n=1846; 37%)</li> <li>• ≥2 to &lt;3 months (n=323; 6%)</li> <li>• ≥3 months (n=477; 10%)</li> </ul>
<b>Outcomes</b>
Predictive demographic and tumour-related variables for a delay in CT (with delay defined as a time interval greater than 3 months (84 days) from the date of the last surgical procedure within 6 months after the breast cancer diagnosis to the date of first CT).

Breast cancer-specific survival and overall survival by demographic, tumour related and delay to CT variables.

The demographic and tumour-related variables included in analyses were: age, race, urban/rural habitation, breast cancer stage (I or II), hormone receptor status, grade, comorbidity score, marital status, type of hospital providing care, socioeconomic status, receipt of RT (subsequent to CT) and type of surgery (lumpectomy versus mastectomy).

### **Follow up**

Minimum possible 12 months, maximum possible 9 years (no median reported; but some survival outcomes estimated at 5 years follow-up)

### **Results**

#### **1. Relationship between interval to CT and demographic and tumour-related variables**

In univariate analysis, time interval between surgery, and chemotherapy initiation was statistically significantly associated with each of the clinical variables investigated [age, race, urban/rural habitation, breast cancer stage (I or II), hormone receptor status, grade, comorbidity score, marital status, type of hospital providing care, socioeconomic status, receipt of RT (subsequent to CT) and type of surgery (lumpectomy versus mastectomy)];  $p < 0.05$  for each variable.

In a linear regression analysis, older age, residence outside a metropolitan area, having a hormone receptor negative tumor, being unmarried, and having undergone a mastectomy were statistically significantly associated with an increased number of days between surgery and initiation of chemotherapy ( $p < 0.05$ ). Advanced stage, subsequent treatment with radiation, and worse tumor grade were statistically significantly associated with shorter time to initiate chemotherapy  $p < 0.05$ .

#### **2. Relationship between interval to RT and survival**

Breast cancer specific survival was similar in patients who received chemotherapy within 1 month, 2 months, or within 3 months following surgery. Overall survival also did not differ among patients who started treatment in any of these time intervals.

#### **Interval from surgery to CT dichotomised to delay ( $\geq 3$ months) versus no delay ( $< 3$ months)**

The unadjusted 5-year cancer specific survival for patients who received CT within 3 months was 76% compared to 63% for those who delayed chemotherapy beyond 3 months.

In a multivariate analysis, the breast cancer specific mortality rate was higher among women who delayed chemotherapy 3 months or more following surgery (HR  $> 3$  months  $< 1$  month 1.69, 95% CI 1.31–2.19), as was the overall mortality rate (HR  $> 3$  months  $< 1$

month 1.46, 95% CI 1.21–1.75). The increased breast cancer specific mortality was also statistically significantly associated with advanced age, African American race, residence in a non-metropolitan location, estrogen receptor negative tumors, poorly differentiated tumors, increased number of comorbidities, being unmarried, and undergoing radiation therapy ( $p < 0.05$  in all cases).

**Table: strength of effect of interval to initiation of CT on survival**

Interval to initiation	Cancer specific survival		Overall survival	
	HR (95% CI)	p value	HR (95% CI)	p value
<1 month	Referent		Referent	
1–2 month	0.92 (0.78–1.09)	NS	1.00 (0.88–1.14)	NS
2–3 month	0.89 (0.64–1.25)	NS	1.08 (0.85–1.36)	NS
>3 month	1.69 (1.31–2.19)	$p < 0.01$	1.46 (1.21–1.75)	$p < 0.01$

**General comments**

Only women who received adjuvant chemotherapy within 12 months of their primary breast surgery were included, to ensure treatment was not for recurrent disease.

Distribution of interval to CT may differ in this US study to that of the UK. Study benefits from large size, but retrospective design cannot account for all confounding variables. Note that patients are a selected group: aged 65 years or more, and not treated with RT prior to CT.

Hershman, Wang, McBride, Jacobson, Grann & Neugut . Delay in initiating adjuvant radiotherapy following breast conservation surgery and its impact on survival. International Journal of Radiation Oncology Biology Physics 65[5], 1353-1360. 2006.
<b>Design</b>
Retrospective cohort study Country of origin: USA Evidence grade: 2-
<b>Inclusion criteria</b>
13,907 women identified from the Surveillance, Epidemiology and End-Results (SEER) & Medicare databases, of age 65 years and older, who were diagnosed with Stage I or II breast cancer from 1991 to 1999, and who received RT within 1 year of their diagnosis of breast cancer, but who did not receive chemotherapy.
<b>Exclusion criteria</b>
<ul style="list-style-type: none"> <li>• Women who did not participate in Medicare;</li> <li>• Women treated with adjuvant chemotherapy;</li> <li>• Women who had a prior cancer diagnosed before age 65, a prior breast cancer or other cancer, end-stage renal disease, or a diagnosis without histologic confirmation;</li> <li>• Women who received radiological procedures coded as 'radiation planning', 'hyperthermia', and 'nuclear medicine'.</li> </ul>
<b>Population</b>
N=13,907
<b>Interventions</b>
<p>Aim: to investigate factors that may contribute to delay in the receipt of adjuvant RT, and the effect of timeliness in the initiation of RT on overall survival among elderly women not receiving chemotherapy.</p> <p>The interval from the date of the last surgical procedure within 6 months after the breast cancer diagnosis to the date of first RT was analysed as a categorical variable, with analysis groups arising as follows:</p> <ul style="list-style-type: none"> <li>• &lt;1 month (n=7966; 57%)</li> <li>• ≥1 to &lt;2 months (n=4664; 34%)</li> <li>• ≥2 to &lt;3 months (n=800; 5%)</li> <li>• ≥3 months (n=477; 3%)</li> </ul>
<b>Outcomes</b>
Predictive demographic and tumour-related variables for a delay in RT (with delay defined

as a time interval greater than 3 months (84 days) from the date of the last surgical procedure within 6 months after the breast cancer diagnosis to the date of first RT).

Breast cancer-specific survival and overall survival by demographic, tumour related and delay to RT variables.

The demographic and tumour-related variables included in analyses were: age, race, urban/rural habitation, breast cancer stage (I or II), hormone receptor status, grade, comorbidity score, marital status, type of hospital providing care, socioeconomic status.

### Follow up

Minimum possible 12 months, maximum possible 10 years (no median reported; but some survival outcomes estimated at 5 years follow-up)

### Results

#### 1. Relationship between interval to RT and demographic and tumour-related variables

In univariate analysis, interval between surgery and RT was statistically significantly associated with each of the explanatory variables (age, race, urban/rural habitation, breast cancer stage (I or II), hormone receptor status, grade, comorbidity score, marital status, type of hospital providing care, socioeconomic status).

#### Multivariate analysis (linear regression model): Odds ratios for an interval between surgery and RT of $\geq 3$ months:

## 2. Relationship between interval to RT and survival

Patients who received RT within 1–2 months, 2–3 months, or >3 months after surgery were compared with those who initiated postsurgical radiation within 1 month. Both overall survival and breast cancer–specific survival were similar in patients who received RT within 1 month, 2 months, or within 3 months after surgery (no data shown).

### a) Hazard ratios for survival by interval from surgery to RT and other demographic/tumour-related variables

Variable	Cancer-specific survival			Overall survival

**Interval from surgery to RT dichotomised to delay ( $\geq 3$  months) versus no delay ( $< 3$**

**months)**

The unadjusted 5-year survival for women who received RT within 3 months of surgery was 81% compared with 67% for those who delayed RT beyond 3 months (no p value reported)

In a multivariate analysis, overall mortality rates were higher among women who delayed RT 3 months or more after surgery (HR 1.61; 95% CI, 1.42–1.82), as were cancer-specific mortality rates (HR 2.14; 95% CI, 1.79 –2.57).

**General comments**

Distribution of interval to RT may differ in this US study to that of the UK. Study benefits from large size, but retrospective design cannot account for all confounding variables. Note that patients are a selected group: aged 65 years or more, and not treated with chemotherapy.

## Delay from surgery to radiotherapy

<p>Benchalal, M., Le Prise, E., De Lafontan, B., Berton-Rigaud, D., Belkacemi, Y., Romestaing, P., Peignaux, K., Courdi, A., Monnier, A., Montcuquet, P., Goudier, M. J., Marchal, C., Chollet, P., badie-Lacourtoisie, S., Datchary, J., Veyret, C. &amp; Kerbrat, P. (2005) Influence of the time between surgery and radiotherapy on local recurrence in patients with lymph node-positive, early-stage, invasive breast carcinoma undergoing breast-conserving surgery - Results of the French adjuvant study group. <i>Cancer</i>, 104: 240-250.</p>
<b>Design</b>
Retrospective re-analysis of 7 RCTs. (Level 3 evidence). France
<b>Inclusion criteria</b>
Women with operable lymph node positive breast cancer. The women enrolled in one of seven RCTs WHO performance status 2 or less, normal liver, kidney and blood test results, no cardiac dysfunction.
<b>Exclusion criteria</b>
Metastatic disease, inflammatory or locally advanced breast cancer, history of cardiac disease or previous malignancy, serious physical or mental co-morbidity. Previous radiotherapy, hormone therapy or chemotherapy for breast carcinoma. Start of adjuvant treatment greater than 42 days after surgery.
<b>Population</b>
1831 patients, age 22 to 84. Most were tumour stage I to IIB
<b>Interventions</b>
All women received BCS with axillary dissection (at least 5 nodes removed). Women received either epirubicin based chemotherapy ± tamoxifen, tamoxifen only or no systemic therapy. Radiotherapy was started within 30 days of the third chemotherapy cycle in 2 trials (n=567) and within 30 days of the last chemotherapy cycle in the other 5 trials (n=789) or after BCS in women not receiving chemotherapy (n=475). The RT dose to the breast ranged from 45 to 55 Gy (conventionally fractionated) with a 10 to 15 Gy boost to the primary tumour site. Some women received RT to the superclavicular area, internal mammary chain and axillary area.
<b>Outcomes</b>
Local recurrence.
<b>Follow up</b>
Median follow up in the 7 trials ranged from 76 months to 138 months. Patients underwent clinical and lab tests every 6 months for the first 5 years and then yearly thereafter.
<b>Results</b>

Local recurrence: timing of radiotherapy (after 3 courses of chemotherapy vs. after 6 courses of chemotherapy vs. after BCS) was not a significant predictor of local recurrence in a multivariate Cox-regression, which included pathologic tumour size, use of hormone therapy and number of chemotherapy courses as covariates.

The hazard ratios for local recurrence between the three RT groups were: after 6<sup>th</sup> cycle vs. after BCS 1.18 (95% CI 0.69 to 1.67), after 6<sup>th</sup> cycle vs. after 3<sup>rd</sup> cycle 1.29 (95% CI 0.93 to 1.65).

#### **General comments**

Due to differences in trial protocols there were systematic differences between the systemic therapy received by the different RT-timing groups. Possibly addressed by the use of systemic treatment as a covariate in the analysis. RT timing was not measured directly as a continuous variable, only estimated indirectly from the type of systemic therapy received.

Jobsen, J. J., van der Palen, J., Ong, F. & Meerwaldt, J. H. (2006) Timing of radiotherapy and survival benefit in breast cancer. <i>Breast Cancer Research and Treatment</i> , 99: 289-294.
<b>Design</b>
Prospective cohort study. Netherlands (Quality 2-)
<b>Inclusion criteria</b>
Patients with stage I or II node negative breast carcinoma treated with BCS and radiotherapy in the Twente-Achterhoek region between 1983 and 2003.
<b>Exclusion criteria</b>
Any adjuvant systemic therapy, synchronous bilateral breast cancer.
<b>Population</b>
1446 patients
<b>Interventions</b>
BCS, with level I to III axillary clearance (or sentinel lymph node procedure from 2000 onwards). RT was 50 Gy to the whole breast (2 Gy fractions) followed by a 14 or 15 Gy boost to the tumour bed. Patients were divided into 3 groups depending on timing of radiotherapy after surgery: 1 to 36 days (n=506) – group 1 37 to 53 days (n=483) – group 2 54 to 112 days (n=484) – group 3
<b>Outcomes</b>
Local recurrence, Disease Specific Survival
<b>Follow up</b>
Length of follow up ranged from 5 to 265 months (median 90 months). Survival analysis included follow up to 120 months.
<b>Results</b>
Local recurrence Multivariate Cox regression of local recurrence was done using margin status, age group, metachronous contralateral breast cancer and RT timing group as covariates. RT timing group was not a significant predictor of local recurrence (HR not reported).
Disease Specific Survival Multivariate Cox regression of DSS was done using, age group, family history, in situ carcinoma, histology, tumour size, ER/PR receptor status, lymph-angioinvasion, lumpectomy-axillary delay and RT timing group as covariates.
Death from breast cancer was less likely in RT timing group 2 than group 1 (HR 0.6, 95%

CI 0.4 to 1.0), and less likely in group 3 than group 1 (HR 0.3, 95% CI 0.14 to 0.6). This suggested that shorter delay from BCS to RT was a risk factor for death from breast cancer (although there is a strong risk of bias, see below).

**General comments**

Delay between BCS and RT was also correlated with year of treatment. Women treated in the 1983 to 1993 time period were more likely to be in group 1 than those treated in the 1999 to 2003 period and this confounds the results. Year of treatment does not appear to have been included in the multivariate models.

RT delay categorized into 3 groups, rather than considered a continuous variable. Only variables significant on univariate analysis were included in the multivariate model.

Mikeljevic, J. S., Haward, R., Johnston, C., Crellin, A., Dodwell, D., Jones, A., Pisani, P. & Forman, D. (2004) Trends in postoperative radiotherapy delay and the effect on survival in breast cancer patients treated with conservation surgery. *British Journal of Cancer*, 90: 1343-1348.

**Design**

Cohort. UK (Quality 2+)

**Inclusion criteria**

Female breast cancer patients included in the Northern and Yorkshire Cancer registry, diagnosed between 1986 and 1998.

**Exclusion criteria**

No surgery, mastectomy, no RT, preoperative RT, delay from surgery to RT of more than 6 months.

**Population**

7800 women

**Interventions**

BCS, radiotherapy . 23% had chemotherapy and 82% had hormonal therapy.

**Outcomes**

Overall survival.

**Follow up**

5 years

**Results**

Patients were divided into 6 groups for analysis. Adjusted relative risks for death were calculated using age, stage, grade, deprivation index, time period and chemotherapy as covariates

<b>Surgery-RT interval (weeks)</b>	<b>5 year survival (95% CI)</b>	<b>Adjusted RR(95% CI)</b>
1 to 4	80% (79 to 83%)	1.00
5 to 6	80% (78 to 82%)	1.04 (0.91 to 1.19)
7 to 8	84% (83 to 86%)	0.99 (0.85 to 1.15)
9 to 12	84% (83 to 86%)	1.04 (0.89 to 1.22)
13 to 19	81% (79 to 84%)	1.16 (0.96 to 1.40)
20 to 26	76% (71 to 80%)	1.49 (1.16 to 1.92)

There was a statistically significant increase in the relative risk of death in patients whose RT was delayed for 20 to 26 weeks from surgery, when compared to those who had RT within a month of surgery.

**General comments**

Registry data, it was not always clear whether RT was given as adjuvant or salvage therapy (especially true with longer delays).

## Delay from surgery to the start of chemotherapy

Sanchez, C. J., Ruiz, A., Martin, M., Anton, A., Munarriz, B., Plazaola, A., Schneider, J., del Prado, P. M., Alba, E. & Fernandez-Aramburo, A. (2007) Influence of timing of initiation of adjuvant chemotherapy over survival in breast cancer: A negative outcome study by the Spanish breast cancer research group (GEICAM). <i>Breast Cancer Research and Treatment</i> , 101: 215-223.				
<b>Design</b>				
Cohort study Country of origin: Spain Evidence grade: 2-				
<b>Inclusion criteria</b>				
Women included in a multicentre cohort study, with stage I-III breast cancer, who received surgery and adjuvant chemotherapy (N=7342). Women were treated between 1990 and 1997				
<b>Exclusion criteria</b>				
Missing data on timing of surgery and chemotherapy (N=4560). Male patients, neoadjuvant therapy.				
<b>Population</b>				
N=2782				
<b>Interventions</b>				
Surgery with curative intent and adjuvant chemotherapy.				
<b>Outcomes</b>				
Disease free survival, overall survival				
<b>Follow up</b>				
Not reported. Outcomes analyzed to 5 years after treatment				
<b>Results</b>				
Women were divided into four chemotherapy-timing groups for analysis.				
	<b>Delay from surgery to chemo (weeks)</b>	<b>n</b>	<b>5 yr DFS (%)</b>	<b>5 yr OS (%)</b>
	<3	637	72.5	85.5
	3 to 6	1624	76.1	87.7
	6 to 9	295	72.5	84.7
	>9	226	77.1	89.9
Using a Cox-regression model, delay from surgery to chemotherapy group was not a significant predictor of overall survival, with known prognostic factors included as covariates (HR not reported). This was also the case when delay was considered as a				

continuous variable.

**General comments**

Poor reporting of multivariate model, only statistically significant predictors are reported

Lohrisch, C., Paltiel, C., Gelmon, K., Speers, C., Taylor, S., Barnett, J. & Olivotto, I. A. (2006) Impact on survival of time from definitive surgery to initiation of adjuvant chemotherapy for early-stage breast cancer. *Journal of Clinical Oncology*, 24: 4888-4894.

**Design**

Cohort  
Country of origin: Canada  
Evidence grade: 2-

**Inclusion criteria**

Women aged 90 years or less referred to the British Columbia Cancer Agency between 1989 and 1998 with stage I or II breast cancer and known pathologic nodal status. All received adjuvant chemotherapy.

**Exclusion criteria**

Locally advanced or metastatic disease, those who could not be linked to a pharmacy database. Chemotherapy started more than 24 weeks after surgery. Neoadjuvant chemotherapy. Relapse within 12 weeks of surgery. Delay >17 weeks between diagnosis and surgery. Prior or synchronous breast cancer

**Population**

N=2594

**Interventions**

Surgery with curative intent. Adjuvant chemotherapy (standard regimens included: AC, FAC-CAF, CMF)

**Outcomes**

Recurrence free survival, overall survival

**Follow up** Median follow up was 6.2 years

**Results**

Patients were divided into four chemotherapy timing groups for analysis

Delay from surgery to chemo (weeks)	n	5 yr RFS (%) (95% CI)	5 yr OS (%) (95% CI)
0 to 4	993	73.9 (71.0 to 76.5)	83.5 (81.1 to 85.7)
>4 to 8	1272	78.7 (76.3 to 80.9)	85.1 (82.9 to 86.9)
>8 to 12	217	82.4 (76.5 to 86.9)	88.7 (83.6 to 92.3)
>12 to 24	112	69.3 (59.7 to 77.0)	78.4 (69.5 to 85.0)

On univariate (log-rank) analysis there was a statistically significant difference between groups in both RFS and DFS (P=0.004 and P=0.013 respectively).

On multivariate analysis delay from surgery to chemotherapy between 12 and 24 weeks was an independent predictor of overall survival (HR=1.6, 95% CI 1.2 to 2.3), with tumour size, nodal status, age and LVI as covariates.

**General comments**

Relatively few patients in the 12 to 24 week group, only 4% of the overall cohort.

Shannon, C., Ashley, S. & Smith, I. E. (2003) Does timing of adjuvant chemotherapy for early breast cancer influence survival? <i>Journal of Clinical Oncology</i> , 21: 3792-3797.			
<b>Design</b>			
Prospective case series Country of origin: UK Evidence grade: 3			
<b>Inclusion criteria</b>			
Patients treated with adjuvant anthracycline based chemotherapy at the Royal Marsden Hospital between 1990 and 2001, either in clinical trials or on the basis of service guidelines.			
<b>Exclusion criteria</b>			
None reported			
<b>Population</b>			
N=1161			
<b>Interventions</b>			
Surgery: breast conserving surgery (N=911), mastectomy (N=250) Adjuvant anthracycline based chemotherapy: combinations including epirubicin (N=686), CMF or mitoxantrone and methotrexate (N=475) Adjuvant endocrine treatment (N=974) Local radiotherapy (N=846)			
<b>Outcomes</b>			
Disease free survival (DFS), overall survival (OS), both measured from the date of first surgery.			
<b>Follow up</b>			
Median 39 months (range 12 to 147 months)			
<b>Results</b>			
Patients were divided into 2 chemotherapy timing groups for analysis: within 3 weeks of surgery versus 3 or more weeks after surgery.			
	<b><u>Surgery to Chemotherapy delay group</u></b>		
	<b>&lt;3 weeks</b>	<b>3 or more weeks</b>	<b>Log-rank P</b>
<b>5 yr DFS</b>	70%	72%	0.4
<b>5 yr OS</b>	82%	84%	0.2
DFS			
A Cox-proportional hazards model was used to adjust for known prognostic factors of pathologic size, nodal status, number of involved nodes, grade vascular invasion, ER status, type of chemotherapy and use of endocrine therapy. The timing of chemotherapy			

(within 3 weeks versus 3 weeks) was not an independent predictive factor of disease free survival (HR not reported).

#### OS

A Cox-proportional hazards model was used to adjust for known prognostic factors. The timing of chemotherapy (within 3 weeks versus 3 weeks) was not an independent predictive factor of overall survival (HR not reported).

When chemotherapy timing was considered as a continuous variable, it was still not an independent predictor of survival (HR not reported). Similarly when a 4 week and 5 week cut-offs were used to categorise patients there was still no effect of chemotherapy timing on survival.

#### **General comments**

Slightly higher rate of mastectomy in the late chemotherapy group than in the early group (24% vs. 17%,  $p=0.01$ ).

Cold, S., Durning, M., Ewertz, M., Knoop, A. & Moller, S. (2005) Does timing of adjuvant chemotherapy influence the prognosis after early breast cancer? Results of the Danish Breast Cancer Cooperative Group (DBCG). *British Journal of Cancer*, 93: 627-632.

### Design

Re-analysis of RCTs, observational evidence  
Country of origin: Denmark  
Evidence grade: 3

### Inclusion criteria

Patients with early breast cancer entered into Danish Breast Cancer Cooperative Group adjuvant chemotherapy trials between 1977 and 1999

### Exclusion criteria

Delay of more than 89 days between surgery and chemotherapy, missing pathological data

### Population

N=7501

### Interventions

Breast surgery, not specified in detail  
Adjuvant chemotherapy: classical CMF (N=352), CMF (N=6065) or CEF (N=1084). All included patients started chemotherapy within 13 weeks of surgery.  
Radiotherapy, (N=3555) not specified in detail  
Endocrine therapy, not reported

### Outcomes

Overall survival

### Follow up

Not reported

### Results

#### Overall survival

Patients were divided into 4 chemotherapy to surgery delay groups for analysis. Multivariate analysis of overall survival was adjusted for known prognostic factors: age, tumour size, number of nodes, histological type, malignancy grade and receptor status.

For patients receiving classical CMF adjuvant chemotherapy

Start of chemotherapy	Adjusted HR (95% CI)
1 to 3 weeks	1
4 weeks	0.929 (0.441 to 1.957)
5 weeks	1.549 (0.761 to 3.149)

6 to 13 weeks	1.588 (0.856 to 2.948)
---------------	------------------------

For patients receiving CMF adjuvant chemotherapy

Start of chemotherapy	Adjusted HR (95% CI)
1 to 3 weeks	1
4 weeks	1.021 (0.903 to 1.155)
5 weeks	0.891 (0.782 to 1.012)
6 to 13 weeks	1.002 (0.884 to 1.136)

For patients receiving CEF adjuvant chemotherapy

Start of chemotherapy	Adjusted HR (95% CI)
1 to 3 weeks	1
4 weeks	1.218 (0.800 to 1.854)
5 weeks	1.045 (0.716 to 1.525)
6 to 13 weeks	1.238 (0.861 to 1.782)

The timing of the start of chemotherapy after surgery was not an independent predictive factor for overall survival.

**General comments**

Colleoni, M., Bonetti, M., Coates, A. S., Castiglione-Gertsch, M., Gelber, R. D., Price, K., Rudenstam, C. M., Lindtner, J., Collins, J., Thurlimann, B., Holmberg, S., Veronesi, A., Marini, G. & Goldhirsch, A. (2000) Early start of adjuvant chemotherapy may improve treatment outcome for premenopausal breast cancer patients with tumors not expressing estrogen receptors. The International Breast Cancer Study Group. *Journal of Clinical Oncology*, 18: 584-590.

**Design**

Re-analysis of RCTs  
 Evidence grade: 3  
 Country: International

**Inclusion criteria**

Women enrolled in one of three international RCTs between 1978 and 1993. Premenopausal, positive axillary lymph nodes. Data available on ER levels.

**Exclusion criteria**

Oophorectomy. Patients who did not start chemotherapy.

**Population**

N=1788

**Interventions**

Surgery, not specified in detail  
 Adjuvant chemotherapy, classical CMF  
 Endocrine therapy and radiotherapy not reported

**Outcomes**

Disease free survival (DFS),

**Follow up**

Median follow up was 7.7 years.

**Results**

Patients were divided into two chemotherapy timing groups for analysis: within 3 weeks after surgery versus 3 or more weeks after surgery.

Multivariate analysis of disease free survival was done, adjusting for number of positive axillary nodes, tumour size, age and vessel invasion.

The effect of chemotherapy timing (within 3 weeks after surgery versus 3 or more weeks) on disease free survival is summarized below using hazard ratios and stratified by ER group.

ER group	N	Adjusted HR (95% CI)
Combined	1788	0.88 (0.76 to 1.03)

ER negative	226	0.60 (0.39 to 0.92)
ER 1 to 9	379	0.92 (0.63 to 1.33)
ER 10 or more	1183	0.91 (0.76 to 1.10)

Overall, the timing of the start of chemotherapy after surgery was not an independent predictive factor for disease free survival. In the sub-group of ER negative women disease free survival was significantly lower in those who started chemotherapy later than 3 weeks after surgery.

## Chapter 5 – Adjuvant systemic therapy

### ***5.1 In premenopausal patients with breast cancer, what are the benefits of adjuvant ovarian suppression/ablation?***

#### **Short Summary**

There is a large volume of randomised trials of ovarian ablation and ovarian suppression in women with early breast cancer, and numerous high-quality systematic reviews are also available. Broadly, the literature describes two types of intervention: either ovarian ablation (by surgery or radiotherapy) or ovarian suppression using luteinising hormone releasing hormone agonist (LHRHa), each used adjuvant to surgery to the breast.

Evidence from systematic reviews of randomised trials, meta-analyses of individual patient data from randomised trials and further published randomised trials is suggestive of the following effects of ovarian ablation (by oophorectomy or radiotherapy) or suppression (by LHRH agonist).

**Ovarian ablation or suppression versus none:** In premenopausal women with breast cancer that is ER positive or with unknown ER status, ovarian ablation or suppression is beneficial compared to no ovarian treatment in terms of recurrence (respective rates 47% and 52%,  $p < 0.0001$ ) and breast cancer mortality (respective rates 40% and 44%,  $p < 0.004$ ), both assessed at 15 years follow-up (Early Breast Cancer Trialists' Collaborative Group 2005).

**Ovarian ablation and the role of chemotherapy:** The most recent evidence from a meta-analysis of individual patient data suggests that ovarian ablation has a benefit in terms of recurrence and survival over no ablation in premenopausal women, with or without chemotherapy (EBCTCG 2005). An earlier meta-analysis performed by the same group found that this benefit exists in the absence of chemotherapy, but not where adjuvant chemotherapy is given (EBCTCG 1998). Randomised trials that were not included in these reviews have demonstrated equivalence in terms of 10 year recurrence and survival between ovarian ablation and chemotherapy, with tamoxifen used in some randomised arms (Nomura *et al.* 1999; Thomson *et al.* 2002). An RCT was able to show no advantage of additional goserelin after a risk-adapted chemotherapy with respect to event free survival in hormone receptor negative patients (Kaufmann *et al.* 2007).

**LHRHa versus no systemic therapy:** A relatively small meta-analysis ( $n=338$ ) found no difference in recurrence or survival, comparing LHRH agonists with no systemic therapy (Cuzick *et al.* 2007). From a well conducted RCT, premenopausal women with operable breast cancer showed a 5 and 10 year disease free survival and overall survival rates were significantly improved following adjuvant oophorectomy and tamoxifen (Love *et al.* 2008).

**LHRHa versus chemotherapy:** A larger meta-analysis (n=3184) in the same study found LHRH agonists to be equivalent to chemotherapy in terms of recurrence and survival (Cuzick *et al.* 2007).

**LHRHa plus tamoxifen versus LHRH alone or tamoxifen alone:** A Cochrane Review indicates that recurrence and mortality are reduced in premenopausal women treated with a LHRHa combined with tamoxifen compared to women treated with either drug alone (Sharma *et al.* 2007). In contrast a meta-analysis of individual patient data found no difference in recurrence or death following recurrence arising from treatment with LHRHa plus tamoxifen versus tamoxifen alone (Cuzick *et al.* 2007).

**LHRHa with or without tamoxifen in addition to chemotherapy:** Evidence from a narrative Cochrane Review and meta-analysis of randomised trials indicates that recurrence and mortality are reduced in premenopausal women with ER positive tumours who are treated with a LHRHa, with or without tamoxifen, in addition to chemotherapy (Sharma *et al.* 2007; Cuzick *et al.* 2007).

**LHRHa with or without tamoxifen versus chemotherapy:** Evidence from a narrative Cochrane Review and meta-analysis of randomised trials indicates that LHRHa, with or without tamoxifen, are as effective as chemotherapy for premenopausal women with ER positive tumours, in terms of recurrence and mortality (Cuzick *et al.* 2007; Sharma *et al.* 2007)

**Side effects and quality of life:**

Evidence from randomised trials suggests that ovarian ablation, ovarian suppression and chemotherapy each have adverse side effects and each can induce menopausal symptoms, including amenorrhoea (Brunt *et al.* 2004a; Groenvold *et al.* 2006; Schmid *et al.* 2007; Love *et al.* 1999; Sharma *et al.* 2007; Celio *et al.* 2002). A randomised comparison of oophorectomy and tamoxifen versus observation in Vietnamese women found that menopausal symptoms resulted from oophorectomy and tamoxifen within the first twelve months from start of treatment (Love *et al.* 1999). A Cochrane Review cited trials which found that side effects are more severe following LHRH agonist plus tamoxifen compared to tamoxifen alone (Sharma *et al.* 2007). Health-related quality of life tends to favour ovarian ablation or suppression over chemotherapy, whereas acute adverse effects appear to be worse following chemotherapy. In contrast, menopausal symptoms (for example hot flushes) appear to be worse following ablation or suppression, than following chemotherapy, and with earlier onset. Amenorrhoea can be longer lasting following chemotherapy compared with LHRH agonist (Brunt *et al.* 2004a; Groenvold *et al.* 2006; Sharma *et al.* 2007; Schmid *et al.* 2007). In one study a self assessment of tolerability by patients favoured LHRH agonist over CMF chemotherapy during the first 6 months, but with comparable tolerability at two years (Schmid *et al.* 2007).

## PICO

Population	Intervention	Comparison	Outcome
<p>Premenopausal patients with early invasive breast cancer. Including: Receptor positive and Receptor negative</p> <p><b>Note:</b> Patients with breast cancer who have had ovarian suppression/ablation without chemotherapy will also be considered.</p>	<ul style="list-style-type: none"> <li>• Ovarian suppression (LHRH &amp; oophorectomy) ± chemotherapy</li> <li>• Ovarian ablation</li> <li>• Zoladex</li> </ul>	<ul style="list-style-type: none"> <li>• No treatment</li> <li>• Chemotherapy with or without Tamoxifen</li> </ul>	<ul style="list-style-type: none"> <li>• Disease-free survival (DFS)</li> <li>• Overall survival (OS)</li> <li>• Contralateral breast cancer</li> <li>• Quality of life (SE profile)</li> <li>• Psychological morbidity</li> </ul>

### Evidence Summary

**Population:** The population of interest is women with early breast cancer who are pre-menopausal, and the included studies have good applicability in this regard. Some studies estimated menopausal status using a threshold of age <50 years (Early Breast Cancer Trialists' Collaborative Group 1998; Early Breast Cancer Trialists' Collaborative Group 2005).

ER status is likely to be an important factor in assessing outcomes following ovarian ablation or suppression. Many trials are directed at patients with ER positive tumours. There appears to be more benefit arising from ovarian ablation or suppression in the ER positive subset, and one study offered different randomised treatment plans to patients according to ER status, with ovarian treatment possible as a randomly allocated treatment only in ER positive cases (Nomura *et al.* 1999).

**Interventions:** Broadly, the literature describes two types of intervention: either ovarian ablation (by surgery or radiotherapy) or ovarian suppression using luteinizing hormone releasing hormone (LHRH) agonists, each used adjuvant to surgery to the breast. Some studies present results separately for the two types of intervention, or report only one intervention (e.g. LHRH agonists alone).

Some authors use the terms ablation and suppression inconsistently or interchangeably (Brunt *et al.* 2004b; Groenvold *et al.* 2006). In terms of this question as set out in PICO format, ovarian ablation (by surgery or ovarian radiotherapy) and ovarian suppression (by LHRH agonist) may be regarded as equivalent procedures. The comparison of interest is ovarian ablation or suppression versus no adjuvant treatment, or versus adjuvant chemotherapy or hormone therapy.

Some of the randomised trials that contribute data to the cited systematic reviews were conducted decades ago, particularly trials of ovarian ablation by surgery or radiotherapy. Such trials may have used older adjuvant chemotherapy regimens which differ from modern regimens.

**Outcomes:** The included studies focus heavily on recurrence and survival outcomes, particularly the systematic reviews, but tend less to report side effect data. The Cochrane Review of ovarian ablation (Early Breast Cancer Trialists' Collaborative Group 1998) reported in brief that ablation has major adverse side effects. Additional papers from RCTs published subsequent to the systematic reviews have been sought, as have RCTs that have reported additional side effect data. Even so, side effect and quality of life data may be underrepresented in the selected studies.

**Other factors:** Other publications were sought from randomised trials which meet the following criteria:

- Studies that did not contribute data to the EBCTCG dataset
- Studies published of trials included in the EBCTCG-based systematic reviews which subsequently publish data with longer follow-up e.g. (Schmid *et al.* 2007)
- Studies that publish data on psychosocial or quality of life outcomes; such outcomes were not reported in the EBCTCG-based systematic reviews.

**Evidence:**

### **1. Ovarian ablation or suppression versus control**

The systematic review of RCTs and meta-analysis of individual patient data by (Early Breast Cancer Trialists' Collaborative Group 2005) compared ovarian ablation (by RT or oophorectomy) or suppression with LHRH agonists versus no ovarian treatment (with or without other adjuvant systemic therapy) in women with tumours that were ER positive or of unknown ER status. Results at 15 years follow-up based on analysis of 7601 women of age , entry age <50 years at trial entry indicated a benefit in favour of ablation/suppression in terms of recurrence and breast cancer mortality (Early Breast Cancer Trialists' Collaborative Group 2005):

**Recurrence:**

Ablation or suppression: 47.3%

Control: 51.6%

Logrank 2p=0.00001 (Early Breast Cancer Trialists' Collaborative Group 2005)

**Breast cancer mortality:**

Ablation or suppression: 40.3%

Control: 43.5%

Logrank 2p=0.004 (Early Breast Cancer Trialists' Collaborative Group 2005)

## **2. Ovarian Ablation versus control**

A Cochrane review was published that was based upon the EBCTCG dataset and which compared ovarian ablation (by surgery or RT) versus control (Early Breast Cancer Trialists' Collaborative Group 1998). On the basis of the odds ratios shown below, ovarian ablation resulted in statistically significant benefits in terms of recurrence-free survival and overall survival in the subgroup of patients who did not receive chemotherapy, but with no benefit in the subgroup of patients treated with chemotherapy.

Recurrence-free survival in the absence of chemotherapy: Ovarian ablation versus control: OR 0.75; 95% CI 0.64-0.88;  $p=0.0005$

Recurrence-free survival in the presence of chemotherapy: Ovarian ablation versus control: OR 0.90; 95% CI 0.75-1.08;  $p=0.2$

Total (recurrence-free survival;  $n=2174$ ): Ovarian ablation versus control: OR 0.82; 95% CI 0.72-0.92

Overall survival in the absence of chemotherapy: Ovarian ablation versus control: OR 0.76; 95% CI 0.65-0.89

Overall survival in the presence of chemotherapy: Ovarian ablation versus control: OR 0.92; 95% CI 0.75-1.12

Total (overall survival;  $n=2174$ ): Ovarian ablation versus control: OR 0.82; 95% CI 0.72-0.92

For the reported odds ratios the review does not specify whether they represent patients of age <50 years. However the review concluded that ovarian ablation improves long term survival in pre-menopausal patients with early breast cancer, but also has major adverse effects and is unlikely to be of benefit to post-menopausal women (Early Breast Cancer Trialists' Collaborative Group 1998).

A subsequent publication from the same group (Early Breast Cancer Trialists' Collaborative Group 2005) provided another meta-analysis of individual patient data, comparing ovarian ablation versus control at a mean follow-up of 8 years. The risk ratio for recurrence in women of age < 50 years (ablation: control) was 0.83 (95% CI 0.73-0.93),  $2p=0.0005$  i.e. a statistically significant effect in favour of ablation, where some patients received chemotherapy and others did not. The risk ratio for mortality in women of age < 50 years (ablation: control) was 0.86 (95% CI 0.76-0.96),  $2p=0.01$ . Again, this represents a statistically significant effect in favour of ablation, where some patients received chemotherapy and others did not.

A randomised controlled trial by (Groenvold *et al.* 2006) measured health-related quality of life during the 2 years following randomisation to either CMF chemotherapy versus ovarian ablation by oophorectomy in 196 premenopausal women with oestrogen or progesterone receptor positive breast cancer. Functional and symptom-related aspects of QOL based upon EORTC QLC-C30 mean scores tended to favour ablation when measured up to month five from randomisation: statistically significant differences in mean score in favour of ablation were seen for cognitive function, social function, constipation, fatigue, nausea and vomiting, dyspnoea, sleep, loss of appetite and global health/QOL. In contrast the diarrhoea outcome favoured chemotherapy, but only in the first month. For all EORTC QLC-C30 outcomes after five months there were no differences between groups. For physical symptoms outcomes assessed using the DBCG 89 scale, statistically significant differences in score favoured ablation for use of a wig, anticipatory nausea, regular bleedings, bleedings, urinary incontinence, weight gain (>2kg), hair loss and sore mouth. Some of these differences persisted until, or became apparent at approximately two years follow-up. In contrast, statistically significant differences favoured chemotherapy for hot flushes/sweats and to a lesser extent satisfaction with appearance, but with no difference persisting beyond 9 months. There was no difference between randomised arms for HAD anxiety score over the two year period, whereas HAD depression score favoured ablation at month 3 and at month 5 (Groenvold *et al.* 2006).

The UKCCR ABC randomised controlled trial included a randomised comparison of ovarian suppression (not further specified) or chemotherapy versus none, with tamoxifen in all cases, in 199 Pre/peri-menopausal women with early breast cancer; QOL outcomes were presented in an abstract (Brunt *et al.* 2004a). The addition of chemotherapy was associated with worse QOL during the first 9 months for depression ( $p=0.007$ ), role function ( $p=0.003$ ) and global QOL ( $p=0.001$ ) and a trend to worse QOL for body image concerns ( $p=0.02$ ), and sexual enjoyment ( $p=0.08$ ). Systemic side effects ( $p=0.001$ ) and menopausal problems ( $p=0.02$ ) were worse over 30 months. The addition of ovarian suppression resulted in increased menopausal symptoms ( $p<0.0001$ ), depression ( $p=0.05$ ) and anxiety ( $p=0.04$ ) over 30 months but no deterioration in role function, global QOL, body image or sexual function (Brunt *et al.* 2004a).

A randomised controlled trial reported in abstract form by (Celio *et al.* 2002) compared surgical oophorectomy versus FEC chemotherapy, with Tamoxifen in both arms, in 109 women with invasive, hormone receptor (ER or PR) positive, node-positive breast cancer. Poor accrual resulted in the study being stopped prematurely. All patients in the chemotherapy arm completed all cycles, but only 46 out of 55 patients received more than 95% of the total planned chemotherapy dose. Grade 3-4 neutropenia occurred in 12% of patients, and 75% of normally menstruating patients experienced amenorrhoea persisting after chemotherapy. With a median follow-up of 68 months, there were 10 (18%) vs. 4 (7%)

recurrences and 6 (11%) vs. 3 (5%) deaths in the oophorectomy and chemotherapy arms, respectively.

A randomised controlled trial compared oophorectomy and tamoxifen versus observation (with oophorectomy and tamoxifen initiated if metastatic disease was subsequently detected) in 709 premenopausal Vietnamese women with operable breast cancer of stage I-IIIa (Love *et al.* 2002). In an intention-to-treat analysis at a median 3.6 years follow-up, disease-free survival ( $p=0.0003$ ) and overall survival ( $p=0.0477$ ) were higher in the intervention group compared to the control group. Disease-free survival estimated at 5 years by Kaplan-Meier analysis was 75% in the intervention group and 58% in the observation group. Considering only the ER positive subgroup at a median 3.6 years follow-up, disease-free survival ( $p=0.001$ ) and overall survival ( $p=0.01$ ) were higher in the intervention group compared to the control group. Considering only the ER negative subgroup at a median 3.6 years follow-up, there was no statistically significant difference in disease-free survival or overall survival between the intervention group and the control group. The same authors undertook a sub-study on side effects of treatment in 482 women (Love *et al.* 1999). In the first 12 months from randomisation, the occurrence and severity of hot flashes, vaginal discharge and vaginal pruritus favoured the observation arm, to a statistically significant level. An excess of vasomotor symptoms persisted in women treated with oophorectomy and tamoxifen over three years of follow-up although at 3 years only 23% of treated women had these symptoms, and the majority of these were of grade 1 intensity. While over time small numbers of observation group patients developed recurrent disease and received oophorectomy and tamoxifen treatment and developed associated symptoms, these events do not significantly alter the distribution of vasomotor symptoms between groups. No women stopped tamoxifen because of toxicity.

From a well conducted RCT, premenopausal women with operable breast cancer showed a 5 and 10 year disease free survival and overall survival rates were significantly improved following adjuvant oophorectomy and tamoxifen (Love *et al.* 2008). Disease free Survival and Overall Survival: With a median follow-up of 7.0 years and from intent-to-treat analyses, a significant difference in disease free survival (DFS) ( $P= 0.0003$ ) and overall survival (OS) ( $P= 0.0002$ ) was found, which favoured the intervention group.

- 5-year DFS was 74% in adjuvant group and 61% in observation groups (95% CI for difference, 7% - 21%)
- 10-year DFS was 62% in adjuvant group and 51% in observation groups (95% CI for difference, 4% - 22%).
- 5-year OS rates were 78% in adjuvant group and 71% in observation groups (95% CI for difference, 1% - 21%)
- 10-year OS rates were 70% in adjuvant group and 52% in observation group (95% CI for difference, 6% - 34%).
- The DFS: HR (hazard ratio) for adjuvant versus observation groups = 0.65 (95% CI, 0.51 - 0.82)

- For OS : HR= 0.62 (95% CI, 0.48 - 0.80). (Based on a univariate Cox proportional hazards model)

**ER status:** For women with known estrogen receptor (ER) status (n = 470), the adjuvant treatment effect was more marked in ER+ women.

- A Cox proportional hazards model was designed which included the DFS outcome using treatment, ER status and the treatment by ER interaction as the predictors.
- Estimates from the model indicated that the treatment benefit decreased over time for ER+ patients.
- Using the model estimates and ER+/observation patients as the referent group, the hazard ratio for recurrence for ER+ patients undergoing treatment increased from 0.49 (95% CI, 0.31 to 0.75) at year 3 to 1.10 (95% CI, 0.58 to 2.06) at year 8.
- When considering the significant ER status by treatment interaction, a smaller effect of treatment for ER- patients was not significant (P=0.46 for DFS and 0.29 for OS). The 95%CI for the hazard ratio comparing treatment and observation among ER patients for DFS = 0.56 to 1.29 (authors claim that this CI is not narrow enough to rule out a clinically important effect of treatment in this subgroup)

In a randomised controlled trial reported by (Nomura *et al.* 1999) 789 premenopausal Japanese women with operable breast cancer of stage I-IIIa were randomised according to their ER status. Women with ER positive tumours were randomly allocated to either oophorectomy and Tamoxifen, chemotherapy (mitomycin and cyclophosphamide) or chemotherapy and Tamoxifen. Women with ER negative tumours were randomly allocated to either chemotherapy or chemotherapy and Tamoxifen. At a median follow-up of 10 years in patients with ER positive tumours there were no significant differences in relapse-free survival (p=0.15) or overall survival (p=0.42) among the oophorectomy plus Tamoxifen, chemotherapy, and chemotherapy plus Tamoxifen arms. At a median follow-up of 10 years in women with ER negative tumours there were no significant differences in relapse-free survival (p=0.97) or overall survival (p=0.85) between chemotherapy and chemotherapy plus Tamoxifen arms.

A randomised controlled trial compared ovarian ablation with CMF chemotherapy in 332 premenopausal patients with stage II breast cancer, recruited between 1980 and 1990 (Thomson *et al.* 2002). At a median follow-up of 10.7 years there was no statistically significant difference in overall survival between randomised arms: HR (ablation:CMF) 1.01, 95% CI 0.74-1.37, p=0.96, nor in event-free survival: HR (ablation:CMF) 0.95, 95% CI 0.71-1.26, p=0.7. There was also no difference between randomised groups for these outcomes when the subgroup of patients with ER positive tumours were analysed, or those with ER negative tumours.

### **3. Ovarian suppression with LHRH agonists**

#### **a) LHRH agonist versus no systemic therapy**

The meta-analysis by Cuzick et al. 2007 found no statistically significant difference in the risk of recurrence or death following recurrence on the basis of 5 trials comparing LHRH agonist versus no systemic therapy (n=338):

HR (recurrence: LHRH agonist:no systemic therapy) 0.72; 95% CI 0.49-1.04; p=0.08.

HR (death after recurrence: LHRH agonist:no systemic therapy) 0.82; 95% CI 0.47-1.43; p=0.49 (Cuzick *et al.* 2007).

An RCT was able to show no advantage of additional goserelin after a risk-adapted chemotherapy with respect to event free survival in HR-negative patients (Kaufmann *et al.* 2007). Event Free Survival: The unadjusted hazard ratio (HR) of goserelin versus control pooling HR-negative and HR-positive patients was 0.92 (95% CI, 0.70– 1.21; calculated as 95.66% CI to account for two interim analyses; P = 0.54).

In HR-negative pts: adjusted HR (goserelin versus control) = 1.01 (CI, 0.72–1.42; P = 0.97).

In HR-positive pts: adjusted HR (goserelin versus control) = 0.77 (CI, 0.47–1.24; P = 0.27).

Overall survival: 5-year OS rates of all pts are estimated as 86% in the goserelin group and 85% in the control group. 104 (13%) deaths observed up to time of report (authors' note - it is too early for any definite analysis of OS)

Tolerability and adverse events: Goserelin was discontinued for medical reasons (other than recurrence or death) in 24 pts.

*In the control group:* Serious adverse events related to chemotherapy were reported in 17 pts

*In the goserelin group:* Serious adverse events related to therapy were reported in 14 pts

**General comments:** Overall, this study is underpowered for both the HR-negative and HR-positive population, the results do not indicate an advantage of additional goserelin after a risk-adapted chemotherapy with respect to EFS in HR-negative patients.

### **b) LHRH agonist versus chemotherapy**

The meta-analysis by Cuzick *et al.* 2007 found no statistically significant difference in the risk of recurrence or death following recurrence on the basis of 4 trials comparing LHRH agonist versus chemotherapy (n=3184):

HR (recurrence: LHRH agonist:CT) 1.04; 95% CI 0.92-1.17; p=0.52

HR (death after recurrence: LHRH agonist:CT) 0.93; 95% CI 0.79-1.10; p=0.40 (Cuzick *et al.* 2007).

One of these trials, the TABLE study, recently reported results with a longer median follow-up of 5.8 years (Schmid *et al.* 2007). 599 premenopausal women with ER positive breast tumors of stage II or IIIA were randomly allocated to leuporelin acetate or to CMF chemotherapy. There was no significant difference in recurrence-free survival arising from treatment with leuporelin versus CMF. 5-year RFS rates were 63.9% for leuporelin and 63.4% for CMF (HR, 1.03; P=0.83). Survival favoured leuporelin treatment over CMF (HR, 1.50; 95% CI, 1.13 to 1.99; P=0.005) with 5-year survival rates of 81.0% and 71.9%, respectively. There was also a trend for a higher breast cancer-related mortality in the CMF group (CMF, 39.5%; leuporelin, 28.9%; P=0.05). Amenorrhea was reported in 88% of leuporelin patients by 6 months and more than 95% during the remaining 2-year treatment period, compared with 43.9% of CMF patients after 6-months of chemotherapy and 62.1% at 2 years. The onset of amenorrhea was earlier in the leuporelin group (mean, 22±38 days) compared to the CMF group (mean, 110±151 days). Amenorrhea was reversible within 1 year of stopping leuporelin in 45% of patients. In patients treated with CMF, the rate of amenorrhea steadily increased from 51.5% after 1 year to 62.1% after 2 years and 72.7% after 5 years. Symptoms of oestrogen suppression such as hot flashes and increased sweating were more common in patients treated with leuporelin, whereas acute adverse effects of chemotherapy such as nausea, vomiting, diarrhea, asthenia, and alopecia were reported more frequently in patients treated with CMF. An overall self assessment of tolerability by participants showed markedly better results for leuporelin during the first 6 months. At 6 months, 16.0% and 56.8% of patients in the leuporelin group rated the treatment tolerability as “very good” or “good,” respectively, compared with 15.6% and 37.3% in the CMF group. After the end of chemotherapy, assessments improved markedly in the CMF group. At 2 years, self-assessments of tolerability were comparable in both arms.

### **c) Integration of LHRH agonists into adjuvant hormonal therapy**

The Cochrane systematic review by (Sharma *et al.* 2007) concluded on the basis of four trials of approximately 5000 participants, that recurrence and mortality are reduced in premenopausal women treated with the LHRH agonist goserelin combined with tamoxifen compared to women treated with either drug alone. The authors stated that longer follow-up is needed to estimate the benefits more reliably and that insufficient data are available for a meta-analysis comparing tamoxifen versus goserelin as sole adjuvant therapy. (Sharma *et al.* 2007)

The systematic review by Cuzick *et al.* 2007 did perform a meta-analysis of five trials comparing LHRH agonist plus tamoxifen versus tamoxifen alone (n=1011). There was no statistically significant difference in the risk of recurrence or death following recurrence:

HR (recurrence: LHRH agonist + tamoxifen: tamoxifen) 0.85; 95% CI 0.67-0.20; p=0.2

HR (death after recurrence: LHRH agonist + tamoxifen: tamoxifen) 0.84; 95% CI 0.59-1.19; p=0.33 (Cuzick *et al.* 2007)

#### **d) LHRH agonists with or without tamoxifen in addition to chemotherapy**

The Cochrane systematic review by (Sharma *et al.* 2007) concluded on the basis of six trials that recurrence and mortality are reduced in premenopausal women with ER positive tumours who are treated with a LHRH agonist, with or without tamoxifen, in addition to chemotherapy.

The systematic review by Cuzick *et al.* 2007 performed a meta-analysis of 13 trials comparing the addition of LHRH agonist to chemotherapy with or without tamoxifen (n=2741). The results favoured adding LHRH agonist in terms of recurrence and mortality following recurrence:

HR (recurrence: Addition of LHRH agonist to CT ± Tamoxifen: CT ± Tamoxifen) 0.88; 95% CI 0.77-0.99; p=0.04.

HR (death after recurrence: Addition of LHRH agonist to CT ± Tamoxifen: CT ± Tamoxifen) 0.85; 95% CI 0.73-0.99; p=0.04 (Cuzick *et al.* 2007).

Cuzick *et al.* 2007 also performed meta-analyses for the same comparison but based upon subgroups according to participants age (≤40 years and >40 years). The results of these analyses confirmed the benefit of adding an LHRH agonist to chemotherapy (with or without tamoxifen) in terms of recurrence and mortality following recurrence in women of age ≤40 years. There was no evidence for a similar benefit in women of age 40 years or more:

Recurrence (9 trials)

Age ≤ 40 years:

HR (CT ± Tamoxifen + LHRH: CT ± Tamoxifen) 0.75; 95% CI 0.61-0.92; p=0.01 (Cuzick *et al.* 2007)

Age > 40 years:

HR (CT ± Tamoxifen + LHRH: CT ± Tamoxifen) 0.96; 95% CI 0.82-1.13; p=0.63 (Cuzick *et al.* 2007)

Death after recurrence (8 trials)

Age ≤ 40 years:

HR (CT ± Tamoxifen + LHRH: CT ± Tamoxifen) 0.72; 95% CI 0.55-0.93; p=0.01 (Cuzick *et al.* 2007)

Age > 40 years (8 trials):

HR (CT ± Tamoxifen + LHRH: CT ± Tamoxifen) 0.93; 95% CI 0.75-1.14; p=0.47 (Cuzick *et al.* 2007)

**e) LHRH agonists with or without tamoxifen versus chemotherapy**

The Cochrane systematic review by (Sharma *et al.* 2007) concluded on the basis of six trials that LHRH agonists, with or without tamoxifen, are as effective as chemotherapy for premenopausal women with ER+ tumours, in terms of recurrence free survival and overall survival. Hormone therapy had fewer distressing side effects than the regimens of chemotherapy assessed in these trials (Sharma *et al.* 2007).

The systematic review by Cuzick *et al.* 2007 performed a meta-analysis of three trials comparing LHRH agonist plus Tamoxifen versus chemotherapy (n=1577) and found no statistically significant difference in recurrence or mortality following recurrence:

HR (recurrence: LHRH agonist + Tamoxifen: CT) 0.90; 95% CI 0.75-1.08; p=0.25  
HR (death after recurrence: LHRH agonist + Tamoxifen: CT) 0.89; 95% CI 0.69-1.15; p=0.37 (Cuzick *et al.* 2007).

## EVIDENCE TABLES

### Systematic reviews of randomised trials

<b>Citation</b>
Cuzick, Ambroisine, Davidson, Jakesz, Kaufmann, Regan & Sainsbury . Use of luteinising-hormone-releasing hormone agonists as adjuvant treatment in premenopausal patients with hormone-receptor-positive breast cancer: a meta-analysis of individual patient data from randomised adjuvant trials. Lancet 369[9574], 1711-1723. 2007.
<b>Design</b>
Systematic review of RCTs and meta-analysis of individual patient data. Country of origin: various Evidence grade: 1+
<b>Inclusion criteria</b>
Aim: to perform a meta-analysis based on individual patient data to present an updated overview of the evidence, dealing only with trials in which LHRH agonists were assessed, and focusing specifically on results for patients known to be hormone-receptor-positive.  Eligible studies had to provide an assessment of the randomised addition of an LHRH agonist to an adjuvant therapy or a randomised comparison between a systemic treatment and an LHRH agonist. In some trials, ovarian suppression was done with a range of techniques; the authors only included trials in which more than half the treatments were with an LHRH agonist.
<b>Exclusion criteria</b>
Patients with unknown hormone receptor status.
<b>Population</b>
N=11, 906
<b>Interventions</b>
The randomised addition of an LHRH agonist was studied in the context of no other systemic adjuvant therapy (five trials), tamoxifen in both arms (five trials), chemotherapy in both arms (seven trials), or chemotherapy and tamoxifen in both arms (four trials). A second set of trials assessed a chemotherapy regimen versus an LHRH agonist (four trials), and a third group assessed chemotherapy versus an LHRH agonist combined with tamoxifen (three trials). No trials had assessed the question of chemotherapy versus an LHRH agonist, with tamoxifen in both arms.  LHRH agonists studied:

Goserelin (13 trials)  
Triptorelin (2 trials)  
Leuprorelin (1 trial)

Chemotherapy, where given was most often CMF-based followed by anthracycline-based (with no use of taxanes).

Duration of LHRH agonist was most often 2 years, but 18 months, 3 years and 5 years duration were also studied.

### Outcomes

Recurrence (defined as the first reappearance of breast cancer at any site: local or regional, contralateral, or distant)

Death following recurrence

Meta-analysis was performed for log hazard ratios and their variances, and results presented using Kaplan-Meier charts.

### Follow up

Median 6.8 years

### Results

#### 1.) LHRH agonist versus no systemic therapy (5 trials; n=338)

HR (recurrence: LHRH agonist:no systemic therapy) 0.72 95% CI 0.49-1.04  
p=0.08

HR (death after recurrence: LHRH agonist:no systemic therapy) 0.82 95% CI 0.47-1.43 p=0.49

#### 2.) LHRH agonist + tamoxifen versus tamoxifen (5 trials; n=1011)

HR (recurrence: LHRH agonist + tamoxifen: tamoxifen) 0.85; 95% CI 0.67-0.20; p=0.2

HR (death after recurrence: LHRH agonist + tamoxifen: tamoxifen) 0.84; 95% CI 0.59-1.19; p=0.33

#### 3.) Addition of LHRH agonist to chemotherapy with or without tamoxifen (13 trials; n=2741)

HR (recurrence: Addition of LHRH agonist to CT ± Tamoxifen: CT ± Tamoxifen) 0.88; 95% CI 0.77-0.99; p=0.04

HR (death after recurrence: Addition of LHRH agonist to CT ± Tamoxifen: CT ± Tamoxifen) 0.85; 95% CI 0.73-0.99; p=0.04

#### 4.) LHRH agonist versus chemotherapy (4 trials; n=3184)

HR (recurrence: LHRH agonist:CT) 1.04; 95% CI 0.92-1.17; p=0.52

HR (death after recurrence: LHRH agonist:CT) 0.93; 95% CI 0.79-1.10; p=0.40

**5.) LHRH agonist + Tamoxifen versus chemotherapy (3 trials; n=1577)**

HR (recurrence: LHRH agonist + Tamoxifen: CT) 0.90; 95% CI 0.75-1.08; p=0.25

HR (death after recurrence: LHRH agonist + Tamoxifen: CT) 0.89; 95% CI 0.69-1.15; p=0.37

**6.) Contributions of individual trials for addition of LHRH agonist to chemotherapy with or without tamoxifen by age**

**A) Recurrence, age ≤ 40 years; CT ± Tamoxifen versus CT ± Tamoxifen + LHRH (9 trials)**

HR (CT ± Tamoxifen + LHRH: CT ± Tamoxifen) 0.75; 95% CI 0.61-0.92; p=0.01

**B) Recurrence, age > 40 years; CT ± Tamoxifen versus CT ± Tamoxifen + LHRH (9 trials)**

HR (CT ± Tamoxifen + LHRH: CT ± Tamoxifen) 0.96; 95% CI 0.82-1.13; p=0.63

**C) Death after recurrence, age ≤ 40 years; CT ± Tamoxifen versus CT ± Tamoxifen + LHRH (8 trials)**

HR (CT ± Tamoxifen + LHRH: CT ± Tamoxifen) 0.72; 95% CI 0.55-0.93; p=0.01

**D) Death after recurrence, age > 40 years; CT ± Tamoxifen versus CT ± Tamoxifen + LHRH (8 trials)**

HR (CT ± Tamoxifen + LHRH: CT ± Tamoxifen) 0.93; 95% CI 0.75-1.14; p=0.47

**General comments**

In all trials, treatments were given in an unblinded open-label fashion.

No assessment of heterogeneity is made as part of the meta-analysis. A recent Cochrane Review (Sharma et al. 2007) did not perform a meta-analysis on data from largely the same studies due to unsuitability for meta-analysis.

Comparisons were made by intention-to-treat within the subgroups of hormone-receptor-positive (ie, oestrogen-receptor positive or progesterone-receptor positive, or both) and hormone-receptor-negative (ie, oestrogen-receptor negative and progesterone receptor negative, or oestrogen-receptor negative and progesterone-receptor unknown) patients. Cutoffs for hormone-receptor positivity were as used in the original trials.

Literature search strategy: used PubMed and Springer Link databases and

the database held by the Oxford overview group.

Keywords: "LHRH agonist", "luteinising hormone- releasing hormone", "breast cancer", "adjuvant trials".

Abstracts from major breast cancer meetings examined to identify all trials that assessed an LHRH agonist in at least one arm of a randomised adjuvant trial for early breast cancer.

WOMEN AGED UNDER 50 AT RANDOMISATION</b></p> <p><b>RECURRENCE-FREE SURVIVAL</b> Among women aged under 50, by year 15, there were 6.0 (SD 2.3) fewer events (recurrences or deaths) per 100 women allocated ovarian ablation (45.0 vs 39.0% event free 15 years after randomisation, logrank 2p=0.0007). Proportionally, ovarian ablation reduced the event rate by about one-fifth 18.5% [SD 5.5], both in the first 5 years (i.e., years 0-4) and in later years. The proportional reduction in events appeared to be similar in trials of ablation</p>

by surgery (18%;SD 8) or by radiotherapy (19%; SD 8), but the numbers of patients were not sufficient for this apparent similarity to be reliably informative.

### **OVERALL SURVIVAL**

At 15 years follow-up the absolute difference between groups for overall survival (52.4 vs 46.1% still alive at 15 years after randomisation) was similar to that for recurrence-free survival. This represents an average of 6.3 (SD 2.3) fewer deaths per 100 women treated in all the trials. Again, although the proportional reduction in mortality was about the same in the earlier as in the later years, most of the absolute difference in overall survival appeared during the first 5 years. When these recurrence-free and survival analyses were further subdivided, no material differences between the benefits at ages under 40 or 40-49 were apparent (data not shown).

### **POSSIBLE INFLUENCE OF CYTOTOXIC CHEMOTHERAPY**

Analyses were subdivided by whether or not women in both treatment groups were to receive routine cytotoxic chemotherapy. The proportional improvement in recurrence-free survival among women aged under 50 at randomisation was 25% (SD 7) in the absence of chemotherapy but only 10% (9) in its presence (p=NS).

Similarly, the proportional improvement in survival was 24% (7) in the absence but only 8% (10) in the presence of chemotherapy. Again the number of deaths were too small to assess any such modifications of the size of the survival effects reliably.

In the trials of ovarian ablation in the absence of routine chemotherapy, only 20 (2%) of the 1169 women aged under 50 were classified as postmenopausal at randomisation. Hence, if the analyses are restricted to premenopausal women only (according to the definition used in each trial), the findings are virtually unchanged, with ovarian ablation producing a proportional improvement in recurrence-free survival of 27% (7) in the absence of chemotherapy.

### **POSSIBLE INFLUENCE OF NODAL STATUS IN TRIALS WITHOUT CYTOTOXIC CHEMOTHERAPY**

The indirect comparisons between the size of benefit in the absence and in the presence of cytotoxic chemotherapy are strongly confounded by nodal status, and vice versa. Almost all of the node-negative women (473 of 502) aged under 50 were entered into ovarian ablation trials in the absence of chemotherapy, whereas almost all of the women in the trials in the presence of chemotherapy (904 of 933) were node-positive. Hence, the relevance of nodal status can be assessed only in the ovarian ablation trials in which chemotherapy was not routinely given. As would be expected, the 473 women classified as node-negative (either by axillary clearance or just by axillary sampling) had a better prognosis than the remaining 696 women classified as node-positive (or of unknown nodal status). Because the number of women

studied was not large, the separate effects of ovarian ablation in node-positive and node-negative women cannot be estimated reliably. But, whether or not nodes were involved, ovarian ablation in the absence of chemotherapy was associated with significant improvements in recurrence-free survival and in overall survival. The proportional risk reductions for node-positive and for node-negative women were similar, but the absolute risk reduction was non-significantly greater for node-positive women (figure not reproduced). Most of the patients in these trials were randomised before 1970, and most survivors have been followed up to beyond 1990, so there is information beyond year 15. Even during this late period, the annual death rates, taking all women together, remained lower among those who had been allocated ablation (2.6% [SD 0.3]) than among the controls (3.9% [0.5]). This observation provides some reassurance against the later emergence of any substantial hazards.

### **ER STATUS IN TRIALS WITH CYTOTOXIC CHEMOTHERAPY**

ER measurements on the primary tumour were available for most women aged under 50 at entry in four of the five trials in which both randomised groups received chemotherapy, but not for any women in trials of ovarian ablation in the absence of chemotherapy. Among the 194 women with “ER poor” primary tumours, there was no apparent difference between ablation plus chemotherapy versus chemotherapy alone, either in recurrence-free survival (logrank O-E 0.3, variance 26.9, not significant) or in overall survival (logrank O-E 1.9, variance 24.0, no significant). Among the 550 women with “ER-positive” primary tumours, however, ablation plus chemotherapy appeared to be more effective than chemotherapy alone, both for recurrence-free survival (logrank OE -9.5, variance 67.0, odds reduction 13% [SD 11]) and for overall survival (logrank O-E -9.2, variance 50.5, odds reduction 17% [SD 13]), but these differences were not statistically significant.

### **CAUSE SPECIFIC MORTALITY**

Most studies were able to supply some cause-specific mortality information. Among women aged under 50 at randomisation who died without a distant recurrence of their breast cancer being recorded, 116 were classified as having died of non-breast-cancer causes. After allowance has been made (EBCTCG 1995) for those allocated ablation surviving longer, and therefore being at more prolonged risk of death from other causes, there was no significant difference between the treatment groups in vascular deaths (22/929 ablation vs 20/824 controls in trials with data, logrank OE -1.6, variance 9.5, not significant), in other non-breast-cancer deaths (44/929 vs 30/824, logrank O-E -0.2, variance 16.5, not significant) or in all non-breast-cancer deaths.

### **CONTRALATERAL BREAST CANCER**

The suppression of ovarian function might be expected to reduce the incidence of contralateral breast cancer. But, even in the aggregate of all

available trials, there was not enough information to confirm or refute this suggestion (30 contralateral breast cancers as first event among 712 women allocated ablation vs 32 among 679 controls in trials with data, logrank O-E - 2.8, variance 15.1, not significant).

### **WOMEN AGED 50 OR ABOVE AT ENTRY**

Because ovarian function is generally substantially less at older than at younger ages, any effects of ovarian ablation might be expected to be much less. Of the 1354 women aged 50 or above when randomised, 1018 were reported to have died and a further 48 to have had a distant or local recurrence. Despite these large numbers of events, there was no significant difference between the treatment groups in recurrence-free survival or in overall survival. By year 15 after randomisation there were 3.1 (SD 2.6) fewer recurrences or deaths per 100 women allocated ovarian ablation (32.0 vs 28.9% alive with no history of local or distant recurrence, logrank O-E -17.6, variance 225.9, not significant) and 2.5 (SD 2.7) fewer deaths per 100 (36.9 vs 34.5% alive, logrank O-E -8.9, variance 223.8, not significant).

### **General comments**

This review was first published in the Lancet (EBCTCG 1996) and has been reproduced with the permission of the journal.

Review does not report adverse effects of ovarian ablation, which are noted as considerable under 'Implications for practice' and 'Implications for research'.

Only studies of ovarian ablation by surgery or RT were included in the analyses because data in 4 trials of LHRH agonists were immature at the time of publication.

Literature search strategy: not reported. References provided to EBCTCG publications which describe trial identification procedures.

Being a Cochrane Review, this systematic review has passed a quality assessment by the Cochrane Collaboration. However based on this document alone it is not possible to see precisely how the primary studies were identified, nor to relate included studies to subsequently published papers, which may provide more recent data.

Statistical methods described.

Early Breast Cancer Trialists' Collaborative Group . Effects of chemotherapy and hormonal therapy for early breast cancer on recurrence and 15-year survival: an overview of the randomised trials. Lancet 365[9472], 1687-1717. 2005.
<b>Design</b>
Systematic review of RCTs and meta-analysis of individual patient data. Country of origin: various Evidence grade: 1+
<b>Inclusion criteria</b>
All randomised trials of chemotherapy and hormone therapy in patients with early breast cancer that had started by 1995 (trial data for ovarian ablation by surgery or RT or suppression with LHRH agonists cited here).
<b>Exclusion criteria</b>
Not reported.
<b>Population</b>
N=4317; N=7601 for different analyses.
<b>Interventions</b>
Ovarian ablation by surgery or RT (in women of age <50 years) or ovarian suppression with LHRH agonists versus no adjuvant ovarian treatment, or as a randomised addition to chemotherapy (CT).
<b>Outcomes</b>
Recurrence (defined as the first reappearance of breast cancer at any site, and so includes second primary breast cancers and local or distant recurrences of the original cancer)
Breast cancer mortality
<b>Follow up</b>
5-year outcomes for ablation alone. 15-year outcomes for ablation/LHRH agonists combined

## Results

### 2. Ovarian ablation by RT or oophorectomy or suppression with LHRH agonists in women with ER: positive or ER: unknown tumours; 15-year

**outcomes, n=7601, entry age <50**

**Recurrence:**

Ablation or suppression: 47.3%

Control: 51.6%

Logrank 2p=0.00001

**Breast cancer mortality:**

Ablation or suppression: 40.3%

Control: 43.5%

Logrank 2p=0.004

**General comments**

Data for ovarian suppression by LHRH agonists are more up to date in the meta-analysis by Cuzick et al. 2007.

**Data identification strategy:**

This study uses data that are centrally collated by the EBCTCG from every woman in all randomised trials of the treatment of early breast cancer that had, at the time of the analysis, already been running for at least 5 years. The present report is of the final results from the year 2000 EBCTCG meta-analyses of the trials of systemic adjuvant treatments (chemotherapy, endocrine therapy, or chemoendocrine therapy) that had begun in or before 1995. The preliminary analyses were presented and discussed at a meeting in September, 2000, of the trial investigators. Since then, the data have been extensively checked for internal consistency and completeness and amended or updated through correspondence with the relevant trialists.

Meta-analysis was by a non-fixed effect method; analyses were by intention-to-treat. The Chi square and associated p values indicate some heterogeneity in results.

Sharma, Hamilton & Beith . LHRH agonists for adjuvant therapy of early breast cancer in premenopausal women. Cochrane database of systematic reviews [3]. 2007. Chichester (UK), John Wiley & Sons, Ltd.
<b>Design</b>
Systematic review of RCTs Country of origin: Various. Evidence grade: 1++
<b>Inclusion criteria</b>
Randomised controlled trials of LHRH agonists (Buserelin, Goserelin, Leuprolide, Nafarelin and Triptorelin).  Premenopausal women with a histological diagnosis of early breast cancer. Early breast cancer is defined as operable breast cancer (TNM stage 1 and stage 2) and premenopausal is defined as women less than 50 years of age.
<b>INCLUDED STUDIES</b>
13 RCTs were included, which address the role of LHRH agonists in the adjuvant treatment of pre-menopausal women with ER+ early breast cancer as follows:
<b>1. Integration into adjuvant hormonal therapy</b>
<ul style="list-style-type: none"> <li>• three trials compared an LHRH agonist versus tamoxifen (Norwegian Study, ZBCSG Trial B, ZIPP)</li> <li>• three trials compared an LHRH agonist versus combined LHRH agonist and tamoxifen (ECOG 5188 INT-0101, ZBCSG Trial B, ZIPP)</li> <li>• two trials compared combined LHRH agonist and tamoxifen versus tamoxifen (ZBCSG Trial B, ZIPP)</li> </ul>
<b>2. Integration into adjuvant chemo-hormonal therapy</b>
<ul style="list-style-type: none"> <li>• three trials compared an LHRH agonist versus CMF chemotherapy (IBCSG VIII, TABLE, ZEBRA)</li> <li>• no trials comparing LHRH agonists to other chemotherapeutic regimens were identified</li> <li>• two trials compared combined LHRH agonist and tamoxifen versus CMF chemotherapy (ABCSG 5, GROCTA 02) and one trial compared combined LHRH agonist and tamoxifen versus an anthracycline-based chemotherapy regimen (FASG 06)</li> <li>• one trial compared an LHRH agonist versus chemotherapy followed by</li> </ul>

an LHRH agonist (IBCSG VIII)

- five trials compared chemotherapy versus chemotherapy followed by an LHRH agonist (ECOG 5188 INT-0101, GABG IV-B-93, IBCSG VIII, Pretoria, ZIPP)
- three trials compared chemotherapy versus chemotherapy followed by combined LHRH agonist and tamoxifen (ECOG 5188 INT-0101, MAM 01 GOCSI, ZIPP)

### 3. Comparison with ovarian ablation by surgery or radiotherapy

- no trials were identified comparing an LHRH agonist versus surgical or radiotherapeutic ovarian ablation in the adjuvant setting.

#### Exclusion criteria

Women with locally advanced or metastatic disease.

#### Population

N=11,000

#### Interventions

Aims: to review randomised trials that test the use of LHRH agonists in adjuvant therapy for women with early breast cancer.

The specific objectives of the review are:

1. to make the following comparisons:

- a.any LHRH agonist versus any LHRH agonist plus tamoxifen
- b.any LHRH agonist versus CMF (or other chemotherapy)
- c.any LHRH agonist versus ovarian ablation
- d.any LHRH agonist versus any LHRH agonist plus chemotherapy

2. To describe the best available evidence on the optimum duration of LHRH treatment

3. To discuss the long term impact of amenorrhoea

4. To discuss:

- a.restoration of fertility following ovarian suppression
- b.HER-2+ ER+ disease
- c.women with familial breast cancer syndromes (not cited here)

### **Outcomes**

1. Overall survival (time from date randomised to date of death due to any cause)
2. Disease-free survival (time from date randomised to first recurrence or death)
3. Quality of life
4. Toxicity

### **Follow up**

Reported for 3 trials as follows:

- ZEBRA: median 72 months
- IBCSG VIII: median 84 months
- MAM-01: median 72 months

### **Results**

#### **Reviewers' conclusions**

*For premenopausal women with early breast cancer who are not known to be ER-, the use of an LHRH agonist, with or without tamoxifen as adjuvant therapy is likely to lead to a reduction in the risk of a recurrence and a delay in death. If the treatment decision is a choice between the use of an LHRH agonist and chemotherapy, the evidence in this review suggests that recurrence free survival and overall survival will be similar following both treatments for ER+ women, but with fewer or less severe adverse effects from the LHRH agonist. However, for ER- women, chemotherapy is likely to lead to a reduction in the risk of recurrence and a delay in death compared to an LHRH agonist. The LHRH agonist for which there is most evidence is*

*goserelin, given as a 3.6mg depot subcutaneously every 28 days for a couple of years.*

### **1. Integration of LHRH agonists into adjuvant hormonal therapy (4 trials, n≈5000)**

*Summary: Taken together, the trials point to reductions in recurrence and death for premenopausal women who take goserelin combined with tamoxifen compared to either drug alone, as adjuvant treatment for breast cancer, but longer follow-up of the women is needed to estimate any benefits more reliably. Insufficient data have been presented to date for a meta-analysis that would inform reliably a choice between either tamoxifen or goserelin as sole adjuvant therapy.*

#### **a) LHRH agonist versus tamoxifen**

- ZIPP trial (2x2 factorial design): the proportion of patients who experienced at least one side effect was 56% among patients allocated goserelin alone and 41% among patients receiving tamoxifen alone. The most common side effect was hot flushes (26% versus 17%). The only other side effect reported by more than 10 patients in either group was weight gain (4% versus 7%).
- Norwegian trial: After a median follow up of 88 months, patients randomised to goserelin had a non-statistically significantly higher risk of recurrence than those allocated to tamoxifen (RR: 1.10, 95% CI 0.81 to 1.48, P=0.56) and of death (RR: 1.16, 95% CI 0.80 to 1.69, P=0.42).
- ZBCSG Trial B: there was a non-statistically significant improvement in recurrence free survival for patients allocated goserelin (HR: 0.87, 95% CI 0.47-1.63) while, based on four deaths, overall survival was non-statistically significantly worse (HR: 2.10, 95% CI 0.38 to 11.49).

#### **b) LHRH agonist versus LHRH agonist and tamoxifen**

- ZIPP trial (2x2 factorial design): after a median follow up of 66 months, patients randomised to tamoxifen (which includes those randomised to no goserelin) had significantly better event free survival (HR: 0.79, 95% CI 0.68 to 0.92) and non-significantly better overall survival (HR: 0.83, 95% CI 0.68 to 1.02) compared to those randomised to no tamoxifen. Side effects were experienced by 56% of patients allocated goserelin alone and by 65% of patients allocated goserelin and tamoxifen. The most common side effect was hot flushes (26% versus 44%), followed by weight gain (4% versus 11%).
- ECOG 5188 INT-0101: after a median follow up of 115 months, recurrence free survival was statistically significantly better for patients randomised to tamoxifen in addition to chemotherapy and goserelin (68%) versus chemotherapy and goserelin alone (60%) (HR: 0.73, P<0.01). Overall survival was non-statistically significantly better (76% versus 73%, HR: 0.91, P=0.21).

- ZBCSG Trial B: no data

### c) Tamoxifen and LHRH agonist versus tamoxifen

- ZIPP trial (2x2 factorial design): After a median follow up of 66 months, patients randomised to goserelin had significantly better recurrence free survival (73%) and overall survival (86%) than those allocated to no goserelin (68% and 83%, respectively). These correspond to a hazard ratio of 0.80 (95% CI 0.69 to 0.82, P=0.002) for recurrence free survival and 0.81 (95% CI 0.67 to 0.99, p=0.038) for overall survival. These overall effects of goserelin versus no goserelin were reported to be similar in women who received tamoxifen, either electively or by randomisation. Subgroup analyses have also been reported on the basis of ER status, with benefits for goserelin compared to no goserelin in recurrence free survival and overall survival for women in each of the three subgroups (ER-, ER+ or ER-unknown). However, these subgroup analyses are much less powerful than the overall results, most are non-significant and there is insufficient evidence from the ZIPP trial to assess differences in effect among ER subgroups in the presence of tamoxifen. The proportion of patients who experienced at least one side effect in the ZIPP trial was 65% among patients randomised to tamoxifen and goserelin and 41% among patients allocated to tamoxifen alone. The most common side effects were hot flushes (44% versus 17%) and weight gain (11% versus 7%).
- ZBCSG Trial B: No data.

## 2. Integration of LHRH agonists into adjuvant chemo-hormonal therapy

### a) LHRH agonists with or without tamoxifen versus chemotherapy

*Summary: Taken together, these trials show that LHRH agonists, with or without adjuvant tamoxifen, are as effective as chemotherapy for premenopausal women with ER+ tumours, in terms of recurrence free survival and overall survival. The trials also show that the hormonal therapy has fewer distressing side effects than the forms of chemotherapy assessed in these trials.*

### i) LHRH versus chemotherapy

- ZEBRA Trial: At a median follow-up of 72 months, patients randomised to goserelin had significantly worse recurrence free survival (55.2%) than those allocated to chemotherapy (60.0%) (HR: 1.18, 95% CI 1.02 to 1.37, P=0.029), and worse overall survival (HR: 1.21, 95% CI 0.99 to 1.49, P=0.067). However, a highly significant interaction was found between treatment and ER status (P=0.0016 for recurrence free survival). Patients who were ER+ had similar recurrence free survival and overall survival in both treatment groups (HR for recurrence free survival for goserelin versus CMF: 1.01, 95% CI 0.84 to 1.20, P=0.94;

HR for overall survival: 0.99, 95% CI 0.76 to 1.28,  $P=0.92$ ) with the worse outcome for goserelin treated patients being due to the effect in the ER- patients (HR for recurrence free survival: 1.76, 95% CI 1.27 to 2.44,  $P=0.0006$ ; HR for overall survival: 1.77, 95% CI 1.19 to 2.63,  $P=0.0043$ ) and ER-unknown patients (HR for recurrence free survival: 2.00, 95% CI 1.07 to 3.75,  $P=0.026$ ; HR for overall survival: 1.81, 95% CI 0.81 to 4.05,  $P=0.14$ ). After six months of treatment in ZEBRA, amenorrhoea was more common in patients treated with goserelin (95%) than with chemotherapy (59%). However, after three years, 23% of patients who had received goserelin remained amenorrhoeic compared with 77% of patients treated with chemotherapy. The incidence of adverse reactions, including menopausal side effects, hot flushes, vaginal discharge and vaginal soreness, was similar in both groups (in total, goserelin: 42.6%; chemotherapy: 48.0%). These side effects tended to resolve within a year after stopping goserelin but persisted in the chemotherapy group for the 30 months under investigation. A special assessment of quality of life was done in 86 of the 102 centres, involving 1010 of the randomized patients. Early benefits were noted during months 3 to 6 of treatment for women in the goserelin group. However, at 1, 2 and 3 years, there were no significant differences between the two treatment groups.

- IBCSG VIII trial: CMF alone versus CMF followed by goserelin versus goserelin alone. At a median follow-up of 84 months, there were no significant differences between the treatment groups in disease free survival or overall survival. The five-year disease free survival was 79% (95% CI 75% to 84%) for goserelin alone and 82% (95% CI 78% to 86%) for chemotherapy alone. In the comparison of goserelin versus chemotherapy, the relative risk for disease free survival was 1.13 (95% CI 0.83 to 1.53,  $P=0.44$ ). However, an interaction was found between treatment and ER status. ER+ patients in both the goserelin group and the chemotherapy group had similar disease free survival (5-year DFS: 81%, 95% CI 76% to 87% in both groups; RR: 0.97, 95% CI 0.66 to 1.42,  $P=0.86$ ). In contrast, ER- patients had worse disease free recurrence in the goserelin group (73%, 95% CI 64% to 81%) compared to the chemotherapy group (84%, 95% CI 77% to 91%) (RR: 1.52, 95% CI 0.89 to 2.58,  $P=0.12$ ). Toxicities of grade 3 or worse were experienced by 4.7% of patients allocated to goserelin alone (mostly weight gain) and by 18.8% of patients during chemotherapy (mostly leucopenia, neutropenia and nausea or vomiting).
- IBCSG VIII trial: At 36 months follow-up, amenorrhoea was induced in 90% of patients under 40 years of age within three months of starting goserelin and continued until the end of goserelin treatment, when menses resumed in almost all women. Amenorrhoea happened more slowly among younger women allocated to chemotherapy, being observed in 50% of these patients by the end of six cycles of CMF. Menses resumed in 15% of the patients in the chemotherapy alone

group but amenorrhea continued for 35-40% of women in this group throughout the three years of observation. Among women aged 40 years or older, amenorrhoea was induced in more than 90% of patients within three months of starting goserelin, continued until the end of goserelin treatment, and menses resumed in about half the women. Amenorrhoea due to chemotherapy was observed sooner than among the younger women, affecting 80-90% of these patients by the end of six cycles of CMF, nearly all of whom remained amenorrhoeac throughout the three years of observation. Patients in the goserelin alone group showed a marked improvement or less deterioration in various quality of life indicators during the first six months than those allocated chemotherapy. There were no differences at 36 months, apart from in hot flashes which were more problematic for women in the chemotherapy alone group than the goserelin alone group.

- TABLE study (patients who were not known to be ER or ER+ patients): No significant differences were found between the treatments on either recurrence-free survival or overall survival. The 2-year disease free survival was 59.1% for women allocated leuprorelin, compared to 45.3% for women allocated chemotherapy. All women in the leuprorelin group became amenorrhoeic during treatment, compared to 90.4% of women treated with chemotherapy. The most common adverse events were low-grade hot flushes, weight gain and increased sweating among the leuprorelin patients and alopecia, nausea and vomiting among the chemotherapy patients. The overall assessment of tolerability by patients was markedly better after three and six months of treatment in the leuprorelin group, but there was no significant difference between the two groups at two years.

## ii) LHRH and tamoxifen versus chemotherapy

- ABCSG 5 Trial (most women ER+): after a median follow up of 60 months, patients randomised to goserelin and tamoxifen had significantly better recurrence free survival (81%) than those allocated to chemotherapy (76%) ( $P=0.037$ ). Overall survival was non-significantly better in the hormonal therapy group (92%) than the chemotherapy group (90%) ( $P=0.195$ ). Hot flushes were the main side effect for patients in the goserelin and tamoxifen group: 91% of patients experienced at least one. The side effects of chemotherapy were typical of CMF: nausea (81%), alopecia (55%) and hot flushes (54%).
- GROCTA 02 trial (mostly ER+ women; for one third of the women in the hormonal therapy group, ovarian ablation was achieved by surgery or radiotherapy, instead of goserelin): After a median follow up of 76 months, there were no significant differences in recurrence free survival (HR: 0.94, 95% CI 0.60 to 1.47,  $P=0.80$ ) or overall survival (HR: 0.69, 95% CI 0.36 to 1.33,  $P=0.30$ ) between patients randomised to goserelin and tamoxifen versus those randomised to chemotherapy. This is based on a total of 82 relapses and 39 deaths. All women

treated with goserelin became amenorrhoeic during treatment, but menses returned in 20% within six months of stopping therapy. In the chemotherapy group, 68% of women became amenorrhoeic during treatment and remained so even after the treatment stopped. Hot flushes were the main side effect for patients in the goserelin and tamoxifen group (experienced by approximately 60% of patients) compared to nausea (70%), leukopenia (40%) and alopecia (40%) in the chemotherapy group.

- FASG 06 trial (women with hormone responsive breast cancer): after a median follow up of 54 months, recurrence free survival was 91.7% in the hormonal therapy group and 80.9% in the chemotherapy group. This difference is non-significant ( $P=0.12$ ). The difference was also non-significant for overall survival ( $P=0.18$ ) being 97.0% and 92.9%, respectively. All women treated with triptorelin became amenorrhoeic during treatment compared to 41.5% in the chemotherapy group.

#### **b) LHRH agonists with or without tamoxifen in addition to chemotherapy**

*Summary: Taken together, these trials point to reductions in recurrence and death for premenopausal women with ER+ tumours who take LHRH agonists, with or without tamoxifen, in addition to chemotherapy as adjuvant treatment for breast cancer.*

#### **i) LHRH versus Chemotherapy and LHRH agonist**

- IBCSG VIII Trial (2/3 women ER+): The five-year disease free survival was 87% (95% CI 83% to 91%) for chemotherapy followed by goserelin and 79% (95% CI 75% to 84%) for goserelin alone. The relative risk for chemotherapy followed by goserelin versus goserelin alone was 0.71 (95% CI 0.52 to 0.99,  $P=0.04$ ). However, as noted above, an interaction was found between treatment and ER status. ER- patients appeared to derive much more benefit from the combination of chemotherapy and goserelin than ER+ patients. Among ER- patients, the disease free recurrence was 88% (95% CI 82% to 94%) in the chemotherapy and goserelin group compared to 73% (95% CI 64% to 81%) in the goserelin alone group (RR: 0.49, 95% CI 0.28 to 0.87,  $P=0.01$ ). Whereas, among ER+ patients, the disease free survival was 86% (95% CI 82% to 91%) in the chemotherapy and goserelin group versus 81% (95% CI 76% to 87%) in the goserelin alone group (RR: 0.86, 95% CI 0.56 to 1.26,  $P=0.40$ ).
- IBCSG VIII: At 36 months follow-up, amenorrhoea was induced in 90% of patients under 40 years of age within three months of starting goserelin and continued until the end of goserelin treatment, when menses resumed in almost all women. Amenorrhoea happened more slowly among younger women during chemotherapy, being observed in 50% of these patients by the end of six cycles of CMF, and increasing to 90% within a few months of starting goserelin. Menses resumed in many women when they stopped goserelin but were still absent for 35-

40% of women in this group at month 36. Among women aged 40 years or older, amenorrhoea was induced in more than 90% of patients within three months of starting goserelin, continued until the end of goserelin treatment, and menses resumed in about half the women. Amenorrhoea due to chemotherapy was observed sooner than among the younger women, affecting 80-90% of these patients by the end of six cycles of CMF, increasing to nearly all women after the first couple of months of goserelin, almost all of whom remained amenorrhoeac at month 36. Patients in the goserelin alone group showed a marked improvement or less deterioration in various quality of life indicators during the first six months than those receiving chemotherapy but there were no differences in quality of life at 36 months between the groups allocated chemotherapy followed by goserelin versus goserelin alone.

## ii) Chemotherapy and LHRH agonist versus chemotherapy

- ZIPP Trial: After a median follow up of 66 months, the primary analyses of goserelin versus no goserelin (regardless of the presence or absence of chemotherapy) showed that patients randomised to goserelin had significantly better recurrence free survival (73%) and overall survival (86%) than those allocated to no goserelin (68% and 83%, respectively). These correspond to a hazard ratio of 0.80 (95% CI 0.69 to 0.82,  $P=0.002$ ) for recurrence free survival and 0.81 (95% CI 0.67 to 0.99,  $P=0.038$ ) for overall survival. Exploratory analyses of interactions between the effects of goserelin, the use of chemotherapy and ER status found an apparent improvement in recurrence free survival in ER+ patients in the presence of chemotherapy (0.83, 95% CI 0.62 to 1.10) and a worsening in ER- patients in the presence of chemotherapy (1.19, 95% CI 0.83 to 1.71). However, these subgroup results are not significantly heterogeneous and do not provide sufficient evidence to support or refute true differences in effect between these subgroups.
- ECOG 5188 INT-0101 (premenopausal women who had node positive breast cancer and were ER+); goserelin and tamoxifen versus goserelin versus no hormonal therapy: after a median follow up of 115 months, patients randomised to the addition of goserelin to chemotherapy had non-significantly better recurrence free survival (60%) than those allocated chemotherapy alone (57%) (HR: 0.93  $p=0.25$ ) and non-significantly better overall survival (73% versus 70%, HR: 0.88,  $P=0.14$ ).
- The IBCSG VIII trial (CMF alone versus CMF followed by goserelin versus goserelin alone): at a median follow-up of 84 months, there were no significant differences between the treatment groups in disease free survival or overall survival. The five-year disease free survival was 82% (95% CI 78-86) for chemotherapy alone, and 87% (95% CI 83-91) for chemotherapy followed by goserelin. In the comparison of the combination of chemotherapy and goserelin versus

chemotherapy, the relative risk for disease free survival was 0.80 (95% CI 0.57-1.11,  $p=0.17$ ). This was similar in both the ER+ and ER- subgroups (RR: 0.80, 95% CI 0.54-1.19,  $p=0.26$ ; and RR: 0.75, 95% CI 0.40-1.39;  $p=0.35$ , respectively). Among women under 40 years of age at diagnosis, amenorrhoea occurred gradually during the six months of chemotherapy, reaching 50% in both the chemotherapy alone and the chemotherapy to be followed by goserelin group after the six cycles. Among the former, menses resumed in 15% of the patients but amenorrhoea continued for 35-40% of women in this group throughout the three years of observation. Among the women who received goserelin after their chemotherapy, 90% of the group were amenorrhoeac after a few months of this drug. Menses resumed in many women when they stopped goserelin but were still absent for 35-40% of women in this group at month 36. Among women aged 40 years or older, amenorrhoea due to chemotherapy was observed sooner than among the younger women, affecting 80-90% of these patients by the end of six cycles of CMF. Among the older women who started goserelin after six months of chemotherapy, nearly all of them were amenorrhoeac after the first couple of months of goserelin, almost all of the group remained so at month 36. Quality of life was similar for patients in both groups through the first six months (when, of course, all were receiving chemotherapy) and at 36 months.

- GABG-IV-B-93 trial (60% of the 776 women in the trial were ER-): 5-year event free survival (all patients) was 71.3% (95% CI 66.3% to 76.3%) in the chemotherapy and goserelin group compared to 67.6% (95% CI 62.2% to 73.0%) in the chemotherapy alone group. This is equivalent to a hazard ratio of 0.92 (95% CI 0.70 to 1.21,  $P>0.5$ ).
- Pretoria trial (premenopausal women; CMF versus CMF followed by depo-buserelin): the differences between the treatments on disease free survival and overall survival are non-significant in this relatively small trial, with a disease free interval of 6.8 years for women in the combination therapy group compared to 6.2 years for women in the chemotherapy alone group.

### **iii) Chemotherapy and LHRH agonist and tamoxifen versus chemotherapy**

- ZIPP trial: no acceptable data due to non-randomised comparisons.
- ECOG 5188 INT-0101 trial (premenopausal women who had node positive breast cancer and were ER+); goserelin and tamoxifen versus goserelin versus no hormonal therapy: after a median follow up of 115 months, patients randomised to the addition of goserelin and tamoxifen to chemotherapy had better recurrence free survival (68%) than those allocated chemotherapy alone (57%) and better overall survival (76% versus 70%). However, the associated hazard ratios and significance tests for this comparison have not been published.
- MAM 01 GOCSI (chemotherapy plus goserelin and tamoxifen versus

chemotherapy alone): after a median follow-up of 72 months, the estimated probability of being disease free at five years was significantly higher for the chemotherapy, goserelin and tamoxifen group (64%), compared to the chemotherapy alone group (53%), corresponding to a hazard ratio of 0.74 (95% CI 0.56 to 0.99, P=0.04). The benefits appeared greater for women with ER+/ER-unknown tumours (HR: 0.73) than for women with ER- tumours (HR: 0.89) but the interaction between treatment effect and ER status was not significant. The estimated 5-year overall survival was 82% for the chemo-hormonal therapy group, and 80% for the women who were allocated to chemotherapy alone (HR: 0.84, 95% CI 0.54 to 1.32).

#### **iv) LHRH versus ovarian ablation by surgery or radiotherapy**

No trials were identified comparing an LHRH agonist versus ovarian ablation by surgery or radiotherapy in the adjuvant setting.

### **General comments**

#### **A. Literature search strategy:**

The specialised register maintained by the Secretariat of the Cochrane Breast Cancer Group was searched. Studies coded as "early breast cancer" and "endocrine therapy" were extracted for consideration. In addition, the reference lists of related literature reviews and the list of reports of trials maintained by the Early Breast Cancer Trialists' Collaborative Group were checked. Handsearches were performed of the proceedings of the annual meetings of the American Society of Clinical Oncology and the San Antonio Breast Cancer Symposium in 2005 and 2006.

#### **B. Assessing trials for eligibility**

The eligibility criteria were applied to each potentially eligible trial identified. In the first instance, trial publications were used to assess each trial's eligibility. If a trial had not been published, the necessary information was sought from the trial protocol or from the principal investigator of the trial.

#### **C. Quality Control**

Two reviewers independently assessed each potentially eligible trial for inclusion in the review and quality. A third reviewer resolved any differences of opinion regarding eligibility or quality.

#### **D. Data extraction and Analysis**

A single reviewer extracted data describing the trial and patients' baseline characteristics. Two independent reviewers extracted data on outcomes (including follow-up times). The most complete dataset feasible was assembled from the published reports of the trials. Results of included studies have not been combined in a meta-analysis because this was not judged appropriate or possible. Instead results are presented according to their primary papers.

### **E. Assessing the Methodological Quality of the Included Studies**

Two independent reviewers appraised the design and conduct of each trial to assess its susceptibility to bias. Methodological quality was assessed using a modified subset of the Methods for Evaluating Research and Guideline Evidence (MERGE) criteria (Liddle 1996). The following aspects of each trial were considered:

- a. concealment of treatment allocation
- b. generation of the allocation sequence
- c. comparability between groups at the baseline
- d. inclusion of all randomised participants in the analysis
- e. withdrawals from the trial
- f. valid assessment of endpoints.

A global quality score was assigned to each trial:

A: all or most the evaluation criteria from the MERGE checklist are fulfilled.

Where evaluation criteria are not fulfilled, the conclusions of the study are thought very unlikely to alter.

B1: some evaluation criteria from the MERGE checklist are fulfilled. Where evaluation criteria are not fulfilled or are not adequately described, the conclusions of the study are thought unlikely to alter.

B2: some evaluation criteria from the MERGE checklist are fulfilled. Where evaluation criteria are not fulfilled or are not adequately described, the conclusions of the study are thought likely to alter.

C: few or no evaluation criteria are fulfilled. Where evaluation criteria are not fulfilled or are not adequately described, the conclusions of the study are thought very likely to alter.

Where the two reviewers differed in their quality assessment, arbitration from a third reviewer was sought.

## Randomised controlled trials

<b>Citation</b>
Groenvold, Fayers, Petersen & Mouridsen . Chemotherapy versus ovarian ablation as adjuvant therapy for breast cancer: impact on health-related quality of life in a randomized trial 5. Breast cancer research and treatment. 98[3], 275-284. 2006.
<b>Design</b>
Randomised controlled trial Country of origin: Denmark, UK, Norway Evidence grade: 1-
<b>Inclusion criteria</b>
<p>Aim: to provide a detailed comparison of the impact of CMF chemotherapy versus ovarian ablation by oophorectomy on health-related quality of life during the 2 years following randomization.</p> <p>Participants: premenopausal women with primary, histologically proven estrogen or progesterone receptor positive breast cancer. All patients had axillary lymph node metastases and/or tumours larger than 50 mm.</p> <p>Accrual period for the entire RCT: January 1990-May 1998</p> <p>The quality of life sub-study was opened June 1, 1991 and included the patients randomized in the DBCG 89-b trial in Denmark until a predefined number of approximately 300 patients was reached. Inclusion was stopped February 6, 1996 when 317 patients had been included; follow-up was continued till 1998.</p>
<b>Exclusion criteria</b>
<ul style="list-style-type: none"><li>• Patients with evidence of distant metastases</li><li>• Patients with prior or concomitant malignant disease</li><li>• Patients whose disease recurred within the study period (i.e. the first 2 years after randomization).</li><li>• Patients who did not fill in all the 6 questionnaires</li><li>• Eligible patients for whom no data was collected due to administrative errors (n=23)</li><li>• Eligible patients who selected the other treatment to the one to which they were randomised (i.e. non-intention-to-treat).</li></ul>
<b>Population</b>
N=196
<b>Interventions</b>

Patients underwent lumpectomy or mastectomy, both with axillary dissection. Patients were randomly assigned to one of two adjuvant therapies:

1. CMF Chemotherapy (n=87): (nine cycles of intravenous cyclophosphamide, methotrexate, fluoracil given every 3 weeks for approximately 6 months)
2. Ovarian ablation (n=109): achieved by ovarian radiation in 107 of 109 patients (pelvic irradiation with a total dose of 15 Gy given as 5 daily fractions or in 2 cases, surgical oophorectomy. Ablation was performed 3–5 weeks after randomization

### Outcomes

QOL outcomes were assessed by questionnaire by mail 1 month after randomization. If the patient filled in the questionnaire booklet, identical booklets were sent to the patient 3, 5, 9, 15, and 24 months after randomization.

For women in the ovarian ablation group, the first assessment at 1 month approximately corresponds to the completion of their treatment. For women in the chemotherapy group the first three assessments (1, 3, and 5 months after randomization) reflect the treatment period.

The questionnaire consisted of 69 items, including:

- EORTC QLQ-C30 for use in cancer clinical trials: The Danish EORTC QLQC30 was validated in two studies.
- Hospital Anxiety and Depression Scale (HADS).
- DBCG 89: developed for this study to cover issues identified as relevant but not included in the two standard questionnaires, including physical symptoms and social outcomes.

### Follow up

Outcomes reported until 2 years from randomisation.

### Results

#### 1. Functional and symptom-related aspects of QOL: Based upon EORTC QLQ-C30 mean scores at 1, 3, 5, 9, 15 and 24 months from randomisation

NB: Mean scores are not shown. Direction of effect is shown as either ND; p=NS: 'No difference; p value not statistically significant ( $p > 0.05$ )' or for statistically significant differences between arms: FA: 'favours ablation' or FCT: 'favours chemotherapy'.

Questionnaire item	Direction of effect (p value)

### General comments

Limitations in applicability: results are based upon patients who were recurrence-free throughout the 2 years and those who returned all six questionnaires (with possible selection biases).

The paper uses the term oophorectomy inaccurately because it states that 107 of 109 patients in the ovarian ablation arm had ablation by RT.

The content of the questionnaire was validated as follows:

- literature review
- identification of potential issues to be included in the questionnaire
- validation of the selection of issues against patient interviews
- combination of standard questionnaires and ad hoc developed items
- pilot testing the combination of questionnaires

13 patients randomized to ovarian ablation and one patient randomized to chemotherapy did not receive the allocated treatment because they selected the other treatment. These patients were excluded (i.e. non-intention-to-treat) as the authors report that this would mean that the description of quality of life outcome of ovarian ablation would include patients receiving chemotherapy and vice versa.

Updated 2018

<b>Citation</b>
Brunt, Bliss, Benghiat, Dawson, Dewar, Harnett, Hopwood P, Lawrence & Trask . The impact on quality of life of adding chemotherapy (CT) or ovarian suppression (OS) to adjuvant tamoxifen (TAM): Outcomes from the UK NCRI Adjuvant Breast Cancer (ABC) trial [abstract] 34. Annual Meeting Proceedings of the American Society of Clinical Oncology , 729. 2004.
<b>Design</b>
Randomised controlled trial: QOL outcomes from a sub-study within the UK NCRI ABC trial (cited from ASCO meeting abstract) Country of origin: UK, Malta, New Zealand and countries in the Middle East and Asia. Evidence grade: 1-
<b>Inclusion criteria</b>
Aim: the ABC Trial evaluates whether adjuvant chemotherapy and/or ovarian suppression add to the benefits of prolonged (5 years) tamoxifen for women with early breast cancer. Women with early breast cancer were recruited between the years 1993 and 2000.
<b>Exclusion criteria</b>
Not reported.
<b>Population</b>
N=436 (247 in +/-CT comparison, 199 in +/-ovarian suppression comparison). Median age 49 (range 28-79).
<b>Interventions</b>
Patients were randomly allocated to two treatment plans as follows: <ol style="list-style-type: none"> <li>1. Pre/peri-menopausal women: CT and/or ovarian suppression versus none (where all patients receive tamoxifen)</li> <li>2. Post-menopausal women: CT versus none (where all patients receive tamoxifen)</li> </ol> <p>In the Quality of life (QOL) sub-study, patients reported QOL using the EORTC QLQ-C30, BR23 breast cancer module, Hospital Anxiety and Depression Scale (HADS) and Menopausal Symptom Scale (MSS), before randomisation and at 3, 6, 9, 18, 30, 48 and 72 months.</p>
<b>Outcomes</b>
QOL outcomes including systemic and menopausal symptoms, mood, sexual functioning, body image, role functioning and global QOL.
<b>Follow up</b>
Available from accrual period (1993-2006) to 2006 i.e. minimum 6 years.

**Results**

The addition of CT was associated with worse QOL during the first 9 months for depression ( $p=0.007$ ), role function ( $p=0.003$ ) and global QOL ( $p=0.001$ ) and a trend to worse QOL for body image concerns ( $p=0.02$ ), and sexual enjoyment ( $p=0.08$ ). Systemic side effects ( $p=0.001$ ) and menopausal problems ( $p=0.02$ ) were worse over 30 months.

The addition of ovarian suppression resulted in increased menopausal symptoms ( $p<0.0001$ ), depression ( $p=0.05$ ) and anxiety ( $p=0.04$ ) over 30 months but no deterioration in role function, global QOL, body image or sexual function.

Authors' conclusions: adverse QOL counters the potential benefits of additional CT; therefore treatment choice should consider possible health gains and QOL losses. The negative QOL effect of OS is paralleled by a lack of clinical benefit in the ABC trial.

**General comments**

Although this trial was identified by the team that compile the EBCTCG dataset, the EBCTCG list of trials indicates that data are unavailable, so citing this report is useful (See Appendix; EBCTCG codes 93A3, 93A4 and 93A6).

Compliance with QL forms was high; 99.8% at baseline ranging to 86.3% at 30 months.

Updated 2018

<b>Citation</b>
Celio, Buzzoni, Longarini, Gattinoni, Prtale, Denaro, Oriana S & Bajetta . Surgical oophorectomy (Ovx) and tamoxifen (T) versus chemotherapy (FEC) and T in premenopausal, node-positive breast cancer 31. Annals of Oncology 13[Suppl 5], 37. 2002.
<b>Design</b>
Randomised controlled trial (Abstract) Country of origin: Italy Evidence grade: 1-
<b>Inclusion criteria</b>
Aim: to measure the clinical benefit of complete oestrogen blockade compared to anthracycline-containing chemotherapy (CT) in premenopausal patients with early-stage breast cancer.
<b>Exclusion criteria</b>
Amenorrhoea lasting more than 1 year or cardiac dysfunction.
<b>Population</b>
N=109 women with invasive, receptor positive (ER or PR), node-positive breast cancer. Median age was 48 (37-57) years. Of all patients, 76% had fewer than 4 positive axillary nodes, and 80% had both ER+ and PR+ tumours.
<b>Interventions</b>
Patients ( patients) were randomised to receive either A) surgical oophorectomy and Tamoxifen 20 mg/d for 5 years (n=54) B) 6 cycles of FEC (5FU 750 mg/m <sup>2</sup> , epirubicin 75 mg/m <sup>2</sup> , Cyclophosphamide 500 mg/m <sup>2</sup> ) every three weeks and T for 5 years (n=55).  Local radiotherapy was mandatory in case of breast conservation. In the two arms, 58% of patients underwent breast-conserving surgery.
<b>Outcomes</b>
Recurrence and mortality (crude rates)
<b>Follow up</b>
Median 68 (55-81) months
<b>Results</b>
<b>Tolerability and side effects of chemotherapy</b> All patients in the CT arm completed all cycles, but only 46 patients received more than 95% of the total planned dose. Grade 3-4 neutropenia occurred in 12% of patients, and 75% of normally menstruating patients experienced

amenorrhea persisting after CT.

With a median follow-up of 68 (55-81) months, we observed 10 (18%) vs. 4 (7%) recurrences and 6 (11%) vs. 3 (5%) deaths in the A and B arms, respectively.

Authors' conclusions: After a median follow-up of six years, the very low number of events suggests good clinical benefit with both treatments. Large randomized trials are needed for final recommendations regarding the relative worth of either treatment modality in the premenopausal adjuvant setting.

#### **General comments**

The unexpected poor accrual resulted in the study being stopped prematurely in 1997. No statistical analysis performed, presumably due to small sample size. Unlikely to add value in the light of the cited systematic reviews.

<b>Design</b>
<p>Randomised controlled trial Country of origin: Vietnam, China Evidence grade: 1+</p>
<b>Inclusion criteria</b>
<p>Aim: to evaluate disease-free and overall survival in Vietnamese women with early operable breast cancer following adjuvant oophorectomy and tamoxifen versus observation, with oophorectomy and tamoxifen given at the onset of metastatic disease.</p> <p>Premenopausal women with operable breast cancer; T<math>\geq</math>2cm; Stage I-IIIa with a treatment plan of mastectomy.</p>
<b>Exclusion criteria</b>
<p>Distant metastasis; post-menopausal status.</p>
<b>Population</b>
<p>N=709 [n=482 for the sub-study on side effects]</p>
<b>Interventions</b>
<p>All patients underwent mastectomy and axillary node clearance.</p> <p>Patients were randomised as follows:</p> <p>Intervention arm (n=356): underwent oophorectomy under the same anaesthetic as that for mastectomy (2 patients underwent ovarian ablation by RT), and then five years of tamoxifen.</p> <p>Observation arm (n=353): did not receive oophorectomy or tamoxifen and were observed, with oophorectomy and tamoxifen initiated if metastatic disease was subsequently detected.</p>

In either arm adjuvant chest wall RT was permitted; 50Gy in 2Gy/day fractions, with axillary RT given in node-positive cases.

### Outcomes

Disease-free survival

Overall survival

Side effects of treatment (At each of these visits, physicians asked each about 10 symptoms and completed a one-page symptom questionnaire, which inquired about, listed, and described specific grades of toxicity to note if present. The specific symptoms were edema, nausea, pruritus vulvae, hot flashes frequency and intensity, vaginal bleeding, discharge and dry ness, depression, skin rash, and changes in mood [with irritable, sad spells] frequency and intensity).

### Follow up

Patients were seen at 3-month intervals for 3 years, then 6-monthly.

Median follow-up 3.6 years

### Results

#### Treatment received

124/353 = 35.1% of women in the observation group experienced disease recurrence

Actual treatment received was as follows:

Treatment	Intervention group (n=356)	Observation group (n=124 with recurrence)
Oophorectomy plus tamoxifen	93%	23%
Tamoxifen alone	3.9%	52%
Oophorectomy alone	-	1%
Neither oophorectomy not tamoxifen	3.1%	19%
Unknown	-	5%
Total	100%	100%

#### Recurrence and survival

In an itention-to-treat analysis at a median 3.6 years follow-up, disease-free survival ( $p=0.0003$ ) and overall survival ( $p=0.0477$ ) were higher in the intervention group compared to the control group. Disease-free survival estimated at 5 years by Kaplan-Meier analysis was 75% in the intervention group and 58% in the observation group.

Considering only the ER positive subgroup at a median 3.6 years follow-up,

disease-free survival ( $p=0.001$ ) and overall survival ( $p=0.01$ ) were higher in the intervention group compared to the control group.

Considering only the ER negative subgroup at a median 3.6 years follow-up, there was no statistically significant difference in disease-free survival or overall survival between the intervention group and the control group.

**Side effects reported in the first 12 months (subgroup: first 482 randomised subjects)**

Symptom	Randomised arm	Hot flash grade					p value
		0 (%)	1 (%)	2 (%)	3 (%)	4 (%)

**Narrative to support tabulated side effects data**

Only three of the symptoms enquired about – hot flashes, vaginal discharge, and genital pruritus – were found in the first 12 months to be more frequent in women

treated with adjuvant oophorectomy and tamoxifen.

During the first 12 months 77% of women randomised to oophorectomy/tamoxifen versus 9% of those randomised to observation had some hot flash toxicity, and 44% of those randomised to treatment reported toxicity in numbers of hot flashes of grade 2 or more (3–5 hot flashes per day or more) as compared to 1% of women randomised to observation. Hot flashes of intensity to produce sweating occurred in 20% of treated women versus less than 1% of observation subjects. Vaginal discharge and genital pruritus were about twice as common in tamoxifen-treated patients, and these two side effects were significantly associated ( $p < 0.0001$ ).

An excess of vasomotor symptoms persisted in treated women over three years of follow-up although by that time only 23% of treated women had these symptoms, and the majority of these were of grade 1 intensity. While over time small numbers of observation group patients developed recurrent disease and received oophorectomy and tamoxifen treatment and developed associated symptoms, these events do not significantly alter the pattern or the strength of the association of vasomotor symptoms and initial oophorectomy tamoxifen therapy over time.

No women who began tamoxifen and who have not had recurrence have stopped tamoxifen because of toxicity.

### **General comments**

The study design permits the risk that some patients with tumours  $\geq 2$ cm in size that are found subsequently to be benign, undergo oophorectomy.

Randomisation achieved by sealed envelope, using permuted block design; stratified for nodal status and tumour size. Where patients were found on review to belong within a different randomisation strata, the assigned treatment was continued (there were 35 such errors). Analysis was by intention-to-treat.

Compliance with randomised treatment is poor, especially in the observation arm in cases with recurrent disease.

8 patients received no primary treatment for their breast cancer. 23 patients were lost to follow-up (7 in intervention group, 34 patients had no evidence of invasive disease on pathology review (12 in observation group;  $p = 0.08$ ).

Study sample size/power calculation performed, which indicated a sample size of 700.

The only statistically significant differences in patient-tumour variables at study outset are:

Pathological tumour size:

Intervention: 3.22 cm  
Observation: 3.37 cm;  $p=0.0091$

ER positive (%)

Intervention: 55.7

Observation: 67.95;  $p=0.012$  NB ER status was evaluated for 67% of all patients.

Data on side effects were missing for 1, 1, 2, 2, 3, 4, and 6 subjects at the 3, 6, 12, 18, 24, 30, and 36-month time points, respectively. The authors report that these missing data did not significantly influence the results presented.

1. CT
2. CT + Tamoxifen

### Outcomes

Relapse-free survival  
Overall survival

### Follow up

Median 10 years

### Results

At a median follow-up of 10 years in ER-positive, premenopausal patients there were no significant differences in relapse-free survival ( $p=0.15$ ) or overall survival ( $p=0.42$ ) among the oophorectomy + Tamoxifen, CT, and CT + Tamoxifen arms

At a median follow-up of 10 years ER-negative, premenopausal patients showed no significant differences in relapse-free survival ( $p=0.97$ ) or overall survival ( $p=0.85$ ) between CT and CT + Tamoxifen arms.

**Table: recurrence and survival outcomes in premenopausal patients (separate randomisations for patients with ER+ tumours and for those with ER- tumours)**

	Adjuvant therapy	Recurrence			Multiple cancer			Death		
		n/N	%	p	n/N	%	p	n/N	%	p

	Chemotherapy + Tamoxifen	24/151	16		6/151	4		21/151	14	
<b>ER-</b>	Chemotherapy	28/165	17	0.9	9/165	6	0.449	28/165	17	0.7
	Chemotherapy + Tamoxifen	27/162	17		6/162	4		25/162	15	

### General comments

Most of the narrative is available only in Japanese language; data extracted from tables and figures with English language annotation.

Data are cited from two randomisation strategies; one for premenopausal patients with ER+ tumours and one for premenopausal patients with ER- tumours.

Graded as 1- as a cautious approach, because the reviewer is unable to read Japanese.

CMF chemotherapy	34		

**General comments**

Randomisation method: through a central office by telephone between March 1980 and May 1990 with treatment options allocated from computer-generated lists of random numbers.

The randomised groups did not differ appreciably in terms of most patient and tumour-related variables. Slightly more women whose tumours had an ER concentration of <20 fmol/mg were randomised to receive ovarian ablation than CMF (54/136 and 60/135, respectively).

Randomisation violations:  
There were 43 patients (13%) who did not receive the systemic therapy to which they had been randomised. Of these women, two had CMF instead of ovarian ablation and six received ovarian ablation rather than CMF. Three further women received tamoxifen in place of CMF and three had it in place of ovarian ablation. Another 11 women randomised to CMF received no systemic treatment and 11 randomised to ovarian ablation had no systemic therapy. The remaining seven violations were in relation to the prednisolone randomisation.

Narrative in paper implies that not all patients gave informed consent prior to being accrued on this trial: "According to accepted practice at the start of the trial in 1980, the participating clinician made the decision whether to seek informed consent from each patient." Alternatively this could be interpreted as meaning that not all patients were considered for the trial, which may introduce a selection bias.

All analyses were performed according to the randomised intention to treat groups.

There was no interaction between the two treatment comparisons comprising the 2 by 2 design (P=0.26 for all deaths; Cox model).

Leuprorelin acetate every-3-months depot versus cyclophosphamide, methotrexate, and fluorouracil as adjuvant treatment in premenopausal patients with node-positive breast cancer: the TABLE study. Journal of Clinical Oncology 25[18], 2509-2515. 2007.
<b>Design</b>
Randomised controlled trial: TABLE study Country of origin: Germany, Ukraine Evidence grade: 1+
<b>Inclusion criteria</b>
Aim: to evaluate the efficacy and tolerability of the 3-monthly depot LHRH agonist leuprorelin acetate (LAD-3M) as adjuvant treatment of premenopausal patients with early, node-positive breast cancer.  Participants were premenopausal women with histologically confirmed stage II or IIIA breast cancer, treated at 71 participating centers between September 1995 and November 1998. Patients had to have between one and nine involved axillary lymph nodes, with at least 10 lymph nodes being examined. Initially, patients were required to have ER-positive tumors or tumors with unknown ER status. In March 1998, an amendment was issued, requesting positive ER status for enrollment (ie, patients with unknown ER status were ineligible thereafter).
<b>Exclusion criteria</b>
Patients were ineligible if they had received ovarian ablation, adrenalectomy, or hypophysectomy. Further exclusion criteria included systemic treatment of cancer within 6 months before enrollment, hormone treatment (apart from contraceptives) within 2 weeks before entry, regular steroid therapy, endocrine abnormalities, severe concurrent medical conditions, and impaired renal function. Pregnant or lactating women were ineligible.  Five patients in each treatment group did not receive the allocated study medication and were excluded from ITT and safety analysis. Accordingly, the ITT population and the safety population included 589 patients. Another 63 patients (LAD-3M, n=24; CMF, n=39) were excluded from the primary efficacy population because of premature termination of study treatment or relevant protocol violations. Thus, the primary efficacy population consisted of 526 patients: 270 patients randomly assigned to LAD-3M and 256 to CMF.
<b>Population</b>
N=589
<b>Interventions</b>

A total of 599 patients were randomly assigned to treatment within 6 weeks of surgery as follows:

1. LAD-3M(n=299): 2 years of treatment with the 3-monthly depot LHRH-agonist leuprorelin acetate
2. CMF(n=300): six cycles of chemotherapy with cyclophosphamide, methotrexate, and fluorouracil

### Outcomes

- Relapse-free survival (RFS)
- Overall survival (OS)
- Adverse events
- Oestrogen suppression
- Menstrual status
- Subjective state of health

### Follow up

Median 5.8 years

### Results

#### Treatment compliance

Treatment compliance was high in both arms. A total of 277 (94.2%) patients received at least two doses of LAD-3M, 255 patients (86.7%) received four doses, and 237 (80.6%) patients all eight doses of LAD-3M. The majority of patients without recurrence in the first 6 months completed all six cycles of CMF(93.2%). Cycles of CMF were delayed or dose reduced in 2% of courses.

#### Recurrence and survival

With a median follow-up of 5.8 years, there were 269 recurrences and 197 deaths. Sites of recurrence and types of events are as follows:

#### Sites of First Treatment Failure According to Treatment at Median Follow-Up of 5.8 Years (exploratory two-sided Fisher test)

Outcome	Total (n=589)	LAD-3M (n=294)		CMF (n=295)		p
		No.	%	No.	%	
Recurrence:	269	126	42.9	143	48.5	0.186
• Distant	156	73	24.8	83	28.1	0.401
• Local	35	26	8.8	9	3.1	0.003
• Unspecified	77	26	8.8	51	17.3	0.003
• Contralateral	11	6	2.0	5	1.7	0.772
• 2 <sup>nd</sup> malignancy	4	1	0.3	3	1.0	0.624
Deaths						

• Any cause	197	83	28.2	114	38.6	0.009
• Breast cancer-specific	189	82	27.9	107	36.3	0.034

There was no significant difference in RFS between LAD-3M and CMF. The ITT 5-year RFS rates were 63.9% for LAD-3M and 63.4% for CMF (HR, 1.03; P=0.83). Similar results were obtained for the PP analysis (HR, 1.02; P=0.88).

Exploratory survival analysis favored LAD-3M treatment over CMF (HR, 1.50; 95% CI, 1.13 to 1.99; P=0.005) with 5-year survival rates of 81.0% and 71.9%. Survival differences began to emerge after 2 years of follow-up. There was also a trend for a higher breast cancer-related mortality in the CMF group (CMF, 39.5%; LAD-3M, 28.9%; P=0.05).

### Effects of Treatment on Menstrual Function

Amenorrhea was reported in 88% of LAD-3M patients by 6 months and more than 95% during the remaining 2-year treatment period, compared with 43.9% of CMF patients after 6-months of chemotherapy and 62.1% at 2 years. The onset of amenorrhea was earlier in the LAD-3M group (mean, 22±38 days) compared to the CMF group (mean, 110±151 days).

Amenorrhea was reversible within 1 year of stopping LAD-3M in 45% of patients. In patients treated with CMF, the rate of amenorrhea steadily increased from 51.5% after 1 year to 62.1% after 2 years and 72.7% after 5 years. Further analysis by age showed that more than 90% of patients younger than 40 years at trial entry had normal menstrual function 1 year after the completion of therapy, compared with approximately 70% of patients between 40 and 45 years and 40% of patients older than 45 years.

### Tolerability

Adverse effects were generally of low or moderate intensity. Symptoms of estrogen suppression such as hot flashes and increased sweating were more common in patients treated with LAD-3M, whereas acute adverse effects of chemotherapy such as nausea, vomiting, diarrhea, asthenia, and alopecia were reported more frequently in patients treated with CMF:

### Incidence of adverse effects during the first 2 years (%)

Adverse effect	LAD-3M (n=294)		CMF (n=295)		p
	All grades	Grade 3/4	All grades	Grade 3/4	
Nausea/vomiting	11.6	0.3	69.8	21.0	<0.01
Mucositis	2.4	0	11.2	1.0	<0.01

Diarrhoea	4.4	1.4	12.9	7.8	<0.01
Infection	13.5	2.7	10.5	1.7	0.26
Fatigue	44.6	1.4	67.1	3.1	<0.01
Hot flushes	83.7	16.3	49.5	6.8	<0.01
Oedema	16.7	2.0	10.2	0.7	0.02
Alopecia	9.5	1.0	43.1	5.4	<0.01

The overall self assessment of tolerability by the patients showed markedly better results for LAD-3M during the first 6 months. At 6 months, 16.0% and 56.8% of patients in the LAD-3M group rated the treatment tolerability as “very good” or “good,” respectively, compared with 15.6% and 37.3% in the CMF group. After the end of chemotherapy, assessments improved markedly in the CMF group. At 2 years, self-assessments of tolerability were comparable in both arms.

### General comments

This RCT is included in the Cochrane systematic review by Sharma et al. 2007, but this subsequently published paper provides longer follow-up data (5-year outcomes versus 2-year outcomes).

Patients were randomly assigned in a 1:1 ratio to one of the two treatment groups using a stratified random permuted block design (block size 4). Random assignment was performed centrally according to the order in which information on potential patients was received by fax. Patients were stratified by study center.

There were no significant differences between the groups with respect to any characteristic.

Blinding to, and concealment of allocation not feasible: open label study.

Scale used for self assessment of tolerability is not fully reported.

<p>Kaufmann, M., Graf, E., Jonat, W., Eiermann, W., Vescia, S., Geberth, M., Conrad, B., Gademann, G., Albert, U. S., Loibl, S., von, M. G., Schumacher, M. &amp; German Adjuvant Breast Cancer Study Group (2007) A randomised trial of goserelin versus control after adjuvant, risk-adapted chemotherapy in premenopausal patients with primary breast cancer - GABG-IV B-93. <i>European journal of cancer (Oxford, England : 1990)</i>, 43: 2351-2358.</p>
<p><b>Design:</b> RCT, 1+  <b>Country:</b> Germany</p> <p><b>Aim:</b> To investigate the effectiveness of goserelin compared to no further treatment, after risk-adapted chemotherapy in premenopausal patients with HR negative breast cancer.</p>
<p><b>Inclusion criteria</b>          Premenopausal women with histological diagnosis of breast cancer and either hormone receptor (HR)-negative (node-negative and node-positive) patients were included (stage pT1–3, N0–N3, M0; no prior surgical, systemic or radiation therapy for breast cancer; Karnofsky index P60). Patients were recruited from 66 centres all over Germany.</p>
<p><b>Exclusion criteria</b>          Major exclusion criteria were distant metastases, T4 tumours; incomplete surgical resection; resection of &lt;10 axillary lymph nodes; simultaneous contralateral breast cancer; previous malignancy except basal cell carcinoma of the skin or carcinoma in situ of the cervix uteri; pregnancy or lactation and randomisation not within 28 days of definitive primary surgery.</p>
<p><b>Population</b>          776 patients (pts) were randomised:</p> <ul style="list-style-type: none"> <li>• 465 pts were HR-negative (241 in the control arm, 224 in the goserelin arm),</li> <li>• 311 pts were HR positive (151 in the control arm, 160 in goserelin arm).</li> </ul> <ul style="list-style-type: none"> <li>• HR-negative sub-population 32% of the pts were up to 40 years old and the majority (62%) were nodal negative.</li> <li>• Tumours were greater than 2 cm in largest diameter in 52% and histological grade 3 was found in 59% of the tumours in this subgroup.</li> <li>• Baseline characteristics were reported to be well balanced across both groups</li> </ul>
<p><b>Interventions</b>          Goserelin (Zoladex® 3.6 mg subcutaneously every four weeks for two years) or no further treatment after a risk-adapted adjuvant chemotherapy.</p> <p>– Risk-adapted adjuvant chemotherapy = either three cycles of CMF (cyclophosphamide 500 mg/m<sup>2</sup>, methotrexate 40 mg/m<sup>2</sup> and 5-fluorouracil 600 mg/m<sup>2</sup>, IV day 1, 8, every 4 weeks) for patients with 0–3 positive lymph nodes or four cycles of EC (epirubicin 90 mg/m<sup>2</sup> and cyclophosphamide 600 mg/m<sup>2</sup>, IV every 3 weeks) followed by three cycles CMF in patients with 4–9 positive lymph nodes.</p>
<p><b>Outcomes</b></p>

- The primary outcome: event free survival (EFS) - defined as time from definitive primary surgery to the first event of failure (locoregional recurrence, metastases, second primaries including contralateral breast cancer, or death). The first event of failure was classified as isolated locoregional recurrence if locoregional recurrence occurred at least 4 weeks before an event at a distant site.
- The treatment effect on EFS was estimated as the hazard ratio in a Cox model with a two-sided 95% CI. P-values were based on two-tailed Wald tests.
- The secondary outcome: overall survival (OS) - defined as the interval from definitive primary surgery to death of any cause.
- Tolerability and adverse events

### Follow Up

- Follow-up examinations were scheduled every 3 months for the first 2 years, every 6 months up to year 5, and annually after this point.
- The median follow-up of 5.5 years (HR-negative) and 4 years (HR-positive). Completeness of follow-up was 88–90%. With regard to event-free survival, 215 events had been observed so far. 143 events occurred in HR-negative pts.

### Results

#### Event Free Survival

For all pts 5-year EFS rates are estimated:

71% (95% CI, 66–76%) in the goserelin group

68% (95% CI, 62–73%) in the control group.

The unadjusted hazard ratio (HR) of goserelin versus control pooling HR-negative and HR-positive patients was 0.92 (95% CI, 0.70–1.21; calculated as 95.66% CI to account for two interim analyses; P = 0.54).

In HR-negative pts: adjusted HR (goserelin versus control) = 1.01 (CI, 0.72–1.42; P = 0.97).

In HR-positive pts: adjusted HR (goserelin versus control) = 0.77 (CI, 0.47–1.24; P = 0.27).

#### Overall survival

- 5-year OS rates of all pts are estimated as 86% in the goserelin group and 85% in the control group.
- 104 (13%) deaths observed up to time of report (authors' note - it is too early for any definite analysis of OS)

#### Tolerability and adverse events

Goserelin was discontinued for medical reasons (other than recurrence or death) in 24 pts.

##### *In the control group:*

Serious adverse events related to chemotherapy were reported in 17 pts (leucopenia/thrombopenia- 5, emesis/nausea- 2, seroma- 2, abscess- 2, and thrombophlebitis, hyponatremia, stomatitis, vitiligo, infection, fever 1, respectively).

##### *In the goserelin group:*

Serious adverse events related to therapy were reported in 14 pts:

- 6 during chemotherapy (wound healing disorders- 2, and emesis/nausea, paravasation, leucopenia, infection 1 respectively),
- 8 during or after goserelin treatment (psychiatric disorders 3, erysipelas 2, wound pain, endometrial hyperproliferation, mastopathy 1, respectively).

No patient died during study medication.

### **General comments**

Overall, this study is underpowered for both the HR-negative and HR-positive population, the results do not indicate an advantage of additional goserelin after a risk-adapted chemotherapy with respect to EFS in HR-negative patients.

### **Technical Issues:**

Randomisation reported, no allocation concealment reported and intention to treat analysis was conducted but not described clearly. A power calculation was conducted wrt event free survival (EFS). From prior research EFS would be 60% at five years in the control group. Therefore, 190 events would be required to detect a hazard ratio of 0.67 for goserelin versus control, i.e. an improvement to about 71% in the goserelin group, with a power of 80% using a two-sided log-rank test at the level  $\alpha = 5\%$ . With four years of planned recruitment and two years additional follow-up, at least 700 patients would have to be included.

Updated 2019

Love, R. R., Van, D. N., Quy, T. T., Linh, N. D., Tung, N. D., Shen, T. Z., Hade, E. M., Young, G. S. & Jarjoura, D. (2008) Survival after adjuvant oophorectomy and tamoxifen in operable breast cancer in premenopausal women. *Journal of Clinical Oncology*, 26: 253-257.

**Design:** RCT , 1+

**Country:** RCT (report of mature results from original study, Love et al 2002)

**Aim:** This study reports the mature results of the original study (which aimed to evaluate the effectiveness of oophorectomy and tamoxifen versus observation), and focuses on the differential effects of treatment by ER status.

**Inclusion criteria**

Premenopausal women with operable breast cancer; T $\geq$ 2cm; Stage I-IIIa with a treatment plan of mastectomy.

**Exclusion criteria**

Distant metastasis; post-menopausal status

**Population**

N=709

**Interventions**

1. Intervention arm (n=356): underwent oophorectomy, and then five years of tamoxifen.

2. Observation arm (n=353): did not receive oophorectomy or tamoxifen and were observed (oophorectomy and tamoxifen were initiated if metastatic disease was subsequently detected)

- Details of patient recruitment and entry criteria have been previously published (Love et al 2002).
- This study reports data from an extended follow-up of patients.
- Patients were scheduled visits every 3 to 6 months for the first 5 years after random assignment, and annually thereafter.
- Tamoxifen was provided at each visit for the first 5 years. Extending the median follow-up time to 7.0 years, as compared with 3.6 years in the original report Love et al (2002).
- For patients without events, median follow-up was 7.9 years (first quartile, 6.6 years; third quartile, 9.5 years).

**Outcomes**

- Overall survival (OS) - calculated from the date of random assignment until the date of death from any cause
- Disease-free survival (DFS) time - measured from the date of random assignment until the date of disease recurrence or death before recurrence

**Results**

**Disease free Survival and Overall Survival**

- From the intent-to-treat analyses (using all registered cases), a significant difference in DFS and OS was found, which favoured the treatment group (log-rank test P values=

0.0003 and 0.0002, respectively.)

- 5-year DFS was 74% in adjuvant group and 61% in observation groups (95% CI for difference, 7% - 21%)
- 10-year DFS was 62% in adjuvant group and 51% in observation groups (95% CI for difference, 4% - 22%).
- 5-year OS rates were 78% in adjuvant group and 71% in observation groups (95% CI for difference, 1% - 21%)
- 10-year OS rates were 70% in adjuvant group and 52% in observation group (95% CI for difference, 6% - 34%).
- The DFS: HR (hazard ratio) for adjuvant versus observation groups = 0.65 (95% CI, 0.51 - 0.82)
- For OS : HR= 0.62 (95% CI, 0.48 - 0.80). (Based on a univariate Cox proportional hazards model)

### **ER status**

For women with known estrogen receptor (ER) status (n = 470), the adjuvant treatment effect was more marked in ER+ women.

- A Cox proportional hazards model was designed which included the DFS outcome using treatment, ER status and the treatment by ER interaction as the predictors.
- Estimates from the model indicated that the treatment benefit decreased over time for ER+ patients.
- Using the model estimates and ER+/observation patients as the referent group, the hazard ratio for recurrence for ER+ patients undergoing treatment increased from 0.49 (95% CI, 0.31 to 0.75) at year 3 to 1.10 (95% CI, 0.58 to 2.06) at year 8.

### **DFS**

- Kaplan-Meier survival curves showed that for ER+ women, the DFS probabilities for adjuvant-treatment patients were 83% at 5 years, 82% at 7 years, and 66% at 10 years; compared with 62%, 56%, and 50%, respectively, for the observed patients.

### **OS**

- OS probabilities were 87% at 5 years, 84% at 7 years, and 80% at 10 years, for adjuvant treatment, compared with 76%, 65%, 51% in the observation group, respectively.
- When considering the significant ER status by treatment interaction, a smaller effect of treatment for ER- patients was not significant (P=0.46 for DFS and 0.29 for OS). The 95%CI for the hazard ratio comparing treatment and observation among ER patients for DFS = 0.56 to 1.29 (authors claim that this CI is not narrow enough to rule out a clinically important effect of treatment in this subgroup.)

### **General comments**

Author's conclusions:

In premenopausal women with operable breast cancer not selected for estrogen receptor status or with oestrogen receptor-positive tumors, 5- and 10-year DFS and OS rates are significantly improved following adjuvant oophorectomy and tamoxifen.

### **5.2.1 What is the role of aromatase inhibitors (AIs) as adjuvant therapy in post-menopausal women with hormone receptor positive breast cancer?**

### **5.2.2 Which subgroups of post menopausal breast cancer patients should receive Aromatase Inhibitors as adjuvant therapy?**

There are several high quality RCTS and systematic reviews of RCTS that report the role of aromatase inhibitors (AIs) as adjuvant therapy in post-menopausal women with hormone receptor positive breast cancer.

#### **Anastrozole**

Disease free survival is significantly increased with anastrozole compared to tamoxifen either as first line adjuvant treatment or after tamoxifen. Prior chemotherapy (CMF, anthracyclines or taxanes) reduces the disease free survival advantage of anastrozole (Boccardo *et al.* 2005; Buzdar *et al.* 2006; Buzdar and Cuzick 2006; Dowsett *et al.* 2005; Forbes *et al.* 2008; Hind *et al.* 2007; Howell *et al.* 2005; Jakesz *et al.* 2005; Kaufmann *et al.* 2007). For hormone receptor positive patients DFS favoured the anastrozole group and in the hormone receptor negative subgroup there was no difference (Forbes *et al.* 2008).

There is no difference in overall survival either as first adjuvant treatment or after tamoxifen (Boccardo *et al.* 2005; Buzdar *et al.* 2006; Dowsett *et al.* 2005; Forbes *et al.* 2008; Hind *et al.* 2007; Howell *et al.* 2005; Jakesz *et al.* 2005). However in contrast, Kaufmann *et al.* (2007) showed a significant improvement in survival for patients in the anastrozole group when the benefits of switching to anastrozole after 2 years of tamoxifen treatment were compared with continuing on tamoxifen for 5 years.

The risk of disease recurrence is significantly reduced with anastrozole and is reported to be independent of nodal status, tumour size or prior chemotherapy. All ER positive patients showed a benefit but there was no statistical difference between the progesterone receptor (PR) positive or PR negative subgroup (Boccardo *et al.* 2005; Buzdar *et al.* 2006; Dowsett *et al.* 2005; Forbes *et al.* 2008; Hind *et al.* 2007; Howell *et al.* 2005; Jakesz *et al.* 2005; Kaufmann *et al.* 2007). When patients who were disease free at the end of receiving 5 years of adjuvant tamoxifen (with or without the aromatase inhibitor, amino-glutethimide, for the first 2 years of therapy) were randomly assigned to receive either 3 years of anastrozole or no further treatment; the disease free survival was statistically improved with significantly fewer recurrences. The risk of contralateral breast cancer is significantly reduced only if anastrozole is given as first line adjuvant treatment; it is not significantly different if given after Tamoxifen (Boccardo *et al.* 2005; Buzdar *et al.* 2006; Dowsett *et al.* 2005; Forbes *et al.* 2008; Hind *et al.* 2007; Howell *et al.* 2005; Jakesz *et al.* 2005; Kaufmann *et al.* 2007).

Time to progression was significantly increased for ER positive/PR negative tumours. The data for ER positive/PR positive tumours were significantly different from ER positive/PR negative tumours (non-overlapping confidence intervals). There is no statistical significant difference in the risk of distant disease. Forbes *et al.* (2008) and Kaufmann *et al.* (2007) both showed that statistically fewer patients on anastrozole experienced distant disease recurrence.

There were statistically significant adverse events, with a significant increased in risk of bone fracture with anastrozole compared to tamoxifen. However women treated with tamoxifen were at significantly increased risk of endometrial cancer, deep venous and venous thromboembolic events and ischaemic cerebrovascular events compared to anastrozole.

### **Letrozole**

The BIG 1-98 trial (Crivellari *et al.* 2008; Coates *et al.* 2007; Hind *et al.* 2007; Thurlimann *et al.* 2005; Rasmussen *et al.* 2008) compared letrozole versus tamoxifen in the initial adjuvant setting; and the MA-17 trial (Goss *et al.* 2005, 2007; Hind *et al.* 2007; Ingle *et al.* 2006; Muss *et al.* 2008) compared, letrozole versus placebo in the extended adjuvant setting following standard adjuvant treatment with tamoxifen. For monotherapy arm of the BIG 1 98 trial and the MA-17 trial, disease free survival was significantly improved with letrozole compared to tamoxifen for lymph node-positive tumours (Crivellari *et al.* 2008; Coates *et al.* 2007; Goss *et al.* 2005, 2007, 2008; Hind *et al.* 2007; Ingle *et al.* 2006; Muss *et al.* 2008; Thurlimann *et al.* 2005; Rasmussen *et al.* 2008).

When letrozole was compared to placebo disease free survival showed a significant improvement with letrozole. Over time (6 months to 4 years) the difference in the risk of progression significantly increased in the letrozole group compared to the placebo group. (Goss *et al.* 2005, 2007; Hind *et al.* 2007; Ingle *et al.* 2006; Muss *et al.* 2008). When patients in the placebo arm of the MA-17 trial were subsequently offered letrozole and then compared to those who did not take the letrozole (placebo arm), disease free survival was improved (Goss *et al.* 2008).

Overall survival was not statistically different between letrozole and tamoxifen (Crivellari *et al.* 2008; Coates *et al.* 2007; Hind *et al.* 2007; Thurlimann *et al.* 2005; Rasmussen *et al.* 2008). Overall survival was not statistically different between letrozole and the placebo groups (Goss *et al.* 2005, 2007; Hind *et al.* 2007; Ingle *et al.* 2006; Muss *et al.* 2008). Over time any difference in risk (significant or not) disappears. When patients in the placebo arm of the MA-17 trial were subsequently offered letrozole and then compared to those who did not take the letrozole (placebo arm), the overall survival adjusted hazard ratio was 0.30 for the letrozole arm.

Risk of contralateral breast cancer did not report statistically significant results; letrozole vs tamoxifen: 0.4% vs 0.7% (Crivellari *et al.* 2008; Coates *et al.* 2007; Hind *et al.* 2007; Thurlimann *et al.* 2005; Rasmussen *et al.* 2008). Risk of contralateral breast cancer when letrozole was compared to placebo showed no difference for time to recurrence (Goss *et al.* 2005, 2007; Hind *et al.* 2007; Ingle *et al.* 2006; Muss *et al.* 2008). There was a reduction in contralateral breast cancer in the letrozole arm of the Goss *et al.* (2008) trial.

There were fewer thromboembolic events with letrozole compared with tamoxifen but there was a significantly higher risk of bone fracture and some cardiac events with letrozole. (Crivellari *et al.* 2008; Coates *et al.* 2007; Hind *et al.* 2007; Thurlimann *et al.* 2005; Rasmussen *et al.* 2008). The incidence of bone fractures, observed more often in the letrozole group, did not differ by age. In elderly patients, letrozole had a significantly higher incidence of any grade 3 to 5 non-fracture adverse event compared with tamoxifen. Incidence of bone fractures was higher among patients treated with letrozole. Differences were not significant for thromboembolic or cardiac adverse events (Crivellari *et al.* 2008)

There was a significantly higher incidence of osteoporosis but no difference in the fracture rate with letrozole compared to placebo. (Goss *et al.* 2005, 2007; Hind *et al.* 2007; Ingle *et al.* 2006; Muss *et al.* 2008). There were statistically significantly more self-reported new diagnoses of osteoporosis with letrozole compared with placebo. There were significantly more clinical fractures in the women who took letrozole and there was a non-significant difference in the number of cardiac events occurring between the groups. Thromboembolic events occurred rarely in both groups.(Goss *et al.* 2008).

The time to any disease recurrence was significantly decreased with letrozole compared to tamoxifen or placebo. (Crivellari 2008; Coates 2007; Goss 2005, 2007, 2008; Hind 2007; Ingle 2006; Muss 2008; Thurlimann 2005; Rasmussen 2008).

There was no significant difference between letrozole and tamoxifen with respect to quality of life (Crivellari *et al.* 2008; Coates *et al.* 2007; Hind *et al.* 2007; Thurlimann *et al.* 2005; Rasmussen *et al.* 2008).

When letrozole was compared to placebo; the disease free survival for ER positive/PR positive tumours was significantly increased with letrozole. For ER positive/PR negative tumours the reported data had very wide confidence intervals spanning the line of no effect as well as that of the ER positive/PR positive tumours (Goss *et al.* 2005; Muss *et al.* 2008). When letrozole was compared to placebo, lymph node-positive and lymph node-negative women had significantly improved disease free survival (Goss *et al.* 2005). Goss *et al.* (2007) demonstrated a significant benefit in disease free survival in this subgroup and significant benefits were also observed for distant disease-free survival and overall survival versus placebo. When letrozole was compared to tamoxifen the

lymph node-negative tumour data also had very wide confidence intervals which spanned a line of no effect as well as that for the lymph node-positive data (Crivellari *et al.* 2008; Coates *et al.* 2007; Hind *et al.* 2007; Thurlimann *et al.* 2005). These findings make it very difficult to interpret nodal status outcomes. Letrozole significantly improved disease free survival compared with placebo for both lymph node-negative and lymph node-positive patients younger than 60 years and for patients with negative nodes  $\geq$  70 years old (Muss *et al.* 2008). When letrozole was compared with placebo in lymph node positive patients the results indicated a significant improvement in distant disease free survival in those aged 60 to 69 years and a significant improvement in overall survival for those aged  $\geq$  70 years (Muss *et al.* 2008).

### **Exemestane**

Disease free survival was significantly increased with exemestane compared with tamoxifen and nodal status did not affect outcome. (Coombes *et al.* 2004; 2007; Eisen *et al.* 2008; Hind *et al.* 2007).

Overall survival was not significantly different between exemestane or tamoxifen or between exemestane and placebo (Coombes *et al.* 2004; Eisen *et al.* 2008; Hind *et al.* 2007). A modest improvement in overall survival was reported for patients who switch to exemestane after 2–3 years on tamoxifen (Coombes *et al.* 2007).

There was a significant increase in bone fractures with exemestane (Coombes *et al.* 2004; Eisen *et al.* 2008; Hind *et al.* 2007).

The risk of contralateral breast cancer was significantly decreased with exemestane. Endocrine events decreased for all women with no difference between exemestane or tamoxifen. Disease free survival was significantly increased for women with ER positive histology regardless of PR status (Coombes *et al.* 2004; Hind *et al.* 2007). Significant improvements in overall survival were reported in the update Coombes (2007) study when receptor-negative patients were excluded. There is difficulty with interpretation of results in order to determine the outcomes for ER/PR status (Coombes *et al.* 2004; Hind *et al.* 2007).

A decision modelling exercise found that women with ER positive/ PR positive tumours gained more benefit from over 10 years by starting with tamoxifen then crossing over to an aromatase inhibitor whereas women with ER positive/ PR negative gained benefit from initial treatment with an aromatase inhibitor (Coombes *et al.* 2004; Hind *et al.* 2007).

## **Evidence Summary**

The literature search was limited to papers published between 2005 and 2008. The content of evidence available was mainly primary RCTs and secondary analyses of data from these trials. The studies were directly relevant to postmenopausal women with early breast cancer and ER + status aged up to 80 years. Analyses were included in the review when conducted on women with PR+ and PR – status since emerging trial data suggests that PR status does not affect the performance of aromatase inhibitors (AIs). Findings from women who were ER negative were also included, where reported, for comparison.

## **Anastrozole**

Event Free Survival (EFS) improved in the anastrozole group compared with tamoxifen in both RCTs of women with ER positive tumours (Boccardo *et al* 2005, ITA; Jakesz *et al* 2005, ARNO-95/ABCSG-8). The hazard ratio for time to recurrence of all breast cancer events was found to be significantly lower in the ER+/PR- subgroup than the ER+/PR+ subgroup from one analysis (Dowsett *et al* 2005, ATAC). Another subgroup analysis from a different trial found that the risk of recurrence did not depend on PR status (Jakesz *et al* 2005).

The ITA trial found that the benefit of anastrozole in preventing recurrence was independent of tumour size, grade, number of involved nodes and prior chemotherapy [HR 0.35 (0.18-0.69) p=0.002]. Whilst the ARNO-95/ABCSG-8 trial found the benefit of anastrozole was independent of nodal status, age at surgery, or progesterone receptor positivity. The benefit was greatest in the ER+/PR- subgroup (HR 0.42) than the ER+/PR+ subgroup (HR 0.66) although the difference between these two hazard ratios was not statistically significant from confidence intervals [ER+/PR+ HR 0.66 (0.46-0.93) p=0.017; ER+/PR- HR 0.42 (0.19-0.92) p=0.029].

Distant metastases free survival was improved (HR 0.49) for women taking anastrozole in the largely ER+ ITA trial. Contralateral breast cancer incidence was low in the two studies that reported this outcome (ITA trial 0.8%; 0.9%).

One small case series assessed joint symptoms experienced with anastrozole (Ohsako *et al.* 2005). Joint symptoms were more common in patients who had prior chemotherapy. Hormonal therapy did not influence joint symptoms.

### Letrozole

Disease Free Survival (DFS) improved in the letrozole group compared to placebo or tamoxifen in two RCTs for women with ER+ tumours. The largest gains occurred in the placebo controlled trial compared with the tamoxifen controlled trial, and this was also reflected in subgroup analyses. The PR+ subgroup benefited the most compared with placebo in one trial (Goss *et al* 2007, MA.17); the benefit was similar in PR+ and PR- subgroups in another trial when compared with tamoxifen (Thurlimann *et al* 2005, BIG I-98). DFS in lymph node positive and negative patients improved over time compared with placebo in a trend analysis (Ingle *et al* 2006, MA.17). Both lymph node positive and negative patients on letrozole had improved DFS compared to placebo in one trial (Goss *et al* 2005). However this benefit in DFS was only observed in lymph node positive patients when compared with tamoxifen in another trial (Thurlimann *et al* 2005).

There was no improvement in Overall Survival (OS) over all patients when letrozole was compared with either placebo or tamoxifen. However OS was improved in a subgroup of ER+/PR+ women when compared to placebo (Goss *et al* 2007). This benefit was not observed in ER+/PR- women. Another subgroup analysis in the same trial found improved OS in lymph node positive women, but not in lymph node negative women (Goss *et al* 2005).

Time to any recurrence was significantly reduced with letrozole compared to tamoxifen in the BIG I-98 trial [HR 0.72]. Time to distant recurrence was also significantly reduced with letrozole in the BIG I-98 trial [HR 0.73 (0.60-0.88) *P* = 0.001]. Time to contralateral recurrence was not significant compared to placebo in the MA.17 trial [HR 0.63].

### Exemestane

One RCT compared exemestane vs. tamoxifen. There was a significant benefit of exemestane over tamoxifen in DFS overall patients. Subgroups that benefited the most were ER+, PR+, PR-, lymph node positive and lymph node negative patients (Coombes *et al* 2004). Exceptions were ER-ve or unknown status, and PR status unknown where there were no significant differences in the Hazard Ratios between exemestane and tamoxifen. The benefit of exemestane compared to tamoxifen was not influenced by whether patients received prior HRT or chemotherapy. Overall Survival was not statistically significantly different between exemestane and tamoxifen overall patients. Contralateral breast cancer incidence was significantly reduced in patients on exemestane compared to tamoxifen.

**Table 4.2.2.3** Outcomes from the exemestane trial

### Meta-analysis

A meta-analysis (Rubio *et al* 2007, quality 1+) pooled trials of any Aromatase Inhibitor and examined the subgroups by when the AI was administered (at the same time as the group receiving tamoxifen; sequentially after tamoxifen; and after 5 years of tamoxifen). The studies showed the consistent benefits of AIs at different adjuvant treatment stages for DFS and OS. However different AIs were grouped together and no subgroup analyses were performed.

### Guidelines

The ASCO guideline (Winer *et al* 2005, Quality 4) recommended that adjuvant therapy for postmenopausal women with hormone receptor-positive breast

cancer should include an aromatase inhibitor in order to lower the risk of tumour recurrence.

### **Decision analysis**

A decision modelling study (Punglia *et al* 2006, Quality 4) using data on anastrozole from the ATAC and ARNO/ABCSSG trials for women with ER+/PR + and ER+/PR- tumours was conducted to assess whether different treatment strategies may provide benefit to these particular subgroups. The findings were that patients with ER+/PR+ tumours achieved optimal 10-year DFS estimates with tamoxifen followed by a crossover to AI therapy, whereas patients with ER+/PR- tumours gained more benefit when treatment was initiated with an AI.

A summary table of all outcomes is shown below:

**Table 4.2.2.4** Summary of all outcomes

Study	Comparison	DFS	OS	Distant DFS	Recurrence	Contralateral breast cancer

## Evidence Tables

### Systematic Review

<b>Study Identification:</b>	Hind D, Ward S, De Nigris E, Simpson E, Carroll C, Wyld L. Hormonal therapies for early breast cancer: systematic review and economic evaluation. Health Technol Assess 2007; 11(26).
<b>Design:</b>	Systematic review of RCTs evidence level 1++
<b>Country / Setting:</b>	international
<b>Population:</b>	RCTs (postmenopausal women, histologically confirmed invasive breast cancer, completed primary surgery)
<b>Intervention:</b>	Systematic review of RCT of primary adjuvant, sequenced or switch strategies of AI vs Tam
<b>Primary adjuvant</b>	<p><b>ATAC:</b>  T1: anastrozole 1 mg/day for 5 years from surgery, or after CT (n 3125).  T2: tamoxifen 20 mg/day for 5 years from surgery, or after CT (n 3116).  T3: anastrozole 1 mg/day + tamoxifen 20 mg/day for 5 years from surgery, or after CT (n 3125)</p> <p><b>BIG 1-98:</b>  T1: letrozole (2.5 mg/day) for 5 years  T2: letrozole (2.5 mg/day) for 2 years, then tamoxifen (20 mg/day) for 3 years; (T1 + T2, n 4003)  T3: tamoxifen (20 mg/day) for 5 years  T4: tamoxifen (20 mg/day) for 2 years, then letrozole (2.5 mg/day) for 3 years (T3 + T4, n 4007)</p> <p><b>Unplanned switch</b></p> <p><b>GABG :</b>  Following 2 years of adjuvant tamoxifen  T1: anastrozole (1 mg/day), 3 years (n 1618)  T2: tamoxifen (20 or 30 mg/day), 3 years (n 1606)</p> <p><b>ITA:</b>  T1: anastrozole (1mg/day) for 2—3 years (n 223)  T2: tamoxifen for 2—3 years (20 mg/day) (n 225)</p> <p><b>IES:</b>  T1: exemestane 25 mg/day for 2—3 years (n 2362)  T2: tamoxifen 20/30 mg/day for 2—3 years (n 2380)</p> <p><b>Extended adjuvant</b></p> <p><b>MA-17:</b>  T1: letrozole (2.5 mg/day) oral (n 2593)  T2: oral placebo (n 2594)</p> <p><b>ABCSG:</b>  T1: anastrozole 1 mg/day for 36 months  T2: no treatment</p>
<b>Outcomes:</b>	DFS, OS
<b>Follow-up:</b>	ATAC median 68 months; BIG 1-98 median 26; GABG median 28 months; ITA median 36 months; IES median 31 months; MA-17 30 months; ABCSG median 60 months

<b>Results:</b>	<p>A meta-analysis of three trials found a significant difference in overall survival when an unplanned anastrozole switching strategy was compared with 5 years' tamoxifen. Significant improvements in overall survival are yet to be demonstrated in other strategies. Compared with 5 years' tamoxifen, disease-free survival (disease recurrence or death from any cause) was significantly improved in the primary adjuvant setting with anastrozole and letrozole, and with an exemestane switching strategy. Other trials did not report this outcome. Breast cancer recurrence (censoring death as an event) was significantly improved with primary adjuvant anastrozole and letrozole, anastrozole switching, extended adjuvant anastrozole or letrozole. The AIs and tamoxifen have different side-effect profiles, with tamoxifen responsible for small but statistically significant increases in endometrial cancer and, sometimes, thromboembolic events and stroke. AIs show a trend towards increases in osteoporosis, the statistical significance of which increases with follow-up time. The absence of tamoxifen treatment also increases the risk of hypercholesterolaemia and cardiac events in postmenopausal women. There was no significant difference in overall health-related quality of life between standard treatment and either primary adjuvant anastrozole and extended adjuvant letrozole strategies.</p>
-----------------	--

OUTCOME OF INTEREST	COMPARISON	RESULT
<b>Disease-free survival:</b>		
<i>Primary adjuvant strategies</i>		
<p>The 60-month primary adjuvant anastrozole strategy (ATAC) resulted in a difference in DFS that was significant at the 5% level (HR = 0.87, 95% CI 0.78 to 0.97, p = 0.01). In the tamoxifen group 79.0% of participants were alive and disease free versus 81.3% in the anastrozole group: rounding figures up, an extra 2.4% of participants receiving anastrozole benefited from the treatment. For one extra woman to be alive and disease free over 68 months, 41 women would have to be treated using anastrozole. The difference in DFS was significant at the 5% level when only women whose disease had been hormone receptor- positive (HR = 0.83, 95% CI 0.73 to 0.94, p = 0.005) were analysed. In the tamoxifen group, 83.8% of participants were alive and disease free versus 80.9% in the anastrozole group: rounding figures up, an extra 2.9% of participants receiving anastrozole benefited from the treatment. For one extra woman to be alive and disease free over 68 months, 34 women would have to be treated using anastrozole.</p>		
<p>The 60-month primary adjuvant letrozole strategy (BIG 1-98) resulted in a difference in DFS that was significant at the 5% level (HR = 0.81, 95% CI 0.70 to 0.93, p = 0.003). In the tamoxifen group, 89.3% of participants were alive and disease free versus 91.2% in the letrozole group: an extra 1.9% of participants receiving letrozole benefited from the treatment. For one extra woman to be alive and disease free over 26 months, 52 women would have to be treated using letrozole.</p>		
<i>Switching strategies</i>		
<p>Neither the GABG nor ITA reported DFS as defined in this report.</p>		
<p>The 24-36-month anastrozole switching strategy (Jonat meta-analysis) resulted in a difference in DFS that was significant at the 5% level (HR = 0.59, 95% CI 0.48 to 0.74, p &lt; 0.000 1). It was not clear whether the necessary summary statistics were available to calculate the ARR and NNT</p>		
<p>The 24- 36-month exemestane switching strategy (IES) resulted in a difference in DFS that was significant at the 5% level (HR = 0.73, 95% CI 0.62 to 0.86, p = 0.000 1). In the tamoxifen group, 85.1% of participants were alive and disease free compared with 89.0% in the exemestane group: after rounding, an extra 3.8% of participants receiving exemestane benefited from the treatment. For one woman to benefit from exemestane, 26 women would have to be treated using it.</p>		
<i>Extended adjuvant strategies</i>		
<p>Neither of the included studies that evaluated extended adjuvant strategies reported DFS as defined in this review.</p>		
<b>Overall Survival:</b>		
<i>Primary adjuvant strategies</i>		
<p>The 60-month primary adjuvant anastrozole strategy (ATAC) resulted in a difference in overall survival that was not significant at the 5% level (HR = 0.97, 95% CI 0.85 to 1.12,p = 0.7). In the tamoxifen group, 13.6% of participants died versus 13.3% in the anastrozole group; an extra 0.3% of participants receiving anastrozole benefited from the treatment. For every death prevented over 68 months, 354 women would have to be treated using anastrozole. Overall survival rates for the</p>		

hormone receptor-positive population were similar. The difference in “time to breast cancer death” was not significant at the 5% level (HR = 0.88, 95% CI 0.74 to 1.05, p = 0.2). In the tamoxifen group, 8.6% of participants died of breast cancer versus 7.6% in the anastrozole group: an extra 1% of participants receiving anastrozole benefited from the treatment. For every breast cancer death to be prevented over 68 months, 101 women would have to be treated using anastrozole. The outcome for the hormone receptor-positive population was similar

The 60-month primary adjuvant letrozole strategy (BIG 1-98) resulted in a difference in overall survival that was not significant at the 5% level (HR = 0.86, 95% CI 0.70 to 1.06, p = 0.16). In the tamoxifen group, 4.8% of participants died versus 4.1% in the letrozole group: an extra 0.6% of participants receiving letrozole benefited from the treatment. For every death prevented over 26 months, 155 women would have to be treated using letrozole. The difference in “death following cancer event” (data from conference presentation only<sup>72</sup>) was significant at the 5% level (HR not reported). In the tamoxifen group, 3.8% of participants died following a cancer event versus 2.8% in the letrozole group: an extra 1.1% of participants receiving letrozole benefited from the treatment. For every death following a cancer event to be prevented over 26 months, 93 women would have to be treated using letrozole.

### *Switching strategies*

One study evaluating a 36-month anastrozole switching strategy (GABG) demonstrated a difference in overall survival that was not significant at the 5% level (HR not reported). In the tamoxifen group, 3.7% of participants died versus 2.8% in the anastrozole group: an extra 0.9% (95% CI -1.1 to 2.8%) of participants receiving anastrozole benefited from the treatment. For every death to be prevented over 28 months, 113 women would have to be treated using anastrozole. The difference in “deaths: breast cancer related” was not significant at the 5% level (HR not reported). In the tamoxifen group, 1.9% of participants died following a cancer event versus 1.5% in the anastrozole group: an extra 0.4% (95% CI -1.0 to 1.9%) of participants receiving anastrozole benefited from the treatment. For every breast cancer-related death to be prevented over 28 months, 226 women would have to be treated using anastrozole.

Another study evaluating a 24—36-month anastrozole switching strategy (ITA) did demonstrate a difference in overall survival that was borderline significant at the 5% level (HR not reported). In the tamoxifen group, 4.4% of participants died versus 1.8% in the anastrozole group: 2.7% (95%CI 1.0-4.3%) of participants receiving anastrozole benefited from the treatment. For every death prevented over 36 months, 38 women would have to be treated using anastrozole. In the tamoxifen group, 3.1% of participants died as a result of breast cancer versus 1.8% in the anastrozole group: an extra 1.3% (95% CI -0.2 to 2.8%) of participants receiving anastrozole benefited from the treatment. For one death from breast cancer to be prevented, 76 women would have to be treated using anastrozole.

The 24-36-month anastrozole switching strategy (Jonat. meta-analysis) resulted in a difference in overall survival that was significant at the 5% level (HR = 0.71, 95% CI 0.52 to 0.98, p = 0.038). It was not clear whether the necessary summary statistics were available to calculate the ARR and number-needed-to-treat (NNT).

The 24-36-month exemestane switching strategy (IES) resulted in a difference in overall survival that was not significant at the 5% level (HR = 0.83, 95% CI 0.67 to 1.02, p = 0.08). In the tamoxifen group, 7.9% of participants died versus 6.4% in the exemestane group: an extra 1.5% (-0.7 to 3.6%) of participants receiving exemestane benefited from the treatment. For every death prevented over 37 months, 68 women would have to be treated using exemestane. The difference in “breast cancer-

free survival” was significant at the 5% level when reported at 31 months (HR = 0.63, 95% CI 0.51 to 0.77,  $p < 0.001$ ). An HR was not available in the conference presentation of the 37-month follow-up but, in the intervening period, the “breast cancer-related” death rate had risen from 2.8 to 5.2% in the tamoxifen group and from 2.3 to 4.0% in the exemestane group. At 37 months, an extra 1.2% of participants receiving exemestane benefited from the treatment. For every breast cancer-related death to be prevented over this period, 82 women would have to be treated using exemestane.

#### *Extended adjuvant strategies*

The 60-month extended adjuvant letrozole strategy (MA-17) resulted in a difference in overall survival that was not significant at the 5% level (HR 0.82, 95% CI 0.57 to 1.19). In the placebo group, 2.4% of participants died versus 2.0% in the letrozole group: an extra 0.4% (-0.8 to 1.6%) of participants receiving letrozole benefited from the treatment. For death to be prevented, 235 women would have to be treated using letrozole. The difference in overall survival was significant at the 5% level when they analysed only women whose disease had been node-positive (HR 0.61, 95% CI 0.38

to 0.98). The ARR and NNT for this subgroup were not estimable, because event numbers were not reported. The difference in “breast cancer as cause of death” was not significant at the 5% level (HR not reported). In the placebo group, 0.9% of participants died as a result of breast cancer versus 0.6% in the letrozole group: an extra 0.2% of participants receiving letrozole benefited from the treatment. For one death from breast cancer to be prevented, 431 women would have to be treated using letrozole.

#### **Contralateral breast cancer:**

##### *Primary adjuvant strategies*

The 60-month primary adjuvant anastrozole strategy (ATAC) resulted in a difference in the rate of contralateral breast cancers that was significant at the 5% level (odds ratio 0.58, 95% CI 0.38 to 0.88,  $p = 0.01$ ). In the tamoxifen group, 1.9% of participants developed cancer in the contralateral breast compared with 1.1% in the anastrozole group: an extra 0.8% of participants receiving anastrozole benefited from the treatment. For contralateral breast cancer to be prevented in one extra woman over 68 months, 126 women would have to be treated using anastrozole. The difference

in the hormone receptor-positive population was also significant at the 5% level (odds ratio 0.47, 95% CI 0.29 to 0.75,  $p = 0.001$ ). In the tamoxifen group, 2.0% of participants developed cancer in the contralateral breast compared with 1.9% in the anastrozole group: an extra 1.0% of participants receiving anastrozole benefited from the treatment. For contralateral breast cancer to be prevented in one extra hormone receptor-positive woman over 68 months, 93 such women would have to be treated using anastrozole.

It is not clear whether the 60-month primary adjuvant letrozole strategy (BIG 1-98) resulted in a difference in the rate of contralateral breast cancers which was significant at the 5% level (HR not reported). In the tamoxifen group, 0.7% of participants had an event compared with 0.4% in the letrozole group: an extra 0.3% (95% CI not estimable) of participants benefited from receiving letrozole. For contralateral breast cancer to be prevented in one extra woman over 26 months, 333 women would have to be treated using letrozole.

##### *Switching strategies*

It is not clear whether the study evaluating a 36-month anastrozole switching strategy (GABG) demonstrated a difference in the rate of contralateral breast cancers that was significant at the 5%

level (HR not reported). In the tamoxifen group, 1.0% of participants had an event compared with 0.7% in the anastrozole group: an extra 0.3% of participants receiving anastrozole benefited from the treatment. To prevent contralateral breast cancer in one additional woman over 28 months, 396 women would have to be treated using anastrozole.

It is not clear whether the study evaluating a 24-36-month anastrozole switching strategy (ITA) demonstrated a difference in the rate of contralateral breast cancer which was significant at the 5% level (HR not reported). In the tamoxifen group, 0.9% of participants developed a contralateral compared with 0.4% in the anastrozole group: rounding down, contralateral cancer was prevented in an additional 4.0% of participants receiving anastrozole. For every contralateral cancer prevented over 24-36 months, 227 women would have to be treated using anastrozole.

The 24-36-month exemestane switching strategy (IES) resulted in a difference in the rate of contralateral breast cancer that was significant at the 5% level (HR = 0.50, 95% CI 0.26 to 0.97, p = 0.04). In the tamoxifen group, 1.1% of participants had an event compared with 0.5% in the exemestane group: contralateral breast cancer was prevented in an additional 0.6% of participants receiving exemestane. For contralateral cancer to be prevented in one additional woman over 37 months, 173 women would have to be treated using exemestane.

#### *Extended adjuvant strategies*

The 60-month extended adjuvant letrozole strategy (MA-17) resulted in a difference in DR that was not significant at the 5% level (HR = 0.63, 95% CI 0.18 to 2.21, p not reported). In the placebo group, 1.1% of participants had an event versus 0.7% in the letrozole group: contralateral breast cancer was prevented in an additional 0.4% of participants receiving letrozole treatment. For each additional contralateral cancer to be prevented over 30 months, 236 women would have to be treated using letrozole.

It is unclear whether the 36-month extended adjuvant anastrozole strategy (ABC SG) resulted in a difference in the rate of contralateral breast cancers that was significant at the 5% level (HR not reported). In the placebo group, 2.1% of participants developed a cancer in the contralateral breast versus 1.6% in the anastrozole group: an extra 3.3% of participants remained disease free as a result of receiving anastrozole treatment. For each additional contralateral cancer to be prevented over 60 months, 172 women would have to be treated using anastrozole.

### **Quality of Life (including side-effects):**

#### **Adverse events: bone health**

##### *Primary adjuvant strategies*

At 33 months, the relative risk of a fracture in the 60-month primary adjuvant anastrozole strategy was already 1.59 (95% CI not reported, p < 0.0001), with 115 (3.7%) women in the tamoxifen arm and 183 (5.9%) in the anastrozole arm experiencing a fracture (ATAC trial). By 68 months, 7.7% of participants in the tamoxifen group had experienced a fracture compared with 11.0% in the anastrozole group: an extra 3.3% of participants receiving anastrozole were harmed by the treatment. One extra woman would experience a fracture over 68 months for every 30 women treated using anastrozole. The odds ratio for hip fracture, the subcategory most frequently associated with mortality, was not significant (1.20, 95% CI 0.74 to 1.93, p = 0.5).° In the tamoxifen group, 1.0% of participants experienced a hip fracture compared with 1.2% in the anastrozole group: an extra 0.2% of participants receiving anastrozole experienced a hip fracture. One extra woman would experience a hip fracture over 68 months for every 514 women treated with anastrozole.

The 60-month primary adjuvant letrozole strategy (BIG 1-98) resulted in a difference in the fracture

rate that was significant at the 5% level (HR not reported,  $p < 0.001$ ) favouring tamoxifen. In the tamoxifen group, 4.0% of participants experienced a fracture compared with 5.7% in the letrozole group: an extra 1.7% of participants receiving letrozole were harmed by the treatment. One extra woman would experience a fracture over 26 months for every 60 women treated using letrozole. The HR for hip fracture was not reported.

#### *Switching strategies*

The 36-month anastrozole switching strategy (GABG) resulted in a difference in the fracture rate that was significant at the 5% level (HR not reported;  $p = 0.015$ ). In the tamoxifen group, 1.0% of participants experienced a fracture compared with 2.1% in the anastrozole group: an extra 1.1% of participants receiving anastrozole were harmed by the treatment. One extra woman would experience a fracture over 36 months for every 90 women treated using anastrozole. The hip fracture rate was not reported.

The study evaluating a 24—36-month anastrozole switching strategy (ITA) demonstrated no difference in the fracture rate: 0.9% of women in each arm experienced a fracture (HR not reported). The hip fracture rate was not reported.

It is not clear whether the 24-36-month exemestane switching strategy (IES) resulted in a difference in fracture rate that was significant at the 5% level (HR not reported). In the tamoxifen group, 2.3% of participants experienced a fracture compared with 3.1% in the exemestane group: an extra 0.8% of participants receiving exemestane were harmed by the treatment. One extra woman would experience a fracture over 36 months for every 118 women treated using exemestane.

#### *Extended adjuvant strategies*

The 60-month extended adjuvant letrozole strategy (MA-17) did not result in a difference in the fracture rate that was significant at the 5% level (HR not reported,  $p = 0.25$ ). In the placebo group, 4.6% of participants experienced a fracture compared with 5.3% in the letrozole group: an extra 0.7% of participants receiving letrozole were harmed by the treatment. One extra woman would experience a fracture over 30 months for every 141 women treated using letrozole. The hip fracture rates were 0.003% in the placebo group and 0.002% in the letrozole group. The rate of new osteoporosis was highly significant at a median follow-up of 30 months (letrozole 8.1%; placebo 6.0%;  $p = 0.003$ ), whereas at the previous follow-up (median 2.4 years, or 28.8 months)<sup>92</sup> it had been a non-significant trend (letrozole 5.8%; placebo 4.5%;  $p = 0.07$ ).

### **Quality of Life - including side-effects (contd.):**

#### **Adverse events: cardiovascular events**

##### *Primary adjuvant strategies*

The 60-month primary adjuvant anastrozole strategy (ATAC) reported “ischaemic cardiovascular disease”. There was no significant difference between the arms [anastrozole, 127/3092 (4.1%); tamoxifen, 104/3094 (3.4%); HR 1.23, 95% CI 0.95 to 1.60,  $p = 0.1$ ]. ATAC also reported “ischaemic cerebrovascular events”, which does not separate Grade 4 events, such as stroke, from Grade 3 conditions, such as TIA: the results found that there were significantly more events in the tamoxifen arm (anastrozole, 62/3092; tamoxifen, 88/3094; HR 0.70, 95% CI 0.50 to 0.97,  $p = 0.03$ ). They also reported “venous thromboembolic events” (anastrozole, 87/3092; tamoxifen, 140/3094; HR 0.61,

95% CI 0.47 to 0.80,  $p = 0.0004$ ) and deep venous thromboembolic events (anastrozole, 48/3092; tamoxifen, 74/3094; HR 0.64, 95% CI 0.45 to 0.93,  $p = 0.02$ ).

The 60-month primary adjuvant letrozole strategy (BIG 1-98) reported differences in the number of thromboembolic events that were significant at the 5% level [letrozole, 61/3975 (1.5%); tamoxifen, 140/3988 (3.5%); HR not reported,  $p < 0.001$ ], favouring letrozole. There were no significant differences in all cardiac events, but there was a significant difference in Grade 3-5 cardiac events [letrozole, 85/3975 (2.1%); tamoxifen, 44/3988 (1.1%); HR not reported,  $p = 0.000372$ ], favouring tamoxifen. There was no significant difference in ischaemic heart disease, but there was a significant difference in cardiac failure [letrozole, 31/3975 (0.8%); tamoxifen, 14/3988 (0.4%);  $p = 0.01$ ] and “other cardiac events” [letrozole, 19/3975 (0.5%); tamoxifen, 8/3988 (0.2%);  $p = 0.04$ ]. There were more deaths without recurrence in the letrozole arm (55 versus 38 in the tamoxifen arm), including three times as many from cardiac events (16 versus five).<sup>71</sup> There was no significant difference between arms in the recording of cardiovascular accident (CVA) or transient ischaemic attack (TIA) events.

#### *Switching strategies*

One study evaluating a 36-month anastrozole switching strategy (GABG) reported no significant difference in myocardial infarction or “embolism”. There was a significant difference in thromboses favouring anastrozole, 3/1602; tamoxifen, 12/1597,  $p = 0.034$ ).

Another study evaluating a 24—36-month anastrozole switching strategy (ITA) reported no significant difference between treatments in terms of “cardiovascular disease” or “venous disorders”. The 24-36-month exemestane switching strategy (IES) reported “cardiovascular disease other than myocardial infarction”. It also reported separately “thromboembolic disease” and “thromboembolic events”, but did not define what these categories included. Thromboembolic disease was significantly more frequent in the tamoxifen arm (exemestane, 24/2309; tamoxifen, 45/2332;  $p = 0.003$ ). Thromboembolic events were reported as significantly more frequent in the tamoxifen arm (exemestane, 30/2309; tamoxifen, 55/2332;  $p = 0.007$ ). Deaths from vascular (exemestane, 12/2362; tamoxifen, 6/2380), cardiac (exemestane, 10/2362; tamoxifen, 8/2380), thrombotic (exemestane, 1/2362; tamoxifen, 1/2380) or pulmonary (exemestane, 0/2362; tamoxifen, 1/2380) causes were recorded separately (HR and  $p$ -values not reported). In the updated analysis (median follow-up 37 months; data from conference presentation<sup>89</sup>) there were twice as many deaths from vascular causes in women in the exemestane arm (0.6% versus 0.3%) and twice as many myocardial infarctions (0.9% versus 0.4%,  $p = 0.02$ , but non-significant, presumably due to multiple significance testing). Conversely, there was more thromboembolic disease in the tamoxifen arm (3.3%) than in the exemestane arm (1.9%), and this difference was significant at the 5% level ( $p < 0.001$ ).

#### *Extended adjuvant strategies*

The 60-month extended adjuvant letrozole strategy (MA-17) reported that cardiovascular “events” or “disease” were observed in 149 (5.8%) and 144 (5.6%) of patients in the letrozole and placebo arms, respectively ( $p = 0.76$ ). This includes potentially fatal events, such as myocardial infarction and stroke, and also nonfatal conditions such as angina and TIA. Thromboembolic events were reported as a subcategory of CVD with pulmonary embolism, the potentially fatal event, not separated out from other non-fatal conditions. There were five cardiovascular-related deaths and two fatal strokes in women receiving letrozole and five cardiovascular-related deaths and one fatal stroke in women receiving placebo.

No data were available for this outcome from the study evaluating the 36-month extended adjuvant anastrozole strategy.

**Quality of Life - including side-effects (contd.):**

**Adverse events: gynaecological**

*Primary adjuvant strategies*

The 60-month primary adjuvant anastrozole strategy (ATAC) resulted in a difference in the endometrial cancer rate that was significant at the 5% level (HR not reported;  $p = 0.02$ ). In the tamoxifen group, 0.8% of participants developed endometrial cancer compared with 0.2% in the anastrozole group: after rounding, an extra 0.5% of participants receiving anastrozole benefited from the treatment. For endometrial cancer to be prevented in one extra woman over 68 months, 187 women would have to be treated using anastrozole. In the tamoxifen group, 10.2% of participants experienced a vaginal bleeding compared with 5.4% in the anastrozole group: an extra 4.8% of participants receiving anastrozole benefited from the treatment. For vaginal bleeding to be prevented in one extra woman over 68 months, 21 women would have to be treated with anastrozole. The authors also observed a fourfold increase in hysterectomy rates (anastrozole, 1.3%; tamoxifen, 5.1%;  $p < 0.0001$ ).

The 60-month primary adjuvant letrozole strategy (BIG 1-98) did not result in a difference in the rate of “invasive endometrial cancers” that was significant at the 5% level (HR not reported,  $p = 0.18$ ). In the tamoxifen group, 0.3% of participants developed endometrial cancer compared with 0.1% in the letrozole group: an extra 0.2% of participants receiving letrozole benefited from the treatment. For endometrial cancer to be prevented in one extra woman over 26 months, 500 women would have to be treated using letrozole. In the tamoxifen group, 6.6% of participants experienced a vaginal bleeding compared with 3.3% in the letrozole group: an extra 3.3% of participants receiving letrozole benefited from the treatment. For vaginal bleeding to be prevented in one extra woman over 26 months, 30 women would have to be treated with letrozole.

*Switching strategies*

It is not clear whether the 36-month anastrozole switching strategy (GABG) resulted in a difference in the endometrial cancer rate that was significant at the 5% level (HR not reported). In the tamoxifen group, 0.4% of participants developed endometrial cancer compared with 0.1% in the anastrozole group: after rounding, an extra 0.4% of participants receiving anastrozole benefited from the treatment. For endometrial cancer to be prevented in one extra woman over 36 months, 266 women would have to be treated using anastrozole. The GABG study analysed vaginal bleeding and discharge as one outcome: there was no significant difference between treatment arms.

The study evaluating a 24-36-month anastrozole switching strategy (ITA) did not report the incidence of endometrial cancer or vaginal bleeding. The Jonat meta-analysis did not report the incidence of endometrial cancer or vaginal bleeding.

It is not clear whether the 24-36-month exemestane switching strategy (IES) resulted in a difference in endometrial cancer rate that was significant at the 5% level (HR not reported). In the tamoxifen group, 0.5% of participants developed endometrial cancer compared with 0.2% in the exemestane group: after rounding, an extra 0.3% of participants receiving exemestane benefited from the treatment. For endometrial cancer to be prevented in one extra woman over 31 months, 399 women would have to be treated using exemestane. In the tamoxifen group, 5.5% of participants experienced vaginal bleeding compared with 4.0% in the exemestane group: after rounding, an extra

1.5% of participants receiving exemestane benefited from the treatment. For vaginal bleeding to be prevented in one extra woman over 31 months, 66 women would have to be treated using exemestane.

*Extended adjuvant strategies*

It is unclear whether the 60-month extended adjuvant letrozole strategy (MA-17) resulted in a difference in the endometrial cancer rate that was significant at the 5% level (HR not reported). In the placebo group, 0.4% of participants developed endometrial cancer compared with 0.2% in the letrozole group: an extra 0.2% of participants receiving letrozole benefited from the treatment. For endometrial cancer to be prevented in one extra woman over 30 months, 369 women would have to be treated using letrozole. In the placebo group, 7.6% of participants experienced a vaginal bleeding compared with 5.6% in the letrozole group: an extra 2.0% of participants receiving letrozole benefited from the treatment. For vaginal bleeding to be prevented in one extra woman over 30 months, 51 women would have to be treated with anastrozole.

Endometrial cancer and vaginal bleeding rates were not reported by the study evaluating a 36-month extended adjuvant anastrozole strategy (ABCSSG).

Adverse events: gynaecological

<b>Study Identification:</b>	Ellis, M.J., Rigden, C.E. - Initial versus sequential adjuvant aromatase inhibitor therapy: a review of the current data – Current Medical Research and Opinion, 2006 22, 12, pp2479-2487	
<b>Design:</b>	systematic review of RCTs evidence level 1++	
<b>Country / Setting:</b>	international	
<b>Population:</b>	Reports of 6 RCT (ATAC, BIG1-98, ARNO 95, ABCSG8, ITA, IES)	
<b>Intervention:</b>	Interventions in each of the trials (reported elsewhere) reviewed to compare efficacy and safety data for AI's in initial adjuvant and switched adjuvant settings.	
<b>Outcomes:</b>	DFS, total events, QOL	
<b>Follow-up:</b>	Reported elsewhere	
<b>Results:</b>	In the upfront adjuvant setting, anastrozole and letrozole have both demonstrated a significant DFS benefit over tamoxifen. Upfront therapy with a nonsteroidal AI appears to be most critical for patients at risk of an early relapse, illustrated by the finding that upfront letrozole provided a significant early DFS advantage over tamoxifen only in patients with node-positive disease (HR = 0.71, p < 0.001). With respect to safety, both strategies have similar adverse event profiles.	
<b>OUTCOME OF INTEREST</b>	<b>COMPARISON</b>	<b>RESULT</b>
<b>Disease-free survival:</b>		
<i>Upfront AI therapy:</i>		
ATAC trial – anastrozole demonstrated a significant benefit in DFS (HR=0.87, p=0.01)		
Subgroup analysis suggested a more pronounced DFS benefit for anastrozole in the ER+/PR- subgroup (HR = 0.43) than in the ER+/PR+ subgroup (HR = 0.84)		
BIG1-98 - median follow-up showed a 19% improvement in DFS (HR = .0.81; p = 0.003), an estimated absolute increase for 5-year DFS by 2.6% with letrozole compared to tamoxifen. A significant benefit in DFS was only observed in higher-risk patients, i.e., those with node-positive disease (HR = 0.71, p < 0.001)		
<i>Adjuvant switch therapy:</i>		
IES trail – already received tamoxifen therapy for 2-3 years. At a median follow-up of 55.7 months, the results show that exemestane therapy after 2-3 years of tamoxifen therapy significantly improved DFS compared with the standard 5 years of tamoxifen treatment (HR = 0.76, p = 0.0001)		
ARNO95/ABCSG8 - After a median follow-up of 28 months, patients in the anastrozole group had a 40% decrease in the risk for an event compared with the tamoxifen group (67 events for anastrozole vs. 110 events for tamoxifen, for an HR 0.60; p = 0.009).		
IES –patients who had 2-3 (plus) years of tamoxifen followed by 2-3 years of anastrozole (n = 223) experienced a significantly reduced risk of relapse (HR 0.35, p = 0.001) compared with those patients who had only received tamoxifen for 5 years (n = 225).		
<b>Overall Survival:</b>		
<i>Upfront AI therapy:</i>		
ATAC trial – Although there was an absolute reduction in breast cancer deaths, it was not		

significant, and at 68 months of follow-up, there was no significant difference in overall survival between the ER+PR+ and ER+PR- groups (HR = 0.97; p = 0.7). In the hormone receptor positive population there were only 5 fewer deaths in the anastrozole vs tamoxifen arm BIG1-98 - Fewer overall deaths occurred in the letrozole arm when compared with the tamoxifen arm (166 vs. 192), which translated into a non-significant 14% decrease in the relative risk for breast cancer mortality (p = 0.16).

**General comments:** Differences in patient populations, definitions of end points, and prior tamoxifen usage between the trials discussed necessitates careful interpretation.

<b>Study Identification:</b>	Mouridsen, H.T., Incidence and management of side effects associated with aromatase inhibitors in the adjuvant treatment of breast cancer in postmenopausal Women: Current Medical Research and Opinion; Aug 2006; 22, 8; ProQuest Medical Library pg1609
<b>Design:</b>	systematic review of RCTs evidence level 1++
<b>Country / Setting:</b>	international
<b>Population:</b>	
<b>Intervention:</b>	See above
<b>Outcomes:</b>	QOL including side-effects
<b>Follow-up:</b>	See population
<b>Results:</b>	Als alone and sequenced after tamoxifen are an appropriate option for adjuvant endocrine therapy for most postmenopausal patients with hormone-responsive breast cancer. The incidence of endometrial cancer and thromboembolic events is significantly lower with an AI than with tamoxifen. However, there is a small but significant increase in the risk of osteoporosis and fractures with AI therapy. Monitoring and management of bone loss associated with AI treatment are essential. A potential negative effect on the cardiovascular system, specifically on lipid metabolism, has not been conclusively demonstrated. No significant differences in overall quality of life were observed in studies comparing AIs with tamoxifen or placebo. The most commonly reported adverse events associated with adjuvant AI therapy include hot flushes and musculoskeletal complaints arthralgia

<b>Study Identification:</b>	Winer, E.P, Hudis, C., Burstein, H.I., Wolff, A.C., Pritchard, K.I., Ingle, J.N., Chlebowski, R.T., Gelber, R., et al -American Society of Clinical Oncology Technology Assessment on the Use of Aromatase Inhibitors As Adjuvant Therapy for Postmenopausal Women With Hormone Receptor—Positive Breast Cancer: Status Report 20114 – Journal of Clinical Oncology, 2005,23 column 3 pp619-629
<b>Design:</b>	systematic review of RCTs evidence level 1++
<b>Country / Setting:</b>	international
<b>Population:</b>	4 RCT of AI vs tamoxifen or placebo in early breast cancer hormone receptor positive ATAC: n=9366; ITA: n=426; IES: n=4742; MA17: n=5187
<b>Intervention:</b>	ATAC: tamoxifen vs anastrozole vs tamoxifen + anastrozole ITA: anastrozole sequential to 2-3 year course of tamoxifen IES: tamoxifen vs exemestane sequential to 2-3 year course tamoxifen MA17: letrozole vs placebo sequential to 5 year course of tamoxifen
<b>Outcomes:</b>	Rate of recurrence, distant recurrence, total events
<b>Follow-up:</b>	ATAC: median 33.3 months; ITA: median 24 months; IES: median 30.6 months; MA17: median 26.8 months
<b>Results:</b>	Based on results from multiple large randomized trials, adjuvant therapy for postmenopausal women with hormone receptor—positive breast cancer should include an aromatase inhibitor in order to lower the risk of tumor recurrence. Neither the optimal timing nor duration of aromatase inhibitor therapy is established. Aromatase inhibitors are appropriate as initial treatment for women with contraindications to tamoxifen. For all other postmenopausal women, treatment options include 5 years of aromatase inhibitors treatment or sequential therapy consisting of tamoxifen (for either 2 to 3 years or 5 years) followed by aromatase inhibitors for 2 to 3, or 5 years. Patients intolerant of aromatase inhibitors should receive tamoxifen. There are no data on the use of tamoxifen after an aromatase inhibitor in the adjuvant setting. Women with hormone receptor—negative tumors should not receive adjuvant endocrine therapy. The role of other biomarkers such as progesterone receptor and HER2 status in selecting optimal endocrine therapy remains controversial. Aromatase inhibitors are contraindicated in premenopausal women; there are limited data concerning their role in women with treatment-related amenorrhea. The side effect profiles of tamoxifen and aromatase inhibitors differ. The late consequences of aromatase inhibitor therapy, including osteoporosis, are not well characterized.

OUTCOME OF INTEREST	COMPARISON	RESULT

<b>General comments:</b>		

<b>Study Identification:</b>	Scott,L.J., Keam,S.J., Letrozole In Postmenopausal Hormone-Responsive Early-Stage Breast Cancer Drugs 200ts 66 (3): 353-362
<b>Design:</b>	systematic review of RCTs evidence level 1++
<b>Country / Setting:</b>	international
<b>Population:</b>	Postmenopausal women with hormone responsive early stage breast cancer (8000 mean age 61 years; range 38—90 years;5000)
<b>Intervention:</b>	BIG1-98 trial once daily letrozole 2.5mg vs once daily tamoxifen 20mg; MA17 trial once daily letrozole 2.5mg
<b>Outcomes:</b>	DFS, QOL
<b>Follow-up:</b>	Median 25.8 months; 30 months
<b>Results:</b>	<p>As first-line adjuvant therapy in 8000 postmenopausal women with hormone-responsive, early stage breast cancer, once-daily letrozole 2.5mg significantly prolonged disease-free survival (DFS; primary endpoint) and reduced the risk of relapse at distant sites relative to once-daily tamoxifen 20mg in the ongoing Breast International Group 1-98, double-blind, multinational trial. Extended adjuvant therapy with once-daily letrozole 2.5mg significantly prolonged DFS relative to placebo treatment in the MA-17 trial in 5000 postmenopausal women who were disease free after 4.5—6 years of tamoxifen therapy for hormone-responsive, early-stage breast cancer.</p> <p>Letrozole treatment for up to 5 years was generally well tolerated in this clinical setting. As first-line treatment, relative to tamoxifen, letrozole was associated with a significantly lower incidence of venous thromboembolic events, vaginal bleeding, hot flushes and night sweating, whereas the incidence of cardiac failure, bone fractures and arthralgia was higher in letrozole recipients.</p>

OUTCOME OF INTEREST	COMPARISON	RESULT
<p><b>Disease-free survival:</b> BIGT trial prospectively planned subgroup analyses, there were significantly (all <math>p &lt; 0.05</math>) fewer DFS events in letrozole than tamoxifen recipients who were aged <math>&lt;65</math> (<math>n = 5143</math>; 187 vs 230 events; HR 0.82; 95% CI 0.67, 0.99) or <math>\geq 65</math> years (<math>n = 2867</math>; 164 vs 198 events; HR 0.79; 95% CI 0.64, 0.97), tumour <math>&gt;2\text{cm}</math> (<math>n = 2973</math>; 190 vs 251 events; HR 0.76; 95% CI 0.63, 0.92), node positive (<math>n = 3311</math>; 205 vs 274 events; HR 0.71; 95% CI 0.59, 0.85), mastectomy (<math>n = 3452</math>; 223 vs 271 events; HR 0.76; 95% CI 0.64, 0.91), radiotherapy - yes (<math>n = 5744</math>; 227 vs 273 events; HR 0.82; 95% CI 0.69, 0.98) no (<math>n = 2258</math>; 124 vs 155 events; HR 0.77; 95% CI 0.61, 0.98) chemotherapy - yes (<math>n = 2024</math>; 92 vs 126 events; HR 0.70; 95% CI 0.54, 0.92).</p>		
<p>The magnitude of the beneficial reduction in the risk of disease recurrence with letrozole treatment was similar in estrogen receptor-positive women, irrespective of whether they were progesterone receptor PR-positive (179 vs 208 events with tamoxifen; DFS HR 0.84; 95% CI 0.69, 1.03, <math>p = 0.09</math>), PR-negative (89 vs 107 events; DFS HR 0.83; 95% CI 0.62, 1.10, <math>p = 0.18</math>) or PR status unknown (70 vs 92 events; DFS HR 0.72; 95% CI 0.53, 0.98, <math>p = 0.04</math>)</p>		
<p>MA17 trial; 122 events in the letrozole vs 193 in the placebo group; HR 0.62; 95% CI 0.49, 0.78, <math>p = 0.00003</math>) Notably, in a prospectively planned subgroup analysis of lymph node-positive patients, letrozole significantly (<math>p &lt; 0.05</math>) reduced the risk of disease recurrence by 39% (DFS HR 0.61; 95% CI 0.45, 0.84), distant recurrence by 47% (distant DFS HR 0.53; 95% CI 0.36, 0.78) and overall survival by 39% (HR 0.61; 95% CI 0.38, 0.98)</p>		
<p>In a separate analysis evaluating the relationship between the duration of letrozole therapy in the extended adjuvant setting and hazard for recurrence of disease, the benefits of letrozole to placebo treatment increased as the duration of treatment increased. There was a significant (<math>p &lt; 0.0001</math>) reduction in the HR for DFS (primary endpoint) from 0.52 (95% CI 0.40, 0.64) at 12 months to 0.19 (95% CI 0.04, 0.34) at 4 years in the placebo/letrozole group. Similarly, the distant DFS HR was reduced from 0.43 to 0.21 (<math>p = 0.0013</math>).</p>		
<p><b>Overall Survival:</b> There was no between group difference in terms of 4-year overall survival rates (95.4% vs 95.0%); the HR for the risk of death from any cause was 0.82 (95% CI 0.57, 1.19).</p>		
<p><b>Contralateral breast cancer:</b> Not reported other than DDFS</p>		
<p><b>Quality of life (including side effects):</b> In the MA-17 trial, there was generally no significant difference in the frequency or nature of adverse events that occurred in the letrozole (<math>n = 2572</math>) and placebo groups (<math>n = 2577</math>) although there was a slightly higher incidence of treatment discontinuation because of adverse events in the letrozole group (4.9% vs 3.6%, <math>p = 0.019</math>).</p>		

Approximately 97% of all treatment- emergent adverse events were grade 1 or 2 according to the National Cancer Institute's common toxicity criteria. The frequency of cardiovascular events (5.8% vs 5.6%), hypercholesterolaemia (16% vs 16%) and endometrial cancer (0.2% vs 0.4%) was similar in both groups.

Hot flushes (58% vs 54%,  $p = 0.003$ ), arthralgia (25% vs 21%,  $p < 0.001$ ), myalgia (15% vs 12%,  $p = 0.004$ ), anorexia (6% vs 4%,  $p = 0.039$ ) and alopecia (5% vs 3%,  $p = 0.01$ ) occurred significantly more frequently in letrozole than placebo recipients, whereas significantly fewer letrozole recipients experienced vaginal bleeding (6% vs 8%,  $p = 0.005$ ). In addition, although the incidence of new self-reported osteoporosis increased in letrozole recipients compared with placebo recipients (8.1% vs 6%,  $p = 0.003$ ), there was no difference between the two treatment groups in the proportion of patients experiencing a clinical fracture during the study period (5.3% vs 4.6%)

**Psychological morbidity:** Not reported.

**General comments:**

<b>Study Identification:</b>	Boccardo, F., Rubagotti, A., Aldrighetti, D., Buzzi, F., et al - Switching to an Aromatase Inhibitor Provides Mortality Benefit in Early Breast Carcinoma-Cancer 2007 109:6 pp1060-1067
<b>Design:</b>	Pooled analysis of RCTs evidence level 1+
<b>Country / Setting:</b>	Italy
<b>Population:</b>	Post-menopausal women with ER+ tumours and node + disease
<b>Intervention:</b>	Pooled analysis of 2 prospective multi-centre trials with the same study design and identical inclusion criteria: tamoxifen for 2 or 3 years + randomisation to continuing tamoxifen for 2 or 3 years or switch to aminoglutethimide or anastrozole.
<b>Outcomes:</b>	Mortality
<b>Follow-up:</b>	GROCTA 4B median 61 months, ITA median 64 months
<b>Results:</b>	All-cause mortality (HR 0.61 [0.42—0.88] p= .007) and breast cancer-related mortality (HR 0.61 [0.39— 0.94] p = .025) was significantly improved in women who switched to AG or ANA. On the contrary, even though more women in the tamoxifen group appeared to have died in the absence of obvious disease recurrence, there was no significant difference between groups in breast cancer-unrelated mortality. The probability of death increased over time both for the women who died after breast cancer recurrence and for those who died before disease recurrence. However, the average time before death was about double for women in the latter group compared with those in the former group (average time before death being 96 and 54 months, respectively). Multivariate analysis shows that patient age, tumour size, allocated treatment, and nodal status, in that order, were independent predictors of the risk of dying.
<b>General comments:</b> Both trials were concluded without having reached the planned recruitment size and therefore lack statistical power to analyse the impact of switching on mortality. In GROCTA 4B trial the aminoglutethimide is no longer in use for the treatment of cancer.	

<b>Study Identification :</b>	Buzdar, A.U., Guastalla, J.P., Nabholz, J.M., Cuzick, J. Impact of Chemotherapy Regimens Prior to Endocrine Therapy: Results From the ATAC (Anastrozole and Tamoxifen, Alone or in Combination) Trial – Cancer 2006, 107:3, pp. 472-480
<b>Design:</b>	RCT; evidence level 1++
<b>Country / Setting:</b>	International
<b>Population:</b>	1345 patients from the ATAC trial population who have received prior chemotherapy

<b>Intervention:</b>	5 years tamoxifen alone vs. anastrozole alone – impact of prior chemotherapy sub-study: chemotherapy regimens divided into 3 subgroups: 1) CMF only; 2) anthracycline-containing regimens (anthracycline or anthracycline and CMF); and 3) other chemotherapy regimens, including taxane-containing combinations.												
<b>Outcomes:</b>	Time to recurrence												
<b>Follow-up:</b>	Median 68 months												
<b>Results:</b>	<p>On the basis of the 5-year Completed Treatment Analysis, the ATAC trial does not indicate that the relative treatment benefits of anastrozole differ significantly between patients who received prior chemotherapy and those who did not. No evidence was found for an interaction between prior chemotherapy and anastrozole (HR, 0.89 vs. 0.74 for those with or without prior chemotherapy, respectively; p = .21 for interaction).</p> <p>For those with prior chemotherapy, the HR of anastrozole when compared with that of tamoxifen shifted from 0.98 (95% CI, 0.76—1.28) at 47 months' median follow-up to 0.89 (95% CI, 0.71—1.12) at 68 months' median follow-up and was closer to the overall treatment effect (HR, 0.79; 95% CI, 0.70—0.90). No differences according to type of chemotherapy were seen, and a benefit for anastrozole was also apparent for patients receiving prior CMF (HR 0.89; 95% CI, 0.63—1.24).</p>												
<table border="1"> <thead> <tr> <th data-bbox="120 1024 698 1062">OUTCOME OF INTEREST</th> <th data-bbox="698 1024 1104 1062">COMPARISON</th> <th data-bbox="1104 1024 1502 1062">RESULT</th> </tr> </thead> <tbody> <tr> <td data-bbox="120 1094 698 1570"> <p><b>Time to recurrence:</b> At 68 months' median follow-up, the previously reported potential treatment interaction between patients who had received prior chemotherapy and those who had not was no longer apparent (HR, 0.89 vs. 0.74 for those with or without prior chemotherapy, respectively; p= 0.21 for interaction). A longer time to recurrence was maintained for anastrozole than for tamoxifen in the anthracycline containing (HR, 0.92; 95% CI, 0.60—1.40) and taxane containing (HR, 0.85; 95% CI, 0.52—1.38) subgroups. ### Randomised controlled trials:

<b>Study Identification :</b>	Buzdar, A.U., and Jack Cuzick, J. -Anastrozole as an Adjuvant Endocrine Treatment for Postmenopausal Patients with Breast Cancer: Emerging Data, Clinical Cancer Research, 2006, 12:3, pt. 2, pp 1037-1048	
<b>Design:</b>	RCT; evidence level 1++	
<b>Country / Setting:</b>	International	
<b>Population:</b>	6,241 post-menopausal women with early breast cancer were randomized between the two monotherapy arms (intent-to-treat population). Mean age 64 years; 61% lymph node negative, 84% hormone receptor positive, and 64% tumor $\leq$ 2 cm in maximum diameter	
<b>Intervention:</b>	5 years tamoxifen alone vs anastrozole alone	
<b>Outcomes:</b>	DFS, OS, AESAE,	
<b>Follow-up:</b>	Median 68 months	
<b>Results:</b>	Using an aromatase inhibitor as initial adjuvant therapy is a better option than switching to an aromatase inhibitor after 2 years of tamoxifen. Treatment with anastrozole showed superior disease-free survival, time to recurrence, and time to distant recurrence, as well as contralateral recurrence benefits, compared with tamoxifen. Without adjuvant treatment, the recurrence rate observed over 5 years is 26.5% in women with ER+ disease, a rate that is reduced to 15.1% with tamoxifen. The efficacy benefits for anastrozole are over and above the benefits seen with tamoxifen and lead to a further 3.3% absolute reduction in the risk of recurrence at 5 years for patients receiving anastrozole compared with those receiving tamoxifen. The main features are suppression by anastrozole of the early peak of recurrence observed with tamoxifen treatment and continued hazard reduction throughout the entire treatment period, which seems to extend beyond the end of treatment. Therefore, waiting for 2 to 3 years before switching from tamoxifen to anastrozole will result in some patients developing recurrences that could have been prevented by initial adjuvant treatment with anastrozole. Adverse events judged by the investigator to be treatment related were significantly less common with anastrozole than with tamoxifen, as were treatment-related serious adverse events. Withdrawals due to adverse events were significantly less frequent for anastrozole than tamoxifen.	
<b>OUTCOME OF INTEREST</b>	<b>COMPARISON</b>	<b>RESULT</b>
<p><b>Disease-free survival:</b> Disease-free survival was significantly greater in the anastrozole group compared with the tamoxifen group in the intent-to-treat population (HR. 0.87; 95% CI 0.78-0.97; <math>p = 0.01</math>) and in the hormone receptor—positive population (HR. 0.83; 95% CI, 0.73-0.94; <math>p = 0.005</math>), with a 17% lesser risk of recurrence and an absolute difference of 3.3% between treatment arms in hormone receptor— positive patients at a median follow-up of 68 months.</p> <p><b>Overall Survival:</b> Although there was no material difference for overall survival (<math>p = 0.7</math> in both the intent-to-treat and hormone receptor— positive populations; HR. 0.97; 95% CI, 0.85-1.12 and HR. 0.97; 95% CI, 0.83-1.14, respectively), there was a nonsignificant trend in favor of anastrozole for time to breast cancer death (<math>p = 0.2</math> in both the intent-to-treat and hormone receptor—positive populations; HR, 0.88; 95% CI, 0.74-1.05 and HE, 0.87; 95% CI, 0.70-1.09, respectively).</p> <p><b>Contralateral breast cancer:</b> Not reported other than time to recurrence. The advantage of anastrozole in reducing the risk of recurrence was more pronounced in the estrogen receptor—</p>		

<p>positive (ER+)/PR-negative (PR—) group (HR. 0.43; 95% CI, 0.31-0.61) than in the ER+/PR+ group (HR, 0.43; 95% CI, 0.69-1.02;).</p> <p><b>Quality of life (including side effects):</b> Treatment-related adverse events leading to death that occurred while receiving study treatment numbered 6 (0.2%) in the anastrozole group and 10 (0.3%) in the tamoxifen group (difference between groups not significant, p = 0.5).</p> <p><b>Psychological morbidity:</b> Not reported.</p> <p><b>General comments:</b> -</p>
--

<b>Study Identification :</b>	Howell,A., Cuzick,J., Baum,M., Buzdar,A., Results of the ATAC (Arimidex, Tamoxifen, Alone or in Combination) trial after completion of 5 years' adjuvant treatment for breast cancer. Lancet, 2005 365, 9453 pp.60-62
<b>Design:</b>	RCT; evidence level 1++
<b>Country / Setting:</b>	International
<b>Population:</b>	9366 Post-menopausal women with hormone receptor positive localised breast cancer Baseline patients characteristics; see ATAC trial
<b>Intervention:</b>	A double-blind randomised trial, compared 5 years of the aromatase inhibitor anastrozole alone with tamoxifen alone, or the combination, as adjuvant therapy in 9366 postmenopausal women with localised breast cancer.
<b>Outcomes:</b>	DFS, time to recurrence, distant metastases, contralateral breast cancer
<b>Follow-up:</b>	5 years median 68 months
<b>Results:</b>	5 years of anastrozole should be considered as the preferred initial adjuvant endocrine treatment for post- menopausal women with hormone-receptor-positive localised breast cancer. anastrozole significantly prolonged disease-free survival (575 events with anastrozole vs 651 with tamoxifen, hazard ratio 0.87, 95% CI 0.78—0.97, p=0 .01) and time-to-recurrence (402 vs 498, 0-79, 0-70—0-90, p=0 .0005), and significantly reduced distant metastases (324 vs 375, 0.86, 0-74—0.99, p=0 .04) and contralateral breast cancers (35 vs 59, 42% reduction, 12—62, p=0 .01).

OUTCOME OF INTEREST	COMPARISON	RESULT
<p><b>Disease-free survival:</b> Treatment with anastrozole led to significant improvements compared with tamoxifen for disease-free survival (575 vs 651 events, hazard ratio 0.87, 95% CI 0.78—0.97, p=0.01) and time-to-recurrence (402 vs 498 0.79, 0.70—0.90, p=0.0005). A greater advantage was seen in disease-free survival (0.83, 0.73—0.94, p=0.005) and in time-to-recurrence (0.74, 0.64—0.87, p=0.0002) in hormone-receptor-positive patients. This 26% risk reduction over tamoxifen for time-to-recurrence is in addition to the 47% risk reduction previously shown for 5 years of tamoxifen versus placebo in adjuvant studies. No significant differences were noted in effect according to subgroup at the 1% level, and the hazard rate was lower for anastrozole in all subgroups except for patients who were hormone-receptor-negative or whose hormone-receptor status was unknown.</p>		
<p><b>Overall Survival:</b> Overall survival was similar for anastrozole and tamoxifen (hazard ratio 0.97, 95% CI 0.85—1.12, p=0.7); a 12% reduction in deaths from breast cancer in the anastrozole group was not significant (0.88, 0.74—1.05; p=0.2). However, since the trial population had a relatively good prognosis (5695 [61%] of patients were lymph-node-negative and 5959 [64%] had tumours 2cm or smaller in diameter), it is too early to expect a difference in survival.</p>		
<p><b>Contralateral breast cancer:</b> The incidence of contralateral breast cancer was substantially reduced by anastrozole compared with tamoxifen (all patients 35 vs 59, 42% reduction, 95% CI 12 - 62, p=0.01; hormone-receptor-positive patients 53%, 25—71, p=0.001). Since tamoxifen shows a 50% reduction in the occurrence of these tumours in hormone-receptor-positive patients compared with placebo, the findings from the ATAC study suggest that anastrozole treatment might prevent 70—80% of hormone-receptor-positive tumours in women at high risk of breast cancer.</p>		
<p><b>Quality of life (including side effects):</b> Withdrawals due to adverse events were significantly less common with anastrozole (344, 11.1%) than with tamoxifen (442, 14.3%; p=0.0002). Drug-related serious adverse events were also significantly less common with anastrozole (146, 4.7%) than with tamoxifen (271, 9.0%; p&lt;0.0001). Treatment with anastrozole was associated with significant reductions in the incidence of endometrial cancer, thromboembolic events, ischaemic cerebrovascular events, vaginal bleeding, hot flushes, and vaginal discharge, compared with tamoxifen.</p>		
<p><b>Psychological morbidity:</b> Not reported.</p>		
<p><b>General comments:</b> -</p>		

<b>Study Identification :</b>	Thurlimann, B., Keshaviah,A., Coates, AS., Mouridsen, H., Mauriac, L., Forbes, JF. Et al. A Comparison of Letrozole and Tamoxifen in Postmenopausal Women with Early Breast Cancer N Engl J Med, Vol.353(26),2005 pp2747-2757
<b>Design:</b>	RCT; evidence level 1++
<b>Country:</b>	International
<b>Population:</b>	8010 postmenopausal women with hormone-receptor-positive breast cancer
<b>Intervention:</b>	The Breast International Group (BIG) 1-98 study is a randomized, phase 3, double-blind trial that compared five years of treatment with various adjuvant endocrine therapy regimens in postmenopausal women with hormone-receptor-positive breast cancer:letrozole, letrozole followed by tamoxifen, tamoxifen, and tamoxifen followed by letrozole. This analysis compares the two groups assigned to receive letrozole initially with the two groups assigned to receive tamoxifen initially; events and follow-up in the sequential-treatment.
<b>Outcomes:</b>	DFS local recurrence contralateral breast cancer regional recurrence
<b>Follow-up:</b>	Median 25.8 months
<b>Results:</b>	In postmenopausal women with endocrine-responsive breast cancer, adjuvant treatment with  letrozole, as compared with tamoxifen, reduced the risk of recurrent disease, especially at distant sites. Five-year disease-free survival estimates of 84.0 percent and 81.4 percent, respectively. As compared with tamoxifen, letrozole significantly reduced the risk of an event ending a period of disease-free survival (hazard ratio, 0.81; 95 %CI, 0.70 to 0.93; P=0.003), especially the risk of distant recurrence (hazard ratio, 0.33; 95 %CI, 0.60 to 0.88; P=0.001). Thromboembolism, endometrial cancer, and vaginal bleeding were more common in the tamoxifen group. Women given letrozole had a higher incidence of skeletal and Cardiac events and of hypercholesterolemia.

**OUTCOME OF INTEREST****COMPARISON****RESULT**

**Disease-free survival:** Disease-free survival was significantly greater in the letrozole group than in the tamoxifen group (HR, 0.81; 95 %CI, 0.70 to 0.93; p=0.003 by the log-rank test), especially reducing recurrence at distant sites (HR, 0.73; 95 %CI, 0.60 to 0.88; p=0.001 by the log-rank test). The five-year estimates of disease-free survival were 84.0% in the letrozole group and 81.4% in the tamoxifen group. A beneficial effect of letrozole was also seen in analyses comparing the two monotherapy groups. Subgroup analyses of DFS showed a greater effect of letrozole than of tamoxifen among patients who received chemotherapy, those who did not receive radiotherapy, and those with involved axillary lymph nodes. 5 year DFS rate among patients with node-positive cancer was 77.9% in the letrozole group and 71.4% in the tamoxifen group; the value among patients with node-negative cancer was 88.7% in both groups. The beneficial effect of letrozole on disease-free survival was similar for all combinations of estrogen-receptor and progesterone-receptor status.

**Overall Survival:** The overall survival did not differ significantly between groups.

**Contralateral breast cancer:** Significantly fewer events were reported in the letrozole group 16 (0.4%) compared to the Tamoxifen group 27 (0.7%)

**Quality of life (including side effects):** More patients in the letrozole group than in the tamoxifen group reported at least one protocol-specified adverse event of any grade (2912 patients vs. 2554 patients), but the number of patients with life-threatening or fatal protocol-specified adverse events was similar in the two groups (67 of 3975 [1.7%] and 69 of 3988 [1.7%], respectively). Fractures were significantly more frequent in the letrozole group than in the tamoxifen group (5.7% vs. 4.0%, p<0.001) (Table 3), with a significantly shorter time to a first fracture reported within four weeks after the end of treatment (P<0.001). As compared with tamoxifen, letrozole was associated with fewer thromboembolic events (1.5% vs. 3.5%, p<0.001), a lower rate of vaginal bleeding (3.3% vs. 6.6%, p<0.001), fewer endometrial biopsies (72 of 3089 women [2.3%] vs. 288 of 3157 women [9.1%], p<0.001), and fewer invasive endometrial cancers (4 of 3089 women [0.1%] vs. 10 of 3157 women [0.3%], p=0.18).

**Psychological morbidity:** Not reported.

<b>Study Identification :</b>	Coates, A., Keshaviah,A., Thurliman, B., Mouridsen, H., Mauriac, L., Forbes, J.F., et al Five Years of Letrozole Compared With Tamoxifen as Initial Adjuvant Therapy for Postmenopausal Women with Endocrine-Responsive Early Breast Cancer: Update of Study BIG 1-98: Journal of Clinical Oncology 2007,25,5 pp 486-492
<b>Design:</b>	RCT; evidence level 1++
<b>Country / Setting:</b>	International
<b>Population:</b>	4922 of the 8,028 postmenopausal women with receptor- positive early breast cancer randomly assigned (double-blind) to the BIG 1-98 trial
<b>Intervention:</b>	5 years of continuous adjuvant therapy with either letrozole (2.5mg daily) or tamoxifen (20mg daily)
<b>Outcomes:</b>	DFS, OS, Systemic DFS, Time to recurrence, time to distant recurrence,
<b>Follow-up:</b>	Median 51 months
<b>Results:</b>	The present updated analysis, which was limited to patients on monotherapy arms in BIG 1-98, yields results similar to those from the previous primary analysis but more directly comparable with results from other trials of continuous therapy using a single endocrine agent At a median follow-up time of 51 months, 352 DFS events were observed among 2,463 women receiving letrozole and 418 events among 2,459 women receiving tamoxifen. This reflected an 18% reduction in the risk of an event (HR, 0.82, 95%CI, 0.71 to 0.95; p= .007). No predefined subsets showed differential benefit. Adverse events were similar to previous reports. Patients on tamoxifen experienced more thromboembolic events, endometrial pathology, hot flashes, night sweats, and vaginal bleeding. Patients on letrozole experienced more bone fractures, arthralgia, low-grade hypercholesterolemia, and cardiovascular events other than ischemia and cardiac failure.

**OUTCOME OF INTEREST****COMPARISON****RESULT**

**Disease-free survival:** 352 DFS events were recorded among the 2,463 patients assigned to letrozole, and 418 DFS events were recorded among the 2,459 patients assigned to tamoxifen. The hazard ratio for DFS was 0.82 (95%CI, 0.71 to 0.95; p= .007), and the 5-year DFS survival estimates were 84.0% and 81.1% for letrozole and tamoxifen, respectively.

**Overall Survival:** 194 OS events were recorded among the letrozole patients compared to 211 in tamoxifen patients.  
(HR 0.91, 95%CI 0.75-1.11, p=0.35)

**Contralateral breast cancer:** Not reported other than time to recurrence and time to distant recurrence .

**Quality of life (including side effects):** More patients receiving letrozole, compared with patients receiving tamoxifen, reported at least one adverse event of any grade (2,292 patients v 2,165 patients, respectively) and at least one life-threatening or fatal adverse event (113 of 2,448 patients [4.6%] v 92 of 2,447 patients [3.8%], respectively).

**Psychological morbidity:** Not reported.

**General comments:** -

<b>Study Identification :</b>	Ingle, JN., Tu, D., Pater, JL., Martino, S., Robert, NJ., Muss, HB., et al. Duration of letrozole treatment and outcomes in the placebo-controlled NCIC CTG MA.17 extended adjuvant therapy trial. <i>Breast Cancer Research and Treatment</i> (2006) 99:295—300
<b>Design:</b>	RCT; evidence level 1++
<b>Country / Setting:</b>	International
<b>Population:</b>	5187 postmenopausal women that established letrozole to be of value in reducing recurrence of breast cancer when given in the extended adjuvant therapy setting after about 5 years of tamoxifen. Hormone receptor status was positive in 97.4%, negative in 0.15% and unknown or missing in 2.4%. 2360 women had node-positive status and 2568 had node-negative status.
<b>Intervention:</b>	Randomized to letrozole, 2.5 mg orally daily, or placebo with a planned treatment duration of 5 years. Prior adjuvant tamoxifen therapy for 4.5—6 years for a histologically confirmed breast cancer that was estrogen receptor and/or progesterone receptor positive defined as $\geq 10$ fmol/mg protein by a biochemical assay or positive by immunohistochemical stain or hormone receptor unknown.
<b>Outcomes:</b>	DFS, DDFS, OS
<b>Follow-up:</b>	median 48 months
<b>Results:</b>	<p>Longer duration of letrozole treatment is associated with greater benefit in the extended adjuvant therapy setting at least out to about 48 months. Considering all patients, HRs for events in DFS and DDFS progressively decreased over time, favoring letrozole, with the trend being significant (<math>p &lt; 0.0001</math> and <math>p = 0.0013</math>, respectively) whereas the trend for OS was not significant.</p> <p>Considering the 2360 patients with node-positive status, the HRs for DFS, DDFS and OS all decreased over time with tests for trend all showing significance (<math>p = 0.0004</math>, <math>0.0005</math> and <math>0.038</math>, respectively).</p> <p>Considering the 2568 patients with node-negative status, the HRs for DFS decreased over time with the test for trend being significant (<math>p = 0.027</math>) whereas the HRs for DDFS and OS showed no significant change over time.</p>

**OUTCOME OF INTEREST****COMPARISON****RESULT**

**Disease-free survival:** The HR for an event in DFS decreased in all patients from 0.59 at 6 months to 0.19 at 48 months with the decreasing trend in HRs being significant ( $p < 0.0001$ ). For node-positive cohort, the HR decreased from 0.66 at 6 months to 0.24 at 48 months with the decreasing trend in HRs being significant ( $p = 0.0004$ ). For node-negative cohort the HR decreased from 0.72 at 6 months to 0.43 at 48 months with the decreasing trend in HRs being significant ( $p = 0.027$ ).

**Overall Survival:** For all patients, the HRs were similar between 6 months (HR = 0.87) and 48 months (HR = 0.79) and the test for trend in HRs was not significant ( $p = 0.33$ ). For node positive patients, the HR for death decreased from 0.64 at 6 months to 0.40 at 48 months with the decreasing trend in HRs being significant ( $p = 0.038$ ). For node negative patients, the HRs likewise were similar between 6 months (HR = 2.50) and 48 months (HR = 2.75) and the test for trend was not significant ( $p = 0.34$ ).

**Contralateral breast cancer:** Not reported other than DDFS.

**Quality of life (including side effects):** Not reported.

**Psychological morbidity:** Not reported.

**General comments:** -

<b>Study Identification :</b>	Mann, BS., Johnson, JR., Kelly, R., Sridhara, R., Williams, G., Pazdur, R.- Letrozole in the Extended Adjuvant Treatment of Postmenopausal Women with History of Early-Stage Breast Cancer Who Have Completed 5 Years of Adjuvant Tamoxifen. Clin Cancer Res 2005;11 (16)
<b>Design:</b>	RCT; evidence level 1+
<b>Country / Setting:</b>	International
<b>Population:</b>	5187 Postmenopausal women with history of hormone receptor — positive or unknown early-stage breast cancer that had been surgically removed, who had completed 5 years of adjuvant tamoxifen within 3 months before randomization, free of breast cancer recurrence, ECOG status of $\leq 2$ , life expectancy of $\geq 5$ years, adequate bone marrow and liver functions.
<b>Intervention:</b>	Randomized to letrozole, 2.5 mg orally daily, or placebo with a planned treatment duration of 5 years. Prior adjuvant tamoxifen therapy for 4.5— 6 years for a histologically confirmed breast cancer that was estrogen receptor and/or progesterone receptor positive defined as $\geq 10$ fmol/mg protein by a biochemical assay or positive by immunohistochemical stain or hormone receptor unknown.
<b>Outcomes:</b>	DFS, DDFS, OS
<b>Follow-up:</b>	median 48 months
<b>Results:</b>	Letrozole administration led to a statistically significant prolongation in DFS. No statistically significant improvement in overall survival was observed. Hot flushes, arthralgia/arthritis, myalgia, and new diagnosis of osteoporosis were more common on letrozole. Frequency of fractures and cardiovascular ischemic events was not significantly different. A statistically significant mean decrease in bone mineral density in the hip occurred at 24 months on letrozole.

OUTCOME OF INTEREST	COMPARISON	RESULT
<b>Disease-free survival:</b>	DFS:122 events on letrozole and 193 events on placebo were observed (HR, 0.62; 95%CI, 0.49-0.78; p=0.00003).	
<b>Overall Survival:</b>	No statistically significant improvement in OS was observed. 68 and 78 deaths in the letrozole and the placebo arms, respectively (HR, 0.87; 95%CI, 0.63-1.21).	
<b>Contralateral breast cancer:</b>	Not reported other than DDFS. Distant disease-free survival DDFS also improved with letrozole, 55 vs92 events (HR, 0.61; 95% CI. 0.44-0.84; p=0.003).	
<b>Quality of life (including side effects):</b>	Hot flushes, arthralgia/arthritis, and myalgia were significantly more common in the letrozole arm (50% vs 43%, 28% vs 22%, and 10% vs 7%, respectively; p < 0.001 for each comparison).	
	Incidence of new diagnosis of osteoporosis reported by the patients was significantly higher in the letrozole arm, both while on treatment (6.4% vs 4.9%, p = 0.02) and at any time after randomization (6.9% vs 5.5%, p = 0.042).	
	The frequency of fractures was not significantly different between the two groups (5.9% vs 5.5%, p = 0.6196).	
<b>Psychological morbidity:</b>	Not reported.	
<b>General comments:</b> - Short duration of treatment and follow-up precluded assessment of long-term safety and efficacy.

<b>Design:</b>	Cohort study, evidence level 2++	
<b>Country / Setting:</b>	International	
<b>Population:</b>	3,612 (69.9%) participating in the QOL substudy of MA17 trial comparing letrozole with placebo after adjuvant tamoxifen: 1,799 allocated to placebo and 1,813 allocated to letrozole.	
<b>Intervention:</b>	Mean change scores from baseline were compared between groups for summary measures and domains in the short form 36-item Health Survey (SF-36) and the Menopause Specific Quality of Life Questionnaire (MFNQOL) at baseline, 6 months, and annually. A response analysis compared the proportion of patients who demonstrated an important change in QOL	
<b>Outcomes:</b>	QOL	
<b>Follow-up:</b>	5 years	
<b>Results:</b>	Letrozole did not have an adverse impact on overall QOL. Small effects were seen in some domains consistent with a minority of patients experiencing changes in QOL compatible with a reduction in estrogen synthesis. No differences were seen between groups in mean change scores from baseline for the SF-36 physical and mental component summary scores at 6, 12, 24, and 36 months. Small (< 0.2 standard deviations) but statistically significant differences in mean change scores from baseline were seen for the SF-36 domains of physical functioning (12 months), bodily pain (6 months) and vitality (6 and 12 months), and the MENQOL vasomotor (6, 12, and 24 months) and sexual domains (12 and 24 months). On the response analysis, a significant difference was seen between groups for the bodily pain domain (percentage of patients reporting a worsening of QOL, 47% placebo v 51% letrozole; P = .009) and the vasomotor domain (22% placebo v 29% letrozole; p = .001).	
<b>OUTCOME OF INTEREST</b>	<b>COMPARISON</b>	<b>RESULT</b>
<b>Disease-free survival:</b>	Not reported	
<b>Overall Survival:</b>	Not reported	
<b>Contralateral breast cancer:</b>	Not reported.	
<b>Quality of life (including side effects):</b>	Significant predictors for worsening in quality of life for SF-36 physical component summary (PCS) included: age 50 to 59 v < 49 years, odds ratio [OR] = 1.70, p = .0008 60 to 69 v < 49 years, OR = 2.04, p = .0001	

$\geq 70$  v  $< 49$  years, OR = 2.56,  $p < .0001$   
and baseline PCS score (OR 1.03;  $p < .0001$ )

Sole predictor for worsening of the SF-36 mental component summary (MCS) was the baseline MCS score (OR = 1.05;  $p < .0001$ ).

For the SF-36 bodily pain domain, predictors included

age 50-59 v  $< 49$  years, OR = 1.71,  $p = .0004$

60 to 69 v  $< 49$  years, OR = 1.51,  $p = .007$

70 v  $< 49$  years, OR 1.72,  $p = .0006$

baseline bodily pain score (OR = 1.02;  $p < .0001$ )

and treatment (OR = 1.27;  $P = .002$ )

Predictors for worsening in the MENQOL vasomotor domain included

age ( $\geq 70$  v  $< 49$  years, OR = 0.54;  $p = .0003$ ),

baseline vasomotor score (OR=0.86;  $p < .0001$ ),

and treatment (OR = 1.46;  $p < .0001$ ).

Symptom analysis

No. of patients experiencing being 'very bothered' by a specific symptom

Quality of life response analysis

**Psychological morbidity:** Not reported.

<b>Study Identification :</b>	Fallowfield, L.J., Bliss, J.M., Porter, L.S., Price, M.H., Snowdon, C.F., Jones, S.E., Coombes, R.C., Hall, E., - Quality of Life in the Intergroup Exemestane Study: A Randomized Trial of Exemestane Versus Continued Tamoxifen After 2 to 3 Years of Tamoxifen in Postmenopausal Women With Primary Breast Cancer – Journal of Clinical Oncology 2006, 24 column 6 pp910-917
<b>Design:</b>	Cohort study; evidence level 2++
<b>Country / Setting:</b>	International
<b>Population:</b>	582 postmenopausal women with early-stage, operable invasive breast cancer, had completed their primary treatment (surgery ± radiotherapy ± chemotherapy) according to local practice, and had received 2 to 3 years of adjuvant tamoxifen before enrolment.  Baseline Demographic and Clinical Characteristics
<b>Intervention:</b>	This is a QOL subsidy of the IES trial (switched from tamoxifen to exemestane or continue with tamoxifen until 5 years of treatment were completed) QOL was measured using the Functional Assessment of Cancer Therapy - Breast (FACT-B) questionnaire (version 3), together with an endocrine symptom subscale (ES) questionnaire (FACT-B+ES) The FACT-B is a 38 item questionnaire with six subscales assessing physical (seven items), social (seven items), emotional (six items), and functional (seven items) well being, relationship with doctor (two items), and additional concerns more specific to women with breast cancer (nine items). The ES was designed for use with the FACT-B and comprises 18 items. Four other items (sleep, fatigue, nervousness, and nausea) are already included in the FACE B. Patients indicated how true a statement had been for them over the past 7 days using a 5-point scale as follows: 0, not at all; 1, a little bit; 2, somewhat; 3, quite a bit; and 4, very much. All items receive equal weighting.
<b>Outcomes:</b>	Trial Outcome Index (TOI- the sum of the scores from the 23 items of the physical and functional wellbeing and the breast cancer subscales), total FACT-B+ES (reflecting overall QOL) and ES (reflecting burden of endocrine symptoms)
<b>Follow-up:</b>	60 months
<b>Results:</b>	The switch from tamoxifen to exemestane neither increased nor decreased endocrine symptoms present after 2 to 3 years of tamoxifen; the switch also did not initiate significant reports of new symptoms. Results indicate that the clinical benefits of exemestane over tamoxifen are achieved without significant detrimental effect on QOL. QOL was generally good and stable over 2 years, with no clinically meaningful differences found between groups in TOI or ES. Prevalence of severe endocrine symptoms at trial entry was high for vasomotor complaints and sexual problems, which persisted for both groups during the study. No significant differences between groups were seen for any endocrine symptoms apart from vaginal discharge, which was more pronounced with tamoxifen (p < .001).

**OUTCOME OF INTEREST****COMPARISON****RESULT**

**Disease-free survival:** Not reported

**Overall Survival:** Not reported

**Contralateral breast cancer:** Not reported

**Quality of life (including side effects):** There were no significant treatment *differences in TOI scores* over the total time period from 3 to 24 months (mean TOI score for patients allocated to tamoxifen was 0.89 points higher than the score for patients in the exemestane group; 95%CI, -0.22 to 1.99).

There were no significant within-group changes in TOI for patients in the tamoxifen arm. Neither group displayed clinically meaningful mean changes at any time point, and the repeated-measures analysis suggested that, irrespective of treatment, TOI did not change significantly with time.

The proportions of patients who maintained a clinically meaningful TOI point increase from baseline at all the points and, thus, had a sustained improvement were 3.9% for exemestane (95%CI, 2.0% to 6.9%) and 4.7% for tamoxifen (95%CI, 2.5% to 7.9%) (p=.64).

The proportions of patients who had a clinically meaningful sustained decrease at each time point compared with baseline were 2.5% for exemestane (95%CI, 1.0% to 5.1%) and 3.6% for tamoxifen (95%CI, 1.8% to 6.6%) (p = .43).

There was no significant difference between treatment groups in **ES change** scores over time. At individual time points, no difference was seen at 6 months (mean difference [exemestane - tamoxifen] = -0.79; 95%CI, -2.02 to 0.44; p= .21) or at any other time point. Irrespective of treatment, mean ES scores increased (ie, endocrine symptoms decreased) over time.

Patients in the exemestane and tamoxifen arms had significantly higher ES scores compared with baseline (ie, fewer endocrine symptoms) at 9, 12, 18, and 24 months (all p≤0.01)

**Total FACT-B +ES.** No significant differences in total FACTB+ES scores were seen by treatment group or over time after adjustment for baseline score and known prognostic factors. There were no significant differences between treatment groups at 6 months (mean difference [exemestane - tamoxifen] = -3.08; 95% CI, -6.10 to -0.06; p= .05) or at any other time point. The only statistically significant within-treatment group change was seen at 6 months for patients in the exemestane arm, although this change was not clinically meaningful (mean change = -3.12; 95% CI, -5.37 to -0.87; p= .007).

**Psychological morbidity:** Not reported.

## Guideline

<b>Study Identification:</b>	Thuerlimann, B., Koeberle, D., Senn, H.J., Guidelines for the adjuvant treatment of postmenopausal women with endocrine-responsive breast cancer: Past, present and future recommendations EUROPEAN JOURNAL OF CANCER 43 (2007) 46—52	
<b>Design:</b>	Guideline; evidence level 4	
<b>Country / Setting:</b>	Switzerland	
<b>Population:</b>	Guideline developed on the systematic review of RCT	
<b>Intervention:</b>	ATAC (comparing tamoxifen and anastrozole alone or in combination) BIGT 1-89 MA17 (comparing letrozole and tamoxifen alone or in combination)	
<b>Outcomes:</b>	DFS, relapse rates	
<b>Follow-up:</b>	Up to 5 years	
<b>Results:</b>	<p>It has been suggested that patients with ER-positive/PgR-negative, and/or HER-2--positive tumours appear to have an increased benefit with AI therapy compared with tamoxifen therapy. Retrospective, exploratory data from ATAC trial suggest that a benefit of anastrozole over tamoxifen is confined to the ER-positive/PgR-negative subgroup (for time to recurrence, hazard ratio (HR) = 0.84 versus 0.45, respectively).</p> <p>In contrast, data from assessment of ER/PgR in the BIG 1-98 trial show a benefit of letrozole irrespective of PgR status. The analysis of nearly 4400 tumours has shown that the small group of patients with HER-2 overexpression/amplification in the tumour had a higher rate of recurrence with both treatments. PgR status in ER-positive tumours did not predict responsiveness to letrozole when compared with tamoxifen. Thus, at present, neither HER-2 status nor PgR status help to select letrozole over tamoxifen for postmenopausal patients with ER-positive tumours.</p>	
	<b>OUTCOME OF INTEREST</b>	<b>COMPARISON</b>
	<b>RESULT</b>	
	<b>Disease-free survival</b> – not reported	
	<b>Overall survival</b> – not reported	
	<b>Contralateral breast cancer</b> – benefit of anastrozole over tamoxifen in the ER-positive/PgR-negative subgroup, reported as time to relapse hazard ratio (HR) = 0.84 versus 0.45, respectively).	
	<b>Quality of life</b> – not reported

Gines Rubio J, Fernandez Cortez F, Rifa Ferrer J. [A meta-analysis of the effectiveness of aromatase inhibitors as adjuvant treatment for postmenopausal patients with breast cancer]. [Spanish]. Farmacia Hospitalaria 2007 Jan;31(1):5-16.

Design: Meta-analysis of RCTs (2000-2005)

Level 1+

Country: Spain setting:

Aim: To evaluate the efficacy and safety of aromatase inhibitors (AIs) as adjuvant hormonal therapy for postmenopausal patients with hormone receptor positive breast cancer compared with tamoxifen therapy, or as a subsequential treatment to this therapy.

### **Inclusion criteria**

RCT phase III studies of AIs compared with tamoxifen.

Trials where an AI was given after 5 years of tamoxifen treatment.

Search of MEDLINE database between years 2000 and Dec 2005.

Papers from ASCO and SABCS conferences.

### **Exclusion criteria**

### **Population**

Postmenopausal women with hormone receptor positive early stage breast cancer.

### **Interventions**

AI and tamoxifen treatments were compared either directly after surgery or following 2-3 years of treatment with tamoxifen.

Trials that incorporated the administration of an AI after 5 years of tamoxifen treatment as a continuation of hormone therapy.

### **Outcomes**

DFS (defined as interval between randomisation and either disease recurrence or death with no recurrence)

OS (interval between randomisation and death due to any cause)

Side effects.

### **Follow up -**

### **Results**

7 studies were included:

ATAC 2005      Anastrozole

BIG 1-98 2005    Letrozole

IES 2004        Exemestane

ITA 2005        Anastrozole

ABCSG 8 and ARNO 95 combined (2005)    Anastrozole

Ma.17 2005      Letrozole

ABCSG-6a 2005 (abstr)                      Anastrozole

Meta-analysis was conducted using the Mantel-Haenszel fixed effects model for DFS and OS. Analysis of subgroups was conducted by stratification into when the AI was administered (at the same time as the group receiving tamoxifen; sequentially after tamoxifen; and after 5 years of tamoxifen).

**DFS**

Seven studies reported DFS. AIs were shown to increase DFS in comparison to tamoxifen as a first-line therapy (MH OR = 0.83; 95% CI: 0.76-0.92) and when administered sequentially for 2-3 years following 2-3 years of tamoxifen treatment (MH OR = 0.65; 95% CI: 0.57-0.75). Use after 5 years of tamoxifen therapy also increased DFS (MH OR = 0.63; 95% CI: 0.51-0.77). The overall effect of AIs was significant in improving DFS (MH OR 0.75; 95% CI 0.69-0.81)  $p < 0.00001$ , however statistical heterogeneity was present between studies ( $I^2$  65%).

**Meta-analysis for DFS outcomes**

Study	AI n/N	Control n/N	OR (95% CI)	p value

heterogeneity  
P=0.008

Forest Plot of DFS outcomes for RCTs:

**OS**

Five studies reported OS. A statistically significant improvement in OS was obtained when the AI was administered following 2-3 years of tamoxifen treatment (MH OR = 0.77; 95% CI: 0.64-0.94). The difference was not significant when the AI was administered instead of tamoxifen as first-line therapy (MH OR = 0.93; 95% CI: 0.83-1.05) from two studies of different pharmaceuticals (Anastrozole and Letrozole). The overall effect of AIs was significant in improving OS (MH OR 0.88; 95% CI 0.80-0.98) p=0.02, and no statistical heterogeneity was present between studies (I<sup>2</sup> 14%).

**Meta-analysis for OS outcomes**

Study	AI n/N	Control n/N	OR (95% CI)	p value
<b>AI monotherapy vs. tamoxifen</b>

I <sup>2</sup> 13.6% No significant heterogeneity P=0.33				

Forest plot of OS outcomes from RCTs: see figure in paper

### *Toxicity*

There was no subgroup analysis for toxicity effects.

#### **Anastrozole**

Anastrozole showed a lower incidence of gynaecological and vascular events. However, bone fractures, mainly spinal fractures, and arthralgias were significantly higher (this data is from the ATAC trial comparing anastrozole with tamoxifen alone or in combination with tamoxifen). Gastrointestinal problems and alterations in lipid metabolism were also significantly higher with anastrozole than with tamoxifen (ITA study).

#### **Letrozole**

The incidence of arthralgias, myalgias, hot flashes, anorexia, and alopecia was found to be significantly higher in patients treated with letrozole than placebo. The incidence of osteoporosis appeared to be higher with letrozole than with placebo, although the difference was not statistically significant when measuring the number of bone fractures. Patients receiving placebo had a higher incidence of vaginal bleeding than those treated with letrozole. There were no differences observed in the incidence of cardiac events between the letrozole group and the placebo group.

#### **Exemestane**

Exemestane showed fewer thromboembolic events and gynaecological side-effects, as well as a lower incidence of second primary tumours. However, musculoskeletal toxicity, diarrhoea, and sight problems are more frequent with exemestane. The incidence of osteoporosis appeared to be higher in the exemestane group although the difference was not statistically significant when measuring the number of bone fractures. A higher number of myocardial infarctions occurred in the exemestane group compared with tamoxifen (1 vs. 0.4%, respectively) although the difference was not statistically significant.

#### **Author conclusions**

In comparison with tamoxifen, AIs reduce the incidence of thromboembolic and gynaecologic events, although they increase bone toxicity. The clinical studies evaluated show the consistent benefits of AIs at different adjuvant treatment stages; however, we have been unable to establish the optimum moment for their introduction due to the absence of direct comparisons between the different strategies. We now need to focus on the selection of patient sub-groups which could benefit from their use as a first-line therapy, the long-term toxicity of AIs, and their capacity to increase OS, regardless of the strategy followed, after a longer monitoring period. In light of the evidence available, bearing in mind certain limitations, we propose criteria for the use of AIs in daily clinical practice.

#### **General comments –**

$I^2 > 50\%$  indicates substantial statistical heterogeneity.

The overall effects (ORs) of AIs for DFS and OS were not reported in the paper, these were obtained by transferring the data to Review Manager.

Subgroup analyses were not performed. This study was included to show the effects of AIs on outcomes from the major RCTs comparing tamoxifen or placebo with AIs.

Jakesz R, Jonat W, Gnant M, Mittlboeck M, Greil R, Tausch C, et al. Switching of postmenopausal women with endocrine-responsive early breast cancer to anastrozole after 2 years' adjuvant tamoxifen: combined results of **ABCSG trial 8 and ARNO 95** trial.[see comment]. Lancet 2005 Aug 6;366(9484):455-62.

Design: Analysis of data from 2 RCTs (1996-2003)

Level

1+

Country: Austria, setting:

Aim: To investigate whether women who received a period of adjuvant tamoxifen would benefit from being switched to anastrozole.

### **Inclusion criteria**

ABCSG-8 postmenopausal women  $\leq$  80 years

ARNO-95 postmenopausal women  $\leq$  75 years

All had histologically verified, locally radically treated invasive or minimally invasive breast cancer without previous chemotherapy, hormone therapy, or radiotherapy, tumour infiltration of up to ten (ABCSG trial 8) or nine (ARNO 95) lymph nodes, and absence of organ metastases.

### **Exclusion criteria**

Exclusion criteria for both trials were indeterminate menopausal status (or menopausal status maintained by medication), presence of secondary malignant disease, tumour infiltration of skin or breast muscle (T4 tumours), and presence of other concomitant serious medical conditions.

**Population** number of patients = 3224 analyzed

(ABCSG- 8 N=2262

ARNO 95 N=962)

HR status:

Randomization was to either continue tamoxifen (n=1606) or switch to anastrozole (n=1618).

	Tamoxifen	Anastrozole
ER+/PgR+	1247 (78%)	1272 (79%)
ER+/PgR-	281 (18%)	283 (18%)
ER-/PgR+	39 (2%)	28 (2%)
Unknown	39 (2%)	35 (2%)

### **Interventions**

Postmenopausal women with hormone-sensitive early breast cancer who had completed 2 years adjuvant oral tamoxifen (20 or 30 mg daily) were randomised to receive 1 mg oral anastrozole (n=1618) or 20 or 30 mg tamoxifen (n=1606) daily for the remainder of their adjuvant therapy.

Patients had modified radical mastectomy or breast-conserving surgery with axillary lymph-node dissection or sentinel lymph-node biopsy (with or without radiotherapy),

followed by adjuvant tamoxifen therapy started within 6 weeks (ABCSG trial 8) or 4 weeks (ARNO 95) of surgery or radiotherapy. Two years of adjuvant oral tamoxifen therapy was completed.

### Outcomes

Event-free survival – event defined as local or distant metastasis, or contralateral breast cancer

Distant recurrence free survival

Tolerability

### Follow up

Median follow-up 28 months (95% CI 26-30)

At the time of disclosure of trial data 882 (55%) of patients on anastrozole and 884 (55%) on tamoxifen had completed 5 years of treatment.

### Results

Analysis was by intention to treat. Hazard ratios (HR) were calculated from the Cox proportional-hazards regression model.

#### *Event free survival*

Higher in patients on anastrozole (67 events) than those continuing treatment with tamoxifen (110 events).

HR 0.60 (95% CI 0.44–0.81,  $p=0.0009$ ) favouring anastrozole at 3 years after switching.

HR for first events was 0.59 (0.44–0.81,  $p=0.0008$ ).

Event-free survival 3 years after switching:

92.7% (SD 0.81) for the tamoxifen group and 95.8% (SD 0.65) for the anastrozole group.

Absolute benefit of 3.1% at 3 years for anastrozole.

#### *Distant metastases*

62% of recurrences (110/177)

3% for women on anastrozole

5% for women on tamoxifen

HR 0.61 95% CI 0.42–0.87,  $p=0.0067$

Corresponds to a 39% decrease in risk of metastases for women switching to anastrozole.

#### *Recurrence*

More recurrences occurred in the tamoxifen group than the anastrozole group.

Contralateral recurrences  $n=28$  (16%)

Ipsilateral recurrences  $n=41$  (23%)

### Summary table of events

	Tamoxifen	Anastrozole	Total
Total N of events	110	67	177
Locoregional events	24	20	44

Distant metastases	75	46	121
Contralateral events	16	12	28
Deaths:			
Breast cancer related	31	24	55
Non-breast cancer related	28	21	49

*Overall survival*

At 3 years OS was marginally higher in patients on anastrozole (97%) than tamoxifen (96%), but not statistically significant p=0.16.

*Risk of recurrence after stratification by nodal status, tumour grade, age and receptor status*

None of the subgroup analyses were statistically significant between each component but the authors suggested from the Forest plot that women with G1, G2 and Gx lobular tumours (n=3044) responded better to anastrozole than tamoxifen compared to women with G3 tumours (however it should be noted that the G3 group was small (n=167), and had a wide confidence interval).

Overall the benefit of switching to anastrozole compared with remaining on tamoxifen was not dependent on nodal status, age at surgery, or progesterone receptor positivity. (Univariate analysis).

**Author conclusions**

These data lend support to a switch from tamoxifen to anastrozole in patients who have completed 2 years' adjuvant tamoxifen.

**General comments –**

This study was included in the meta-analysis by Rubio (2007). It was added to this table because of the subgroup analyses.

**Subgroup analysis**

Dowsett M, Cuzick J, Wale C, Howell T, Houghton J, Baum M. Retrospective analysis of time to recurrence in the <b>ATAC</b> trial according to hormone receptor status: an hypothesis-generating study.[see comment]. J Clin Oncol 2005 Oct 20;23(30):7512-7		
Design: Analysis of RCT data	(1996 - ?)	Level 1+
Country: UK, setting:		

**Aim:**

To retrospectively assess the effect of PgR status on time to recurrence (TTR) in the arimidex, tamoxifen, alone and in combination (ATAC) trial.

**Inclusion criteria**

Postmenopausal women with histologically proven, operable, invasive breast cancer who had completed primary surgery and radiotherapy or chemotherapy (when given).

**Exclusion criteria**

**Population** number of patients = 9366 total

**Interventions**

The **ATAC** trial is a (1:1:1) randomized, double-blind trial of adjuvant use of 1 mg of anastrozole versus 20 mg of tamoxifen versus a combination of the two for 5 years in postmenopausal women with early invasive breast cancer. After the first analysis, with a median 33 months follow-up, the combination arm was discontinued and patients were offered the opportunity to switch to anastrozole or tamoxifen.

TTR was compared between the three treatment groups (tamoxifen and anastrozole; and between tamoxifen and the combination as used in the trial) for subgroups defined by ER and PgR status using Cox's proportional hazards model, with and without adjustment for baseline variables. Subgroups analyzed were ER+/PgR+ and ER+/PgR- (n=7081). Patients with ER+/PgRuk (n=518) were also included in the analysis. (uk=unknown)

Variables analyzed were:

nodal status (negative or unknown; one to three nodes positive; greater than three nodes positive)

tumour size ( $\leq 2$  cm;  $> 2$  cm)

tumour grade (well differentiated, moderately differentiated, poorly differentiated, or undifferentiated)

previous adjuvant chemotherapy (no; yes).

All significant baseline variables were included in multivariate models.

**Outcomes**

Time to recurrence (TTR)

Breast cancer events (includes contralateral tumour incidence)

**Follow up**

Median follow-up at time of analysis was 68 months.

**Results**

Results from an associated report in the Lancet (Results of the ATAC (Arimidex, Tamoxifen, Alone or in Combination) trial after completion of 5 years' adjuvant treatment

for breast cancer. *Lancet* 2005; 365: 60–62) found that the hazard ratio for time to recurrence of all hormone receptor positive women in the study was:

Hazard ratio 0.74 (95% CI 0.64–0.87) p=0.0002 Risk reduction = 26%

This same study reported the incidence of contralateral breast cancer as substantially reduced by anastrozole compared with tamoxifen (all patients 35 vs. 59, 42% reduction, 95% CI 12–62, p=0.01; hormone-receptor-positive patients 53%, 25–71, p=0.001).

In the present analysis hazard ratios (HR) for breast cancer events were compared by different receptor groups for anastrozole, tamoxifen and for the combination of both:

		Breast cancer events			An vs. Tam	Comb vs Tam
		Anastrozole	Tamoxifen	Combined		
	N of patients	N %	N %	N %	HR 95% CI p	HR 95% CI p
ER+/PgR+	5709	191 10	222 12	205 11	0.84 (0.69-1.02) 0.07	0.95 (0.78-1.15) 0.6
ER+/PgR-	1372	50 11	102 24	102 21	<b>0.43</b> <b>(0.31-0.61)</b> <b>&lt;0.001</b>	0.87 (0.66-1.15) 0.3
ER-/PgR+	220	17 27	25 33	22 27	0.79 (0.43-1.47) 0.5	0.84 (0.47-1.49) 0.5
ER-/PgR-	703	66 28	79 32	71 32	0.90 (0.65-1.25) 0.5	1.08 (0.78-1.48) 0.7
ER+/PgRuk	518	22 13	20 11	24 14	1.29 (0.71-2.37) 0.4	1.34 (0.74-2.43) 0.3
ERuk/PgRuk	743	46 19	47 19	49 19	0.96 (0.64-1.44) 0.8	0.98 (0.65-1.46) 0.9
Other	101	Not	reported			
Total	9366	402 12.9	498 16.0	479 15.3	<b>0.79</b> <b>(0.70-0.90)</b>	0.97 (0.86-1.10)

					<b>0.0005</b>	0.6
--	--	--	--	--	---------------	-----

Figures in **bold** font were statistically significant

The Hazard Ratio of breast cancer events was significantly lower for the ER+/PgR- group [0.43 (95% CI, 0.31 to 0.61)]. This is equivalent to a reduction of 57% in breast cancer events on anastrozole compared with tamoxifen.

After adjusting for baseline nodal status, tumour size, tumour grade and use of adjuvant chemotherapy before hormonal adjuvant therapy the HRs were:

ER+/PgR+ 0.83 95% CI (0.68-1.00)

ER+/PgR- 0.45 95% CI (0.32-0.63) equivalent to a 55% reduction in breast cancer events with anastrozole.

TTR is shown as Kaplan-Meier curves in Figure 1 (A) for the ER+/PgR+ subgroup and (B) for the ER+/PgR- subgroup. (Taken from the paper).

The TTR for the anastrozole-treated group was better than either the tamoxifen or combination-treated arms in both subgroups. The outcomes for the tamoxifen and combination arms were similar. The difference in TTR with anastrozole was greater for the ER+/PgR- subgroup than the ER+/PgR+ subgroup. For comparison, the outcome of patients treated with anastrozole was only marginally worse in the ER+/PgR- subgroup (11% had a recurrence) than the ER+/PgR+ subgroup (10% had a recurrence) over 68 months.

A further analysis was made excluding the contralateral tumour incidence from the recurrence rates:

		<b>Breast cancer events excluding contralateral tumours</b>							
		<i>Anastrozole</i>		<i>Tamoxifen</i>		<i>Combination</i>	<i>An vs. Tam</i>	<i>Comb vs Tam</i>	
	<b>N of patients</b>	<b>N</b>	<b>%</b>	<b>N</b>	<b>%</b>	<b>N</b>	<b>%</b>	<b>HR 95% CI p</b>	<b>HR 95% CI p</b>
ER+/PgR+	5709	174	9	186	10	173	9	0.92 (0.75-1.13) 0.4	0.96 (0.78-1.18) 0.7
ER+/PgR-	1372	43	10	91	21	90	18	<b>0.42 (0.29-0.60)&lt;0.001</b>	0.87 (0.65-1.16) 0.3
Total	9366	367	11.7	439	14.1	425	13.6	<b>0.83 (0.72-0.95) 0.007</b>	0.98 (0.86-1.12) 0.7

**Author conclusions**

Time to recurrence was longer for anastrozole- than tamoxifen-treated patients in both ER+/PgR+ and ER+/PgR- subgroups, but the benefit was substantially greater in the PgR- subgroup. As this was an "exploratory" analysis, this effect should be considered as hypothesis generating and assessed prospectively in other trials comparing the adjuvant use of an aromatase inhibitor with tamoxifen.

**General comments –**

The authors noted that this analysis was exploratory in nature and hypothesis generating.

Ingle JN, Tu D, Pater JL, Martino S, Robert NJ, Muss HB, et al. Duration of letrozole treatment and outcomes in the placebo-controlled **NCIC CTG MA.17** extended adjuvant therapy trial. *Breast Cancer Research & Treatment* 2006;99(3):295-300.

Design: RCT (1996-2002) Level 1+  
Country: USA, Canada, Belgium, Switzerland, UK, setting: Multicentre  
Aim: Analyses were conducted to examine the relationships between duration of treatment on MA.17 and outcomes.

**Inclusion criteria**

Previous adjuvant tamoxifen therapy for 4.5 – 6 years;  
Histologically confirmed primary breast cancer;  
A tumour that was positive for estrogen receptor (ER), progesterone receptor (PR), or both;  
Discontinuation of tamoxifen therapy less than 3 months before enrollment;  
An Eastern Cooperative Oncology Group (ECOG) performance status of 0, 1, or 2 (scored on a scale of 0 to 4, with lower scores indicating better function);  
Life expectancy of more than 5 years;  
Postmenopausal status

**Exclusion criteria**

**Population** number of patients = 5187 (17 excluded)

Letrozole n=2593 (2583 analyzed)

Placebo n=2594 (2587 analysed)

Hormone receptor status:

Positive 5035 (97.4%)

Negative 8 (0.15%)

Unknown 91 (1.8%)

Missing 36 (0.7%)

Node positive 2360 (45.6%)

Node negative 2568 (49.7%)

**Interventions**

Patients were stratified according to tumour hormone receptor status (ER- and/or PR-

positive or unknown), lymph node status (negative, positive, or unknown), and prior adjuvant chemotherapy (yes or no).

Randomized, double-blind, placebo-controlled trial of letrozole (2.5 mg orally daily) versus placebo (orally daily), given for a period of 5 years.

The hazard rates for disease-free survival (DFS), distant DFS (DDFS) and overall survival (OS) at 6, 12, 24, 36 and 48 months of follow-up and the hazard ratios (HRs) of letrozole to placebo were determined. The trend in HRs over time was tested based on a Cox model with a time-dependent covariate.

**Outcomes**

DFS reported at 6 monthly intervals between 6 and 48 months (test for trend analysis)

OS as above

Distant DFS as above

Subgroup analyses within these outcomes- node positive and node negative

**Follow up** Median follow-up of 30 months

**Results**

Considering all patients, HRs for events in DFS and DDFS progressively decreased over time in favour of letrozole. The trend was significant for DFS and DDFS, but not significant for OS.

In patients with node-positive status, the HRs for DFS, DDFS and OS all decreased over time with statistically significant tests for trend.

In patients with node-negative status, the HR for DFS showed a decreasing trend over time. Whilst the HRs for DDFS and OS showed no significant change over time.

Hazard ratios for node status subgroups at different time points are shown in the following table:

<b>Subgroup</b>	<b>HR at 6 months</b>	<b>HR at 48 months</b>	<b>P value test for trend</b>
Overall:			
DFS	0.59	0.19	<0.0001
DDFS	0.51	0.21	0.0013
OS	0.87	0.79	0.33
Node positive:			
DFS	0.66	0.24	0.0004
DDFS	0.45	0.24	0.0005
OS	0.64	0.40	0.038
Node negative			
DFS	0.72	0.43	0.027
DDFS	0.22	0.18	0.22
OS	2.50	2.75	0.34

**Author conclusions:** These analyses suggest that, at least out to about 48 months, longer duration of letrozole treatment is associated with greater benefit in the extended adjuvant therapy setting.

**General comments –**  
Confidence intervals for HRs were not reported.

Goss PE, Ingle JN, Martino S, Robert NJ, Muss HB, Piccart MJ, et al. Efficacy of letrozole extended adjuvant therapy according to estrogen receptor and progesterone receptor status of the primary tumor: **National Cancer Institute of Canada Clinical Trials Group MA.17**. J Clin Oncol 2007;25(15):2006-11.

Design: RCT (1998-2002) Level 1+

Country: USA, Canada, Belgium, Switzerland, UK setting: Multicentre

Aim: Retrospective analysis to assess the effect of the ER and PgR status of the primary tumour on DFS, distant DFS (DDFS), and OS in the MA.17 trial.

### **Inclusion criteria**

These were reported in an earlier publication (Goss 2003). Postmenopausal women with histologically confirmed primary breast cancer. Tamoxifen discontinued < 3 months before enrolment. ECOG performance status 0, 1 or 2. Life expectancy > 5 years.

### **Exclusion criteria**

Concurrent use of investigational drugs or prior or concurrent malignancy other than skin cancer or carcinoma in situ of the cervix.

**Population** number of patients = 5187 (ITT analysis)

4653 with known ER and PR receptor status.

534 at least one of two receptors of unknown status.

ER+/PR+ n=3809 (73%)

ER+/PR- n=636 (12%)

ER-/PR+ n=200 (4%)

ER-/PR- n=8

### **Interventions**

The MA.17 trial was a randomized, double-blind placebo-controlled trial of extended adjuvant therapy with letrozole for 5 years in patients with breast cancer who were disease-free after standard adjuvant tamoxifen. Postmenopausal women (N=5,187) who had completed 4.5 to 6 years of tamoxifen were randomly assigned from August 1998 to September 2002.

Women were stratified based on tumour hormone-receptor status (positive or unknown), lymph node status (negative, positive, or unknown), and previous adjuvant chemotherapy (yes or no).

A Cox model with interaction terms was used to assess the differential treatment effects between ER+/PR+ and ER+/PR- groups, adjusting for nodal status and prior chemotherapy.

### **Outcomes**

DFS - defined as time from randomization to time of any breast cancer recurrence

(breast, chest wall, nodal, or metastatic site), or contralateral breast cancer.  
 Distant DFS - defined as time from randomization to time of distant metastasis.  
 OS - defined as time from randomization to time of death from any cause.

### Follow up

Median follow-up 30 months (range 1.5-61.4 months).

### Results

Results of Hazard Ratios for Disease-Free Survival, Distant Disease-Free Survival, and Overall Survival by Hormone-Receptor Subset, adjusted for nodal status and prior chemotherapy are shown in the table:

		Events on Letrozole	Events on Placebo	
Subset	N (%)	n (%)	n (%)	HR (95% CI)
<b>DFS</b>				
ITT	5187 (100)	92 (3.6)	155 (6)	0.58 (0.45-0.76)
ER+/PR+	3809 (73)	60 (3)	117 (6)	0.49 (0.36-0.67)
ER+/PR-	636 (12)	19 (6)	17 (5)	1.21 (0.63-2.34)
ER-/PR+	200 (4)	4 (4)	5 (5)	0.56 (0.15-2.12)
ER-/PR-	8 (0)	-	-	-
<b>DDFS</b>				
ITT	5187 (100)	52 (2)	82 (3.2)	0.60 (0.43-0.84)
ER+/PR+	3809 (73)	36 (2)	65 (3)	0.53 (0.35-0.80)
ER+/PR-	636 (12)	13 (4)	11 (3)	1.25 (0.56-2.80)
ER-/PR+	200 (4)	3 (3)	4 (4)	0.55 (0.12-2.47)
ER-/PR-	8 (0)	-	-	-
<b>OS</b>				
ITT	5187 (100)	51 (2)	62 (2.4)	0.82 (0.57-1.19)
ER+/PR+	3809 (73)	31 (2)	52 (3)	0.58 (0.37-0.90)
ER+/PR-	636 (12)	9 (3)	6 (2)	1.52 (0.54-4.30)
ER-/PR+	200 (4)	3 (3)	1 (2)	2.16 (0.22-20.77)
ER-/PR-	8 (0)	-	-	-

Women with ER+/PR+ status on Letrozole benefited the most across all 3 outcomes (DFS, DDFS, OS). The smaller subgroup of ER+/PR- women benefited less (HR values), however, the confidence intervals were much wider. The difference in outcomes between women with ER+/PR+ receptor status and ER+/PR- receptor status was only statistically significant for DFS (p=0.02). Corresponding p values for DDFS and OS were p= 0.06 and p = 0.09 respectively.

Confidence intervals were very wide for the ER- subgroup since event rates were small.

Adjustments for nodal status and prior adjuvant chemotherapy did not alter the data.

### **Authors Conclusions**

These results suggest greater benefit for letrozole in DFS, DDFS and OS in patients with ER+/PgR+ tumours, implying greater activity of letrozole in tumours with a functional ER. However, because this is a subset analysis and receptors were not measured centrally we caution against, using these results for clinical decision making.

### **General comments -**

Randomized controlled trial

Goss PE, Ingle JN, Martino S, Robert NJ, Muss HB, Piccart MJ, et al. Randomized trial of letrozole following tamoxifen as extended adjuvant therapy in receptor-positive breast cancer: updated findings from **NCIC CTG MA.17**. [see comment]. J Natl Cancer Inst 2005 Sep 7;97(17):1262-71.

Design: RCT (1998-2002) Level 1++

Country: USA, Canada, Belgium, Switzerland, UK. Setting: Multicentre

Aim: To present the final efficacy and toxicity results of the **MA.17** trial including all preplanned subset analyses, based on all events that occurred up to the unblinding of study participants in October 2003.

### **Inclusion criteria**

Previous adjuvant tamoxifen therapy for 4.5 – 6 years;

Histologically confirmed primary breast cancer;

A tumour that was positive for estrogen receptor (ER), progesterone receptor (PR), or both;

Discontinuation of tamoxifen therapy less than 3 months before enrollment;

An Eastern Cooperative Oncology Group (ECOG) performance status of 0, 1, or 2 (scored on a scale of 0 to 4, with lower scores indicating better function);

Life expectancy of more than 5 years;

Postmenopausal status.

### **Exclusion criteria**

**Population** number of patients = 5187 (17 excluded)

Letrozole n=2593

Placebo n=2594

Hormone receptor status:

Positive 5035 (97.4%)

Negative 8 (0.15%)  
 Unknown 91 (1.8%)  
 Missing 36 (0.7%)

**Interventions**

Patients were stratified according to tumour hormone receptor status (ER- and/or PR-positive or unknown), lymph node status (negative, positive, or unknown), and prior adjuvant chemotherapy (yes or no).

Randomized, double-blind, placebo-controlled trial of letrozole (2.5 mg orally daily) versus placebo (orally daily), given for a period of 5 years.

**Outcomes**

DFS - time from randomization to the earliest recurrence of breast cancer (breast, chest wall, regional nodes, or distant metastasis) or a contralateral new primary breast cancer.

Distant DFS

OS- time from randomization to death by any cause

Incidence contralateral tumours

Toxic effects.

**Follow up**

The median follow-up of patients was 30 months, and the range was 1.5 to 61.4 months.

**Results**

At a median follow-up of 2.5 years there were:

247 breast cancer events;

113 deaths;

1115 and 503 patients followed for 40 and 48 months, respectively.

*Summary of events in analysis of DFS*

<b>Event or Outcome</b>	<b>Letrozole N (%)</b>	<b>Placebo N (%)</b>
All patients	2583	2587
Any event	92 (3.6)	155 (6)
All recurrences	75 (2.9)	127 (4.9)
Local breast recurrence	9	22
Local chest wall recurrence	2	8
Regional recurrence	7	3
Distant recurrence	52	82
Contralateral breast	17	28
4 year DFS	94.4% (95% CI 93.0-95.8)	89.8% (95% CI 87.9-91.8)

Absolute reduction DFS	4.6%	-
------------------------	------	---

*Hazard Ratios*

From Cox proportional hazards model of letrozole vs. placebo

Outcome	Hazard Ratio (95% CI)	Risk reduction
Local or Distant Recurrence or contralateral breast cancer (HR+ve)	0.58 (95% CI = 0.45 to 0.76)	42% favouring letrozole
Adjusted value for menopausal status and duration of tamoxifen treatment	Adjusted HR = 0.59 (95% CI =0.45 to 0.76)	
Distant DFS	HR = 0.60, (95% CI = 0.43 to 0.84; <i>P</i> = 0.002)	40% favouring letrozole
Time to contralateral breast cancer	HR = 0.63, (95% CI = 0.18 to 2.21; <i>P</i> = 0.12)	37.5% favouring letrozole (NS)

After adjusting for receptor status, lymph node status, and prior adjuvant treatment at random assignment, the stratified log rank test for the difference in DFS between subgroups was significant *P* <0.001. (not clear where the data for this statement appears in the paper).

Pre-specified subgroup analyses (Forest plot from paper) showed that DFS was better in the letrozole group than placebo in most subgroups, exceptions were the subgroups of patients with unknown hormone receptor status or unknown lymph node status, both had few patients.

HR positive patients were not subdivided by type of hormone receptor positivity, and could be ER+, PR+ or both.

Although Letrozole was more effective in increasing DFS compared with placebo in all subgroups the only subgroup where a significant difference between subgroup HRs was achieved was menopausal criteria (> 50 yrs at start of tamoxifen vs. other).

*Contralateral Breast Cancer Incidence*

Annual incidence:

3.0/1000 on letrozole

4.8/1000 on placebo

(difference = 1.8/1000; 95% CI -1.3 to 4.9 per 1000)

The incidence of contralateral breast cancer was lower in women receiving letrozole, but the difference was not statistically significant.

*Overall survival*

Summary of events for OS

Event or Outcome	Letrozole N (%)	Placebo N (%)
All patients	2583	2587
All deaths	51	62
Breast cancer deaths	16	22
Other primary malignancies (deaths)	9	11
Other conditions or circumstances (deaths)	24	28
Other deaths	1	0
4 year Overall survival	95.4% (95% CI 93.7-97.0)	95% (95% CI 93.5-96.4)
Absolute increase 4 yr OS	0.4%	-
Death from any cause	HR 0.82 (95% CI 0.57-1.19) p=0.3	
OS Lymph node positive	HR 0.61 (95% CI 0.38-0.98) P = 0.04	
OS Tamoxifen > 5 years	HR 0.56 (95% CI 0.33-0.97) P = 0.04	

The pre-specified subgroup analyses showed that letrozole improved OS compared to placebo in lymph node positive patients and those taking tamoxifen more than 5 years. A Forest plot of the subgroup analysis from the paper see table.

Women receiving letrozole experienced more hormonally related side effects than those receiving placebo, but the incidences of bone fractures and cardiovascular events were the same.

**Author conclusions:** Letrozole after tamoxifen is well-tolerated and improves both disease-free and distant disease-free survival but not overall survival, except in node-positive patients.

**General comments –**

Hormone receptor positivity includes oestrogen receptor, progesterone receptor or both.

Goss P. Breaking the 5-year barrier: Results from the **MA.17** extended adjuvant trial in women who have completed adjuvant tamoxifen treatment. European Journal of Cancer Supplement 1990 2006;4(9):10-5.

Design: RCT (1996-2002)

Level 1+

Country: USA, Canada, Belgium, Switzerland, UK, setting: multicentre

**Aim:** Summary of previous findings

**Inclusion criteria** As previously reported

**Exclusion criteria**

Women with significant co-morbid disease.

**Population** number of patients = 5187

**Interventions**

**Outcomes**

Quality of life (additional to previous reported outcomes).

**Follow up**

**Results**

Letrozole therapy was well tolerated.

More common in Letrozole gp

Hot flushes

Alopecia

Arthralgia

Myalgia

Anorexia

Fractures

Self-reported osteoporosis

More common in placebo gp

Vaginal bleeding

No differences were found between groups for the incidence of cardiovascular events (Letrozole n=149, 5.8%; Placebo n=144, 5.6%; p = 0.76); hypercholesterolaemia (Letrozole n=418, 16%; Placebo n=411, 16% p = 0.79) or global quality of life scores compared with placebo.

A MA.17 lipid substudy (Wasan 2005) that evaluated serum lipids at baseline, 6 months, 12 months and annually found that letrozole did not alter lipid profiles compared with placebo in non-hyperlipidaemic postmenopausal women.

*Quality of Life*

3612/5187 (70%) of patients participated in a QoL study.

Letrozole n=1813

Placebo n=1799

There was no adverse effect of letrozole on QoL after 36 months.

There were no differences in SF-36 physical and mental component summary scores at any time point between treatment arms.

Small statistically significant differences in mean change scores from baseline were observed in patients on letrozole for SF-36 domains:

physical functioning (12 months)

bodily pain (6 months)

vitality (6 and 12 months)

MENQOL vasomotor (6, 12 and 24 months)  
sexual domains (12 and 24 months).

In the response analysis, significant differences between placebo and letrozole were observed in the proportions of patients reporting worsening of QoL for:  
bodily pain (placebo 47%, letrozole 51%,  $p = 0.009$ )  
vasomotor domain (placebo 22%, letrozole 29%,  $p = 0.001$ ) (Whelan 2005).

**General comments –**

Subgroup analyses of QoL domains were not reported. The full report on QoL for the MA.17 trial is a separate paper (Whelan 2005) that was not included in the references for this topic.

Thurlimann B, Keshaviah A, Coates AS, Mouridsen H, Mauriac L, Forbes JF, et al. A comparison of letrozole and tamoxifen in postmenopausal women with early breast cancer.[see comment][erratum appears in N Engl J Med. 2006 May 18;354(20):2200 Note: Wardly, Andrew [corrected to Wardley, Andrew]]. N Engl J Med 2005 Dec 29;353(26):2747-57.

Design: RCT (1998-2003) **(BIG) 1-98** Level 1++

Country: Multinational, setting: multicentre

Aim: To compare letrozole monotherapy with tamoxifen monotherapy as initial adjuvant endocrine therapy as well as sequential treatment with the two agents in either order in postmenopausal women with hormone-receptor-positive breast cancer.

**Inclusion criteria**

Postmenopausal women with tumours positive for estrogen receptors, progesterone receptors, or both.

Primary surgery with clear margins.

Adequate haematological, renal and hepatic function.

**Exclusion criteria**

Metastatic disease

Previous or concurrent cancer

At least one month's adjuvant antiestrogen therapy

Systemic investigational drug treatment within 30 days before randomization

**Population** number of patients = 8010 (ITT analysis)

Letrozole n=4003

Tamoxifen n=4007

Median age 61 years (38-90)

Tumour size:<2cm n= 4957 (61.9%)

> 2cm n=2973 (37.1%)

Unknown or missing n=80 (1%)

Node status:

Negative (includes Nx) n=4587 (57.3%)

Positive n=3311 (41.3%)

Unknown or missing n=112 (1.4%)

Hormone receptor status:

ER+/PR+ n=5055 (63.1%)

ER+/PR- n=1631 (20.4%)

ER+/PRuk or missing n=1154 (14.4%)

ER-/PR+ n=143 (1.8%)

ERuk or missing/PR+ n=7 (0.1%)

Other n=20 (0.2%)

**Interventions**

The Breast International Group (**BIG**) 1-98 study was a randomized, phase 3, double-blind trial comparing five years of treatment with various adjuvant endocrine therapy regimens in postmenopausal women with hormone-receptor-positive (ER+, PR+ or both) invasive breast cancer: letrozole, letrozole followed by tamoxifen, tamoxifen, and tamoxifen followed by letrozole.

This analysis compared the two groups assigned to receive letrozole initially with the two groups assigned to receive tamoxifen initially; events and follow-up in the sequential-treatment groups were included up to the time that treatments were switched.

**Outcomes**

DFS - defined as recurrence at local, regional, or distant sites; a new invasive cancer in the contralateral breast; any second, non-breast cancer; or death without a prior cancer event.

DFS- excluding non-breast cancers

Time to recurrence - as DFS excluding second non-breast cancers, and censoring of deaths with no breast cancer recurrence

Time to distant recurrence – defined as time from randomization to first distant recurrence

OS- defined as time from randomization to death from any cause.

Systemic disease –free survival- defined as time from randomization to systemic recurrence (excluding local and contralateral-breast events), the occurrence of a second, non-breast cancer, or death from any cause.

Safety

**Follow up**

Median follow-up 25.8 months

**Results**

Summary of events (Letrozole vs. Placebo)

Event or Outcome	Letrozole N (%)	Tamoxifen N (%)	Hazard Ratio (95% CI)
All patients	4003	4007	
DFS events	351 (8.8)	428 (10.7)	0.81 (95% CI 0.70-0.93) p=0.003
5 Year DFS estimates	84%	81.4%	
Deaths without prior cancer event (included in DFS)	55 (1.4)	38 (0.9)	
Deaths from any cause	166 (4.1)	192 (4.8)	
Systemic DFS events (excludes local and contralateral breast events)	323 (8.1)	383 (9.6)	0.83 (95% CI 0.72-0.97) p=0.02
Overall survival	166 (2.1)	192 (2.4)	0.86 (95% CI 0.70-1.06) p=0.16
DFS excluding 2 <sup>nd</sup> nonbreast cancer	296 (7.4)	369 (9.2)	0.79 (95% CI 0.68-0.92) p=0.002
Local recurrence	21 (0.5)	37 (0.9)	
Contralateral breast cancer	16 (0.4)	27 (0.7)	
Regional recurrence	13 (0.3)	12 (0.3)	
Distant recurrence	177 (4.4)	232 (5.8)	
Second, non-breast cancer	69 (1.7)	82 (2.0)	
Time to recurrence	228 (5.7)	310 (7.7)	0.72 (95% CI 0.61-0.86) p<0.001
Time to distant recurrence	184	249	0.73 (95% CI 0.60-0.88) p=0.001

Subgroup analyses were reported for the following parameters – taken from the paper (the authors suggest caution in the interpretation of this data):

All subgroup analyses favoured letrozole compared to tamoxifen. The largest benefits of letrozole were in patients with node positive disease and those receiving chemotherapy, although differences between components of subgroups compared were not statistically significant (CIs overlap).

There were no significant differences between ER+/PR+ and ER+/PR- subgroups.

Event or Outcome	N of patients	Letrozole N (%)	Tamoxifen N (%)	Hazard Ratio (95% CI)
<b>DFS</b>				
<b>Node negative (includes Nx)</b>	4587	140 (3.0)	147 (3.2)	0.96 (0.76-1.21) p=0.75
<b>Node positive</b>	3311	205 (6.2)	274 (8.3)	0.71 (0.59-0.85) p<0.001
<b>Chemotherapy</b>				
<b>Yes</b>	2024	92 (4.5)	126 (6.2)	0.70 (0.54-0.92) p=0.01
<b>No</b>	5986	259 (4.3)	302 (5.0)	0.85 (0.72-1.00) p=0.06

#### Side effects

Event	Letrozole	Tamoxifen	
Adverse events (patients)	2912	2554	
Fatal adverse events	67/3975 (1.7%)	69/3988 (1.7%)	
Fractures	5.7%	4.0%	P<0.001
Thromboembolic events	1.5%	3.5%	P<0.001
Vaginal bleeding	3.3%	6.6%	P<0.001
Endometrial biopsies	72/3089 (2.3%)	288/3157 (9.1%)	P<0.001
Invasive endometrial cancers	4/3089 (0.1%)	10/3157 (0.3%)	P=0.18
Cholesterol (median change)	6 mths Letrozole 0% Tamoxifen 12%	12 mths 0% -13.5%	24 mths -1.8% -14.1%
Hypercholesterolaemia	43.6%	19.2%	
Cardiovascular events	3.7%	4.2%	

Thromboembolism, endometrial cancer, and vaginal bleeding were more common in the tamoxifen group. Women given letrozole had a higher incidence of skeletal and cardiac events and of hypercholesterolemia.

#### Author conclusions:

In postmenopausal women with endocrine-responsive breast cancer, adjuvant treatment with letrozole, as compared with tamoxifen, reduced the risk of recurrent disease, especially at distant sites.

Boccardo F, Rubagotti A, Puntoni M, Guglielmini P, Amoroso D, Fini A, et al. Switching to anastrozole versus continued tamoxifen treatment of early breast cancer: preliminary results of the **Italian Tamoxifen Anastrozole Trial**. [see comment]. J Clin Oncol 2005 Aug 1;23(22):5138-47.

Design: RCT (1998-2002) Level 1+

Country: Italy, setting: Multicentre

Aim: To test the efficacy of switching postmenopausal patients who were already receiving tamoxifen to the aromatase inhibitor anastrozole.

**Inclusion criteria**

Postmenopausal women.

Histologically confirmed primary breast cancer.

Tumour ER positivity (confirmed- PR status not required)

Positive axillary nodes

No evidence of metastatic disease.

**Exclusion criteria**

Patients with any other cancer (except treated skin cancer, carcinoma in-situ of cervix)

Conditions that may jeopardize compliance to treatments.

**Population** number of patients = 448 enrolled – Intention to treat analysis

	Tamoxifen (n=225)	Anastrozole (n=223)
Age Median 63 years	43-77	38-76
ER +	194 (43%)	203 (45%)
ER -	-	2 (<1%)
Unknown or missing	31 (7%)	18 (4%)
Involved nodes:		
=<3	132 (29%)	152 (34%)
>3	91 (20%)	71 (16%)
Missing	2 (<1%)	-
Time on tamoxifen at randomization, months		
Median	28	28
Range	20-39	23-40

**Interventions**

The Italian Tamoxifen Anastrozole (ITA) trial was a phase III, randomized, multicenter trial including postmenopausal women who had already received 2 to 3 years of tamoxifen treatment. Patients were randomly assigned to receive continued tamoxifen treatment (20 mg/d) or to be switched to anastrozole (1 mg/d) for a total duration of 5 years of endocrine treatment.

Stratification was by participating centre and prior chemotherapy before randomization.

Women undergoing BCS treatment received thoracic wall irradiation. Few women undergoing mastectomy received thoracic wall irradiation (7 in tamoxifen group, 2 in anastrozole group).

## Outcomes

Locoregional recurrence (ipsilateral breast, axilla, thoracic wall, other nodes)

Distant recurrence (excluding contralateral breast cancer)

Event free survival- included locoregional recurrence, distant metastases, second primary tumours (including contralateral breast cancer), and breast cancer-unrelated deaths (ie, deaths occurring in the absence of disease recurrence).

Deaths

Adverse events

Multivariate analyses of subgroups

**Follow up** Median 36 months (range 1-70 months)

## Results

Events occurring in each arm are summarized in the following table:

Event	Tamoxifen (n=225)	Anastrozole (n=223)
Tumour recurrences:		
Locoregional	13	2
Distant metastases with or without locoregional recurrences	19	10
Secondary primary tumours:		
Contralateral breast	2	1
Endometrium	5	1
Other	3	3
Death without relapse	3	-
<b>Total events</b>	<b>45</b>	<b>17 (P = 0.0002)</b>
Breast cancer deaths	7	4

Women switched to anastrozole benefited most for EFS and recurrence FS, and had longer locoregional recurrence FS.

Hazard ratios for EFS, locoregional recurrence free survival and distant metastases-free survival are shown below:

Event	Hazard Ratio (95% CI)	P value
Event free survival	0.35 (0.20-0.63)	0.0002
Recurrence free survival	0.35 (0.18-0.68)	0.001
3 yr difference in Recurrence free survival	5.8% (95% CI 0.5-6.4)	
Locoregional recurrence free survival	0.15 (0.03-0.65)	0.003
Distant metastases-free survival	0.49 (0.22-1.05)	0.06

Disease-free, event free and local recurrence free survival were significantly longer in the

anastrozole group.

Multivariate analyses were conducted on a number of relevant subgroup variables for the risk of developing any event and disease recurrence. These findings are reported in the following table:

Subgroup	Any event		Disease recurrence	
	Hazard Ratio (95% CI)	p value	Hazard Ratio (95% CI)	p value
Treatment: Tamoxifen Anastrozole	1.0 0.36 (0.21-0.63)	0.0004	1.0 0.35 (0.18-0.69)	0.002
Tumour size: ≤ 2cm > 2cm	1.0 1.86 (1.06-3.27)	0.03	1.0 1.67 (0.86-3.24)	0.1
Tumour grade: 1-2 3-Gx	1.0 1.23 (0.73-2.06)	0.4	1.0 1.44 (0.79-2.63)	0.2
N of involved nodes: ≤ 3 >3	1.0 1.48 (0.86-2.52)	0.15	1.0 1.64 (0.87-3.07)	0.1
Prior adjuvant chemotherapy: No Yes	1.0 1.29 (0.71-2.35)	0.4	1.0 1.87 (0.86-4.06)	0.1

The benefit of anastrozole compared with tamoxifen was independent of the other variables tested. (NB the multivariate analysis does not compare subgroups assigned to either drug, other than in the first row of the table)

A further analysis displayed as a Forest Plot for risk of recurrence found the benefit of anastrozole to be consistent across all subgroups (HR adjusted for tumour size, grade, number of involved nodes and treatment of primary tumour). There appears to be no statistically significant difference between the components of each subgroup.

*Subgroup analysis of risk of recurrence:*

Overall, more adverse events were recorded in the anastrozole group compared with the tamoxifen group (203 v 150, respectively; P = 0.04). However, more events were life threatening or required hospitalization in the tamoxifen group than in the anastrozole group (33 of 150 events v 28 of 203 events, P = 0.04).

**Author conclusions:** Switching to anastrozole after the first 2 to 3 years of treatment is well tolerated and significantly improves event-free and recurrence-free survival in

postmenopausal patients with early breast cancer.

Coombes RC, Hall E, Gibson LJ, Paridaens R, Jassem J, Delozier T, et al. A randomized trial of exemestane after two to three years of tamoxifen therapy in postmenopausal women with primary breast cancer. N Eng J Med 2004; 350: 1081-92.

Design: RCT (1998-2003) Level 1++  
Country: Multinational, setting: Multicentre  
Aim: To investigate whether exemestane could prolong disease-free survival, as compared with continued tamoxifen therapy.

### Inclusion criteria

Histologically confirmed, completely resected unilateral invasive breast carcinoma positive for estrogen receptors; postmenopausal; adjuvant tamoxifen therapy for at least two years but not more than three years and one month.

### Exclusion criteria

Tumour with known negative estrogen-receptor status; evidence of local relapse or a distant metastasis since diagnosis; clinically significant skeletal, cardiac, or endocrine disorder; and the use of hormone-replacement therapy within four weeks before randomization.

**Population** number of patients = 4742 from 37 countries

Exemestane = 2362

Tamoxifen = 2380

Age 64.3 ± 8.3 years

Node negative n=2422 (51.1%)

Node positive 1-3 nodes n=1421 (30%)

Node positive =>4 nodes n=651 (13.7%)

Hormone receptor status:

ER+/PR+ n=2619 (55.2%)

ER+/PR- n=735 (15.5%)

ER+/PRuk or missing n=499 (10.5%)

ER- n=59 (1.2%)

ERuk or missing n=830 (17.5%)

Other n=20 (0.2)

PR status

PR+ n=2633 (55.5%)

PR- n=755 (15.9%)

PRuk or missing n=1354 (28.6%)

## Interventions

The Intergroup Exemestane Study (**IES**) is an international, intergroup, phase 3, randomized, double-blind trial comparing the efficacy and safety of continued adjuvant tamoxifen therapy with that of exemestane therapy in postmenopausal women with primary breast cancer free of disease after receiving adjuvant tamoxifen for two to three years. Women were randomly assigned to receive oral exemestane (25 mg) or tamoxifen (20 mg) daily to complete a total of five years of adjuvant endocrine treatment.

## Outcomes

Disease-free survival - defined as time from randomization to recurrence of breast cancer at any site, diagnosis of a second primary breast cancer, or death from any cause.

Overall survival

Incidence of contralateral breast cancer

Long term tolerability

Breast cancer-free survival (with censoring of deaths with no recurrence of breast cancer or a contralateral breast cancer).

## Follow up

30.6 months (interquartile range, 23.9 to 36.6).

## Results

449 first events (local or metastatic recurrence, contralateral breast cancer, or death)

183 in the exemestane group and 266 in the tamoxifen group.

Crude event numbers and adjusted Hazard Ratios are reported in the following tables:

Event	Exemestane n=2362	Tamoxifen n=2380	All patients N=4742
<b>Events in DFS:</b>			
Local recurrence	21	33	54
Distant recurrence	114	174	288
Primary ca in contralateral breast	9	20	29
Intercurrent death (no recurrence)	39	39	78
All events in DFS	<b>183</b>	<b>266</b>	<b>449</b>
<b>Deaths:</b>			
Any cause	<b>93</b>	<b>106</b>	<b>199</b>

Breast cancer related	54	67	121
Intercurrent	39	39	78
<b>Second primary non-breast cancer</b>	27	53	80

<b>Event</b>	<b>Exemestane n=2362</b>	<b>Tamoxifen n=2380</b>
DFS	HR 0.67 (95% CI 0.56 - 0.82) p<0.001	
DFS Absolute benefit at 3 years	4.7% (95% CI 2.6-6.8)	
DFS % at 3 years	91.5% (95% CI 90.0-92.7)	86.8% (95% CI 85.1-88.3)
Br ca free survival events	144	277
Breast cancer free survival	HR 0.62 (95% CI 0.5 – 0.76) p<0.001	
Distant DFS (unadj)	HR 0.66 (95% CI 0.52-0.83) P=0.0004	
Deaths	93	106
OS	HR 0.89 (95% CI 0.67-1.17) p=0.41	
Contralateral breast cancer	HR 0.44 (95% CI 0.20-0.98) p=0.04	

HR values were adjusted for ER status, nodal status, chemotherapy, use of HRT unless stated as unadjusted. All HRs favoured exemestane.

A subgroup analysis was performed for DFS. Most subgroups analysed favoured exemestane over tamoxifen as shown in the forest plot from the paper. Exceptions were ER-ve or unknown status, and PR status unknown.

<b>Subgroup</b>	<b>Hazard Ratio for DFS</b>
Hormone receptor status:	
ER+ (n=3853)	0.64 (0.52-0.79)
PR+ (n=2619)	0.66 (0.51-0.87)
PR- (n=735)	0.58 (0.38-0.90)
PR uk (n=499)	0.67 (0.39-1.16)

ER-ve or uk (n=889)	0.85 (0.57-1.29)
Nodal status:	
Negative (n=2422)	0.68 (0.48-0.95)
1-3 Positive nodes (n=1421)	0.71 (0.51-0.98)
≥ 4 Positive (n=651)	0.58 (0.42-0.81)
Previous HRT:	
Yes (n=1124)	0.63 (0.40-0.99)
No (n=3470)	0.69 (0.56-0.85)
Previous chemotherapy:	
Yes (n=1531)	0.69 (0.51-0.92)
No (n=3171)	0.67 (0.52-0.86)
<b>All patients (N=4742)</b>	<b>0.67 (0.56-0.82)</b>

**Adverse events**

Exemestane was associated with a higher incidence of:

- Arthralgia (p=0.005)
- Aches and pains (p=0.001)
- Diarrhoea (p<0.001)
- Osteoporosis (p=0.023)
- Visual disturbances (p=0.024)
- Headaches (p=0.035)

Symptoms more common with tamoxifen were:

- Gynaecological (p<0.001)
- Cramps (p=0.002)
- Thromboembolic disease (p=0.007)

Severe toxic effects of exemestane were rare.

**Author conclusions:**

Exemestane therapy after two to three years of tamoxifen therapy significantly improved disease-free survival as compared with the standard five years of tamoxifen treatment.

**General comments –**

Incidence of contralateral breast cancer and time to recurrence of contralateral breast cancer seem to have been used interchangeably in the paper.

Observational Studies (eg. Prospective Cohort or Retrospective Cohort or Case Series):

Ohsako T, Inoue K, Nagamoto N, Yoshida Y, Nakahara O, Sakamoto N. Joint symptoms: a practical problem of anastrozole. Breast Cancer 2006;13(3):284-288.

Design: NRS case series (2001-2005)

Level 3

Country: Japan, setting: Single clinic

Aim: Joint symptoms as adverse events of anastrozole in postmenopausal patients with breast cancer.

**Inclusion criteria** Postmenopausal ER+ breast cancer patients treated with anastrozole (1mg daily)

**Exclusion criteria** None specified

**Population** number of patients = 53  
ER+

**Interventions**

Patient examination and interview whilst taking anastrozole

**Outcomes**

Incidence and grade of joint symptoms (examination and interview)

**Follow up**

**Results**

14/53 (26%) had joint symptoms:  
13/14 (25% of total) had digital stiffness  
3/14 (6% of total) had arthralgia of wrist and shoulders

Median time to onset of symptoms 5 months (1-19 months).  
Joint symptoms were more common in patients who had prior chemotherapy.  
Hormonal therapy did not influence joint symptoms.  
Seven patients who discontinued anastrozole treatment showed improved symptoms. Five patients with grade 1 digital stiffness continued anastrozole treatment without additional treatment.  
Other characteristics are shown in the table below:

Characteristic	Joint symptom		Multivariate analysis OR (95%CI)	P value
	+	-		
Age years	58.9 ± 9.7 (47-75)	64.8 ± 11.9 (43-83)	1.02 (0.93-1.11)	0.72

Prior therapy:				
Chemotherapy	9	12	9.94 (1.34-73.51)	0.02
No chemotherapy	5	27		
Hormonal therapy	6	20	3.08 (0.46-20.52)	0.24
No hormonal therapy	8	19		
Administration:				
Adjuvant	13	19	32.51 (2.63-401)	0.007
Metastatic	1	20		

**Author conclusions:** Benefits to patients may possibly be lost by discontinuation of anastrozole or changing to tamoxifen since the clinical superiority of anastrozole to tamoxifen has been reported. We should continue anastrozole in patients with low grade symptoms, while ensuring that patients are aware of the toxicity of anastrozole.

**General comments –**

There is no comparison group in this study.

**DECISION ANALYSIS**

Punglia RS, Kuntz KM, Winer EP, Weeks JC, Burstein HJ. The impact of tumor progesterone receptor status on optimal adjuvant endocrine therapy for postmenopausal patients with early-stage breast cancer: a decision analysis. Cancer 2006 Jun 15;106(12):2576-82.

Design: Decision analysis

Country: USA, setting:

Aim: To conduct a decision analysis using Markov modeling to determine whether treatment strategies of AI upfront or crossover therapy using tamoxifen and then an AI may differ among women with biologically determined breast cancer subtypes. A particular objective was to determine whether patients with ER+/PR- tumours may benefit from different strategies from patients with ER+/PR+ tumours.

**Inclusion criteria**

Model estimates obtained from:

EBC Trialist's Collaborative Group Overview of tamoxifen data

An update of the ATAC study (in abstract form)

The ARNO/ABCSG trial (included earlier in this table – Jakesz 2005)

Both RCTs compared the AI Anastrozole with tamoxifen.

**Exclusion criteria**

**Population**

Women treated with AIs vs tamoxifen

**Interventions**

Comparisons were of AI monotherapy or sequential treatment with tamoxifen followed by AI therapy with crossover at 2 years.

Markov models were used to simulate disease-free survival (DFS) separately among postmenopausal women with ER+/PR+ cancers and women with ER+/PR- cancers.

The models used risk of recurrence for patients receiving 5 years of tamoxifen as baseline, (defined in the Oxford overview analysis) and then factored in the selective gains achieved with the use of AI therapy in the different strategies.

**Outcomes**

Disease free survival

**Follow up****Results**

Among patients with ER+/PR+ cancers, sequential therapy with tamoxifen with crossover to an AI after 2 years improved 10-year disease-free survival compared with 5 years of therapy with an AI monotherapy alone (84.3% vs. 82.2% and 68.8% vs. 64.8% for lymph node-negative and lymph node-positive patients, respectively). (see Table).

For women with ER+/PR- cancers, upfront treatment with an AI yielded improved 10-year DFS rates compared with sequential treatment with tamoxifen followed by an AI (90.5% vs. 88.2% for the lymph node-negative, and 80.1% vs. 76.1% for lymph node-positive groups respectively). (see Table).

**Expected DFS for each treatment strategy**

	<b>Hazard Ratios</b>			
	<b>5 year DFS</b>		<b>10 year DFS</b>	
<b>Patient group</b>	<b>ER+/PR+</b>	<b>ER+/PR-</b>	<b>ER+/PR+</b>	<b>ER+/PR-</b>
<b>Lymph node -ve</b>				
AI only	0.896	0.944	0.822	0.905
Year 2 crossover	0.902	0.917	0.843	0.882
<b>Lymph node +ve</b>				
AI only	0.791	0.887	0.648	0.801
Year 2 crossover	0.807	0.839	0.688	0.761

This data is also illustrated in the survival curves from the paper below:

Key:

A –Lymph Node negative

B- Lymph Node positive

Treatment AI alone red line

Sequential treatment with tamoxifen followed by AI purple line

ER+/PR+ solid lines

ER+/PR- dashed lines

Because this model used the same baseline recurrence rate for tamoxifen-treated patients with either PR+ or PR- tumours, the data showed the paradoxical outcome that patients with ER+/PR- tumours had better disease free survival than patients with ER+/PR+ tumours. This was corrected by identifying relative risks of recurrence for ER+/PR+ and ER+/PR- tumours in tamoxifen-treated patients from the San Antonio Breast Cancer Registry. The analysis was repeated for the impact of PR status on the risk of recurrence with tamoxifen. The treatment strategies did not change -patients with ER+/PR+ benefited from sequential tamoxifen/AI treatment, and ER+/PR- from AI monotherapy. However the resulting survival curves showed that patients who have tumours with PR expression have a better overall prognosis than patients with tumours lacking PR expression.

DFS with adjusted baseline risk of recurrence in tamoxifen treated patients with PR+ and PR - tumours.

Key:

A –Lymph Node negative

B- Lymph Node positive

Treatment AI alone red line

Sequential treatment with tamoxifen followed by AI purple line

ER+/PR+ solid lines

ER+/PR- dashed lines

### **Author conclusions**

Modelling estimates suggested that the optimal endocrine treatment strategy may differ based on the biologic features of breast cancer tumours. Patients with ER+/PR+ tumours achieved optimal 10-year DFS estimates with tamoxifen followed by a crossover to AI therapy, whereas patients with ER+/PR- tumours fared best when they initiated treatment with AI.

## GUIDELINES

Winer EP, Hudis C, Burstein HJ, Wolff AC, Pritchard KI, Ingle JN, et al. American Society of Clinical Oncology technology assessment on the use of aromatase inhibitors as adjuvant therapy for postmenopausal women with hormone receptor-positive breast cancer: status report 2004.[see comment]. [Review] [50 refs]. J Clin Oncol 2005 Jan 20;23(3):619-29.

Design: Update of SR and Guideline recommendations  
Country: USA, setting:

Level 4

Aim: To update the 2003 American Society of Clinical Oncology technology assessment on adjuvant use of aromatase inhibitors

### Inclusion criteria

### Exclusion criteria

### Population

### Interventions

### Outcomes

### Follow up

### Results

### Questions addressed by the panel related to this topic:

*Are there specific patient populations that should receive initial therapy with an aromatase inhibitor in lieu of tamoxifen?*

Postmenopausal women with a hormone receptor-positive invasive tumour should receive an aromatase inhibitor if there is a contraindication to tamoxifen.

Postmenopausal women who develop invasive breast cancer whilst receiving a selective estrogen receptor modulator (SERM) for either breast cancer risk reduction or bone loss, should be treated with an aromatase inhibitor.

There is a suggestion, from a subgroup analysis within the ATAC trial, that women with ER+, progesterone receptor-negative tumours may benefit more from initial therapy with an aromatase inhibitor. Although this subset analysis was retrospective, the number of events considered was relatively large.

Postmenopausal women with breast cancer over-expressing HER-2, have reported higher response rates for aromatase inhibitors when compared with tamoxifen in two randomized **neoadjuvant** trials. However, both studies included a very limited number of women with HER-2-positive tumours. The Panel recognized that debate continues regarding the optimal hormonal management of patients with HER-2-positive tumours. Based on available clinical evidence, the Panel recommended that HER-2 status not be considered when making choices about adjuvant hormonal therapy.

*Do the Results of the MA-17 Trial Provide Sufficient Evidence to Recommend the Use of an Aromatase Inhibitor in Postmenopausal Women With Hormone Receptor–Positive Breast Cancer Who Have Completed a 5-Year Course of Tamoxifen?*

This trial studied a population of postmenopausal women finishing 5 years of tamoxifen therapy. It demonstrated a statistically significant (43%) reduction in breast cancer events with the use of letrozole. Subset analyses suggested that patients with both node negative and node-positive disease derive benefit from letrozole in this setting. Because of the difference in residual risk of recurrence between high and low-risk patients, the absolute difference is larger for node-positive than node-negative cohorts. The most recent analysis revealed a small but statistically significant ( $P=0.04$ ) survival benefit in patients with node-positive disease.

Based on findings from MA-17, postmenopausal women finishing 5 years of tamoxifen for ER-positive, early-stage breast cancer should consider treatment with an aromatase inhibitor. At present, a minimum of 2.5 years of therapy can be recommended based on the median follow-up from MA-17.

In decisions about the use of an aromatase inhibitor after completion of a five-year course of tamoxifen, clinicians and patients should consider the residual risk of recurrence and individual preferences. The survival advantage in the subset of women with node-positive disease is noteworthy and strengthens the argument for use of an aromatase inhibitor after tamoxifen in this patient population.

*Do the Results of the IES and ITA Trials Provide Sufficient Evidence to Recommend the Use of an Aromatase Inhibitor in Postmenopausal Women With Hormone Receptor–Positive Breast Cancer Who Have Received Tamoxifen for 2 to 3 Years?*

The IES and ITA trials compared 5 years of tamoxifen versus 2 to 3 years of tamoxifen followed by 2 to 3 years of an aromatase inhibitor among postmenopausal women with ER-positive early-stage breast cancer. Both studies showed that a change in treatment from tamoxifen to an aromatase inhibitor reduced the risk of breast cancer recurrence (risk reduction 32% in IES).

Subset analyses suggest similar relative benefits among women with node negative or node-positive primary breast cancer. The side effect profiles differed between aromatase inhibitor therapy versus continued tamoxifen therapy in predictable ways.

Based on the findings in the IES trial, with supporting evidence from the ITA trial, postmenopausal women concluding 2 to 3 years of tamoxifen therapy may consider cross-over to an aromatase inhibitor. Patients intolerant of aromatase inhibitors or unwilling to switch from tamoxifen should continue to receive tamoxifen for a total duration of 5 years based on previous randomized trials that demonstrated the benefits of a 5-year course of tamoxifen versus a shorter course.

*Is There Any Role for the Aromatase Inhibitors in Women With Hormone Receptor–Negative Breast Cancer?*

There is strong evidence that adjuvant hormonal therapy is effective only in patients with positive ER and/or progesterone receptors. Aromatase inhibitors have not been evaluated in the adjuvant setting for women with hormone receptor negative tumours. Hormone receptor studies should be performed on all primary invasive tumours to guide the use of adjuvant hormonal therapy. Women with hormone receptor–negative tumours should not receive an aromatase inhibitor as adjuvant therapy. The Panel noted that false-negative hormone receptor assays can occur and would encourage clinicians to repeat hormone receptor studies if the result is in question or is discordant with the clinical picture.

*What Is Known About Bone and Musculoskeletal Toxicity Associated With the Aromatase Inhibitors?*

Aromatase inhibitor use is associated with osteoporosis and fracture risk related to estrogen deprivation. In adjuvant trials, all three aromatase inhibitors have been associated with more fractures than tamoxifen or placebo (letrozole 3.6% v placebo 2.9%,  $P=0.24$ , Goss 2003; exemestane 3.1% v tamoxifen 2.3%,  $P=0.08$ , Coombes 2004; anastrozole 7.1% v tamoxifen 4.4%,  $P<0.001$ , Baum 2003). Clinical trial evidence indicates that intravenous bisphosphonate as well as oral bisphosphonates clodronate and risedronate, are effective in maintaining bone density in breast cancer patients on hormonal therapy and with therapy associated premature menopause.

In otherwise healthy women, a strong body of evidence supports early detection and therapy of osteoporosis. The ASCO bisphosphonate guideline identifies postmenopausal breast cancer patients who receive aromatase inhibitors to be at high risk for osteoporosis and recommends that they have baseline bone mineral density evaluation.

*What Is Known About Vascular Complications and Endometrial Cancer in Women Treated on the Adjuvant Aromatase Inhibitors Trials?*

Both anastrozole and exemestane were associated with significantly fewer endometrial cancers, as well as venous and arterial vascular events (pulmonary emboli and stroke), when compared with tamoxifen.

*What Is Known About Overall Quality Of Life and Sexual Functioning in Women on Aromatase Inhibitors?*

In general, there have been no major differences in symptoms influencing quality of life comparing anastrozole with tamoxifen (Baum 2003) or letrozole with placebo (Goss 2003). Fallowfield (Conference abstr 2002) have reported inferior sexual functioning in women randomly assigned to anastrozole compared with tamoxifen on the ATAC trial. In the IES study, women taking tamoxifen reported less vaginal dryness but more vaginal discharge compared with those on exemestane (Paridaens 2004; Conference abstr). Aromatase inhibitor effects on cognition or dementia have not been reported.

Hot flash frequency data was not measured in a standardized way and difficult to compare between studies.

**RECOMMENDATIONS:**

Based on results from multiple large randomized trials, adjuvant therapy for postmenopausal women with hormone receptor-positive breast cancer should include an aromatase inhibitor in order to lower the risk of tumour recurrence. Neither the optimal timing nor duration of aromatase inhibitor therapy is established. Aromatase inhibitors are appropriate as initial treatment for women with contraindications to tamoxifen. For all other postmenopausal women, treatment options include 5 years of aromatase inhibitors treatment or sequential therapy consisting of tamoxifen (for either 2 to 3 years or 5 years) followed by aromatase inhibitors for 2 to 3, or 5 years. Patients intolerant of aromatase inhibitors should receive tamoxifen. There are no data on the use of tamoxifen after an aromatase inhibitor in the adjuvant setting. Women with hormone receptor-negative tumours should not receive adjuvant endocrine therapy. The role of other biomarkers such as progesterone receptor and HER2 status in selecting optimal endocrine therapy remains controversial. Aromatase inhibitors are contraindicated in premenopausal women; there are limited data concerning their role in women with treatment-related amenorrhea. The side effect profiles of tamoxifen and aromatase inhibitors differ. The late consequences of aromatase inhibitor therapy, including osteoporosis, are not well characterized.

**CONCLUSION:**

The Panel believes that optimal adjuvant hormonal therapy for a postmenopausal woman with receptor-positive breast cancer includes an aromatase inhibitor as initial therapy or after treatment with tamoxifen. Women with breast cancer and their physicians must weigh the risks and benefits of all therapeutic options.

**General comments –**

The main focus of this guideline was the timing and sequencing of aromatase inhibitors. Some subgroup analyses were reported. Side effects of AIs were discussed and are covered in the related topic of timing and sequencing of AIs (topic 29c).

Design: Guideline  
Country: USA, setting:

Level 4

**Inclusion criteria****Exclusion criteria****Population**

All stages of breast cancer.

**Interventions**

Adjuvant systemic therapy.

Only AI therapies are reported here.

## Outcomes

### Follow up

### Results

The National Comprehensive Cancer Network (NCCN) first published the NCCN Breast Cancer Treatment Guidelines in 1996. The Guidelines address the treatment of all stages of breast cancer across the spectrum of patient care. Since adjuvant therapy for breast cancer has undergone a rapid evolution over the past few years the NCCN Breast Cancer Guidelines Panel was supplemented by additional experts to form the Adjuvant Therapy Task Force to provide a forum for extended discussion and expanded input to the adjuvant therapy recommendations for Breast Cancer Treatment Guidelines. One issue discussed was how age, menopausal status, and oestrogen receptor levels impact on the benefits from chemotherapy and endocrine therapy.

#### *Aromatase inhibitors for postmenopausal women*

Data from the ATAC trial suggested a greater benefit of anastrozole in patients with ER+/PR- tumours compared to ER+/PR+ tumours (Dowsett 2005). However, this was not observed in the initial analysis of the BIG 1-98 trial (Thurlimann 2005 abstract).

None of the studies using AIs in breast cancer treatment have led to a clear improvement in survival or quality of life. Also, none of the current trials directly compares initial, sequential or extended hormonal therapy.

Aromatase inhibitors and tamoxifen have differing side effect profiles. AIs are associated with lower risk of peripheral blood clots and endometrial cancer, but a greater risk of bone loss and bone fracture than tamoxifen. AI treatment can be associated with an arthralgia syndrome, hot flashes, night sweats and other menopausal symptoms. Quality of life analyses have been similar between AIs and tamoxifen, but patients on AIs have reported greater sexual dysfunction.

In 2004 the ASCO technology assessment on the use of AIs recommended that from results of multiple large randomized trials, adjuvant therapy for postmenopausal women with hormone receptor positive breast cancer should include an aromatase inhibitor. Neither the optimal timing nor duration of aromatase inhibitor therapy is established.

Design: Expert review

Level 4

Country: USA, setting:

Aim: Review of evidence supporting current NCCN guidelines for use of AI therapy in the treatment of hormone receptor-positive postmenopausal breast cancer patients.

**Inclusion criteria**

**Exclusion criteria**

**Population**

Postmenopausal HR+ breast cancer

**Interventions**

Anastrozole  
Letrozole  
Exemestane

**Outcomes****Follow up****Results**

The National Comprehensive Cancer Network (NCCN) guidelines recommend the following algorithm for postmenopausal women with hormone receptor-positive breast cancer:

- Initial adjuvant endocrine treatment:  
Anastrozole 1 mg daily for 5 years
- Treatment with tamoxifen for 2-4 years, discuss:  
Exemestane 25 mg daily to complete 5 years of total therapy  
Anastrozole 1 mg daily to complete 5 years of total therapy
- Treatment with tamoxifen for 4.5-6 years, discuss:  
Letrozole 2.5 mg daily for 5 years

UPDATE EVIDENCE (literature search 2005 - June 2008)

<p>Goss PE., Ingle JN., Pater JL., Martino S., Robert NJ., Muss HB., Piccart MJ., Castiglione M., Shepherd LE., Pritchard KI., Livingston RB., Davidson NE., Norton L., Perez EA., Abrams JS., Cameron DA., Palmer MJ and Tu DS (2008) Late extended adjuvant treatment with letrozole improves outcome in women with early-stage breast cancer who complete 5 years of tamoxifen. <i>J Clin Oncol</i> <b>26</b>: 1948-1955</p>
<p><b>Design:</b> Cohort study as a follow up of MA-17 RCT (Ingle et al 2006), Evidence level 2+ <b>Country:</b> US <b>Aim:</b> The MA-17 trial reported the efficacy of letrozole (LET) started within 3 months of 5 years of adjuvant tamoxifen in postmenopausal hormone receptor–positive early-stage breast cancer. The trial was un-blinded, patients who received placebo (PLAC) were offered LET. This cohort study describes the outcomes of women assigned PLAC at the initial random assignment after un-blinding. The outcomes of the PLAC patients on MA.17 provides an opportunity to determine whether a later intervention with the aromatase inhibitor also might benefit the many breast cancer patients to whom it may apply.</p>
<p><b>Inclusion criteria</b> As for original MA-17 trial</p>
<p><b>Exclusion criteria</b></p>
<p><b>Population</b> 1. 1,579 women in the PLAC-LET group (median time from tamoxifen, 2.8 years) 2. 804 in the PLAC-PLAC group</p>
<p><b>Interventions</b> Efficacy outcomes of women who chose LET (PLAC-LET group) were compared with those who did not (PLAC-PLAC group) by the hazard ratios and by P values calculated from Cox models that adjusted for imbalances between the groups.</p>
<p><b>Outcomes</b></p> <ul style="list-style-type: none"><li>• Hazard ratio (HR) for disease recurrence</li><li>• Disease-free survival (DFS)</li><li>• Overall Survival</li><li>• Toxicity analyses (only events that occurred after un-blinding)</li></ul>
<p><b>Results</b></p> <ul style="list-style-type: none"><li>• Median follow-up of 5.3 years</li><li>• Patients in the PLAC-LET group were younger; had a better performance status; and were more likely to have had node-positive disease, axillary dissection, and adjuvant chemotherapy than those in the PLAC-PLAC group.</li></ul> <p><b>DFS:</b></p> <ul style="list-style-type: none"><li>• 31 patients (2.0%) in the PLAC-LET group had a DFS event compared with 39 patients (4.9%) in the PLAC-PLAC group</li><li>• Adjusted HR = 0.37, 95%CI 0.23-0.61, P&lt;0.0001. Which corresponded to a 63% reduction in disease recurrence for patients electing to cross over to LET from PLAC.</li></ul>

**Distant DFS:**

Adjusted HR= 0.39; 95% CI 0.20 - 0.74; P= 0.004. A significant 61% reduction in the risk of developing metastases was observed.

**Contralateral primary breast cancer (CLBC):**

- The annual incidence rate for new CLBC = 0.06 in the PLAC-LET group and 0.38 in the PLAC-PLAC group.
- Adjusted HR = 0.18; 95% CI 0.06 - 0.58; P = 0.004. Which corresponded to an 82% reduction in CLBC.

**Overall Survival:**

- Adjusted HR = 0.30 for the PLAC-LET compared with the PLAC-PLAC group, 95%CI 0.17 to 0.53 P<0.0001.

**Toxicity:**

- There were statistically significantly more self-reported new diagnoses of osteoporosis (PLAC-LET group (5.3% v 1.6%; P<0.0001)
- Significantly more clinical fractures occurred in the women who took LET (5.2% v 3.1%, P = 0.02).
- There was a non significant difference in the number of cardiac events occurring between the groups.
- Thromboembolic events occurred rarely in both groups.
- Other malignancies or bone marrow dysplasias was not different between the groups.

**General comments**

The question of whether the addition of LET more than 3 months after stopping tamoxifen is beneficial has been answered in part by this analysis of the crossover patients of the MA-17 trial and provides the only available information that can be used to inform this treatment decision.

The analysis reported here represents a self selected patient group to receive LET and so introduces patients selection bias. The authors caution that “the results to DFS and distant DFS should be viewed in the context of an adjusted, retrospective multivariate analysis and not as a prospective, randomised trial”

Forbes JF., Cuzick J., Buzdar A., Howell A., Tobias JS and Baum M (2008) Effect of anastrozole and tamoxifen as adjuvant treatment for early-stage breast cancer: 100-month analysis of the ATAC trial. *Lancet Oncology* **9**: 45-53

**Design:** RCT, Evidence level 1+

**Country:** UK

**Aim:** To evaluate the efficacy and side-effects that may persist after 5 years of adjuvant treatment with an aromatase inhibitor. This study presents the long-term outcomes in the (ATAC) trial that compares anastrozole with tamoxifen after a median follow-up of 100 months.

**Inclusion criteria**

postmenopausal women with localised invasive breast cancer.

**Exclusion criteria**

**Population**

**Interventions**

anastrozole, n=3125; tamoxifen, n=3116; N= 6241

**Outcomes**

- Disease free survival (DFS)
- Time to recurrence (TTR)
- Incidence of new contralateral breast cancer (CLBC)
- Time to distant recurrence (TTDR)
- Overall survival (OS)
- Death after recurrence

**Results**

- Median follow-up of 100 months (range 0–126)
- Follow-up included 46 202 women-years of follow-up for patients receiving monotherapy
- Mean (SD) duration of treatment for patients receiving anastrozole = 4·11 years compared with 3·97 years for tamoxifen

**DFS:**

For all patients (intention to treat) HR = 0·90 (95%CI 0·82–0·99) P= 0·025, favouring anastrozole

For Hormone-receptor-positive patients: HR = 0·85 (95%CI 0·76–0·94) P= 0·003, favouring anastrozole

In the hormone-receptor-negative subgroup: DFS HR= 1·02 (0·78–1·33) p=0·9, no difference for this group

**TTR:**

For all patients (intention to treat) HR = 0·81 (95%CI 0·73–0·91) P= 0·0004 favouring anastrozole

For Hormone-receptor-positive patients: HR =0.76 (95%CI 0.67–0.87) P= 0.0001 favouring anastrozole

In the hormone-receptor-negative subgroup: HR= 0.96 (0.71–1.29) p=0.8.

**TTDR:**

For all patients (intention to treat) HR = 0.86 (95%CI 0.75–0.98) P= 0.022, favouring anastrozole

For Hormone-receptor-positive patients: HR = 0.84 (95%CI 0.72–0.97) P= 0.022 favouring anastrozole

**CLBC:**

For all patients (intention to treat) HR = 0.68 (95%CI 0.49–0.94) P= 0.020 favouring anastrozole

For Hormone-receptor-positive patients: HR = 0.60 (95%CI 0.42–0.85) P= 0.004 favouring anastrozole

**Adverse events:**

• Deaths after recurrence for all patients = 350 (anastrozole) and 382 (tamoxifen)

HR =0.91 (0.79–1.05) p=0.2

• For the hormone receptor- positive subgroup = 245 (anastrozole) and 269 (tamoxifen)

HR =0.90 (0.75–1.07) p=0.2

**OS:**

• No statistically significant difference was reported for OS

For the ITT population: 629 deaths (anastrozole); 624 deaths (tamoxifen)

HR =1.00 (0.89–1.12) p=0.99

**After Treatment Outcomes:**

**Disease Recurrence:**

• A lower recurrence rate for anastrozole compared with tamoxifen was maintained after treatment was completed, (esp. in hormone-receptor-positive patients)

• Absolute benefit = 2.8% (anastrozole, n=245 events; tamoxifen, n=312 events)

HR =0.77 (0.65–0.91) p=0.002

• At 5 years this difference increased to 4.8%

• At 9 years (anastrozole, 391 events, tamoxifen, 494 events): HR=0.76 (0.67–0.87) p=0.0001

After 5 years, for the hormone-receptor-positive patient population:

• 146 events in 2159 (7%) at-risk patients who received anastrozole

• 182 events in 2075 (9%) at-risk patients who received tamoxifen

• HR= 0.75 (0.61–0.94) p=0.01

➔ Indicating that the carryover benefit after treatment completion with anastrozole is larger than that known to exist after tamoxifen.

Distant recurrence rates continued to diverge with increasing follow-up time:

• 1.3% lower for anastrozole compared with tamoxifen at year 5; 2.4% lower at year 9

For isolated contralateral tumours (as a first event): significantly lower with anastrozole

compared with tamoxifen (hormone-receptor-positive patients: HR=0.60 (0.42–0.85 p=0.004)

The HR recurrence favoured anastrozole for all subgroups based on baseline and treatment characteristics

- Subgroup of oestrogen receptor-positive and progesterone-receptor-negative patients with a significant benefit in favour of anastrozole (larger than for the oestrogen-receptor-positive and progesterone-receptor-positive subgroup) HR= 0.42 (95% CI 0.31-0.58)

**Adverse events:**

- No significant difference for deaths between the groups, however, death without recurrence were higher in patients receiving anastrozole.
- Serious adverse events were similar in both treatment arms
- Treatment-related serious adverse events were lower in those receiving anastrozole compared with those receiving tamoxifen during treatment and similar after treatment completion; OR =0.57 (0.47–0.68) p<0.0001
- Myocardial infarctions were similar in the two treatment groups (both during treatment and after its completion)
- Fewer cerebrovascular accidents reported for patients receiving anastrozole during treatment
- There was no significant difference in risk of cardiovascular morbidity between anastrozole and tamoxifen treatment groups.
- Endometrial cancer remained significantly lower in patients treated with anastrozole than with tamoxifen; OR= 0.21 (0.06–0.56) p=0.0004
- Fracture data was monitored in a blinded manner after treatment cessation: fracture rates were increased on anastrozole during treatment: incidence rate ratio (IRR) = 1.55 (1.31–1.83) p<0.0001. There was no significant difference after 5 years, off treatment: (IRR= 1.03 (0.81–1.31) p=0.79
- There was no significant difference in risk of mortality between anastrozole and tamoxifen treatment groups.

Kaufmann M., Jonat W., Hilfrich J., Eidtmann H., Gademann G., Zuna I and von MG (2007) Improved overall survival in postmenopausal women with early breast cancer after anastrozole initiated after treatment with tamoxifen compared with continued tamoxifen: the ARNO 95 Study. *J Clin Oncol* **25**: 2664-2670

**Design:** RCT, Evidence level 1+

**Country:** Germany

**Aim:** To evaluate the benefits of switching to anastrozole after 2 years of tamoxifen treatment, compared with continuing on tamoxifen for 5 years

This study has been reported by Jakesz et al 2005 (Lancet) which combined results from the ABCSG trial 8 (GABG) study. The report here describes results of only the ARNO 95 trial.

**Inclusion criteria**

Postmenopausal women (age  $\leq$  75 years) with histologically verified, grade 1 to grade 3 invasive breast cancer (pT1-3, node negative, or up to nine tumour-infiltrated lymph nodes [pN0-2] and no distant metastases), who had undergone primary surgery (with or without radiotherapy) and had received 2 years of continuous adjuvant tamoxifen therapy (20 or 30 mg/d) without disease recurrence.

**Exclusion criteria**

**Population**

Randomly assigned n = 979

**Tamoxifen:** Allocated to treatment (n = 490) (*Intent-to-treat population*) - Received treatment (n = 452) (*Safety analysis population*) - Ongoing on study treatment (n = 182) - Completed study treatment (n = 175) - Ongoing on follow-up (n = 172)

**Anastrozole:** Allocated to treatment (n = 489) (*Intent-to-treat population*) - Received treatment (n = 445) (*Safety analysis population*) - Ongoing on study treatment (n = 170) - Completed study treatment (n = 185) - Ongoing on follow-up (n = 182)

**Interventions**

Patients were who had received 2 years of continuous adjuvant tamoxifen therapy were randomly assigned to receive: anastrozole (1 mg/d) or to continue with tamoxifen (20 or 30 mg/d) for 3 years in a 1:1 ratio.

**Outcomes**

- Disease recurrence
- Overall survival
- Serious adverse events

**Results**

Follow-up of live patients ranged from  $< 1$  to  $\geq 7$  years when the database was closed. When the analysis was initiated, 42.5% of patients had completed the planned 5 years of adjuvant treatment (2 years of tamoxifen treatment plus 3 years of study therapy). Median follow-up time = 30.1 months and the median durations of exposure to anastrozole (26.8 months) and tamoxifen (27.4 months) during the randomized treatment period.

**Recurrence:**

- Switching to adjuvant anastrozole from adjuvant tamoxifen showed a statistically significant improvement in disease-free survival:  
34% reduction in the relative risk of disease recurrence or death compared with continuing on tamoxifen: HR= 0.66; 95% CI, 0.44 to 1.00; P =0.049
- The estimate of disease-free survival at 3 years (completion of study treatment) showed an absolute difference of 4.2% in favor of anastrozole (93.5% for anastrozole and 89.3% for tamoxifen)
- Fewer patients who switched to anastrozole experienced first recurrence events of local or distant disease recurrence, contralateral breast cancer, or death compared with those who continued on tamoxifen (38 [7.8%] patients v 56 [11.4%] patients, respectively).
- Numerical results only showed an advantage in favour of anastrozole for the incidence of any recurrence event (local or distant recurrence, contralateral breast cancer - 1.4% in patients switched to anastrozole and 1.0% in patients who continued with tamoxifen.)

**Survival and Disease-Free Survival:**

- Anastrozole group had a 47% improvement in overall survival compared with continued tamoxifen group (HR= 0.53; 95% CI, 0.28 - 0.99; P=0.045)
- After adjustment for potential prognostic factors (age, tumor size and grade, lymph node status, and type of primary surgery), switching to adjuvant anastrozole from adjuvant tamoxifen still resulted in a statistically significant improvement in:
  - disease-free survival: HR= 0.61; 95% CI, 0.40 to 0.93; P =0.023)
  - overall survival: HR= 0.48; 95% CI, 0.25 to 0.91; P=0.026) compared with continuing on tamoxifen.

**Safety:**

- All of the patients in this study tolerated 2 years of treatment with tamoxifen.
- Less patients died after switching to anastrozole treatment (n = 15; 3.4%) compared with those patients who continued on tamoxifen (n=27; 6.0%)
- No serious adverse events with an outcome of death were observed.
- Fewer patients in anastrozole group reported serious adverse events (101/445; 22.7%) compared with those who remained on tamoxifen (139/452; 30.8%).
- This difference was mainly due to a greater number of patients in the tamoxifen group with serious endometrial events (OR =0.66; 95% CI, 0.49 -0.89; P =0.0065)

Rasmussen BB., Regan MM., Lykkesfeldt AE., Dell'Orto P., Del CB., Henriksen KL., Mastropasqua MG., Price KN., Mery E., Lacroix-Triki M., Braye S., Altermatt HJ., Gelber

RD., Castiglione-Gertsch M., Goldhirsch A., Gusterson BA., Thurlimann B., Coates AS., Viale G and Collaborative and International Breast Cancer Study Groups. (2008) Adjuvant letrozole versus tamoxifen according to centrally-assessed ERBB2 status for postmenopausal women with endocrine-responsive early breast cancer: supplementary results from the BIG 1-98 randomised trial.[see comment]. *Lancet Oncology* **9**: 23-28

**Design:** RCT(subset report of BIG1-98 trial), Evidence level 1+

**Country:** International

**Aim:** To evaluate the benefit of letrozole versus tamoxifen according to the ERBB2 status of tumours.

**Inclusion criteria**

postmenopausal women with early breast cancer whose tumours were assessed by local pathologists as either ER-positive or PgR-positive, or both.

**Exclusion criteria**

**Population**

8010 patients randomised → 3650 (117 excluded absent or not assessable .:3533)centrally assessed as having ER present tumours→1782 in letrozole group / 1751 in tamoxifen group

**Interventions**

The BIG 1-98 trial consists of four treatment groups that compare 5 years of monotherapy with letrozole or tamoxifen, and sequential administration of one drug for 2 years followed by the other drug for 3 years.

**Outcomes**

Tumour assessment and associations with DFS and treatment group.

**Results**

- 7% of patients (257 of 3650) tumours were identified to be ERBB2-positive.

Patients with ERBB2-positive tumours were:

- younger than those with ERBB2-negative tumours ( $p=0.04$ ) and were
- treated more frequently with mastectomy ( $p=0.005$ ) and
- treated more frequently with chemotherapy ( $p<0.0001$ ).

- ERBB2-positivity was associated with larger tumour size and higher tumour grade (both  $p<0.01$ ), but not with positive lymph-node status ( $p=0.10$ ), and was associated with lower ER and PgR expression (both  $p<0.0001$ )

Association of ERBB2 status and treatment with DFS in endocrine-responsive disease were based to the 3533 patients who had ER-present tumours assessed.

ERBB2 status was shown to be associated with DFS;

- 6.8% patients whose tumours were ERBB2-positive had a poorer outcome than those whose tumours were ERBB2-negative (HR= 2.09, 95% CI 1.59–2.76;  $p<0.0001$ ),
- Estimated 4-year DFS of 75% (95% CI 68–80) ERBB2-positive and 88% (87–89) ERBB2-negative
- Letrozole improved DFS compared with tamoxifen regardless of ERBB2 status (ERBB2-positive tumours: HR 0.62 (95% CI 0.37–1.03); ERBB2-negative tumours: HR 0.72 (0.59–0.87))

- PgR status of the tumour was associated with DFS ( $p < 0.0001$ ), but no statistical evidence of heterogeneity in the treatment effect existed ( $p = 0.47$  for interaction); suggesting a consistent benefit of letrozole over tamoxifen regardless of PgR expression.
- When heterogeneity of the treatment effect according to PgR and ERBB2 status of the tumour was investigated; there was no statistically significant interaction ( $p = 0.63$ ), suggesting improved DFS with letrozole compared with tamoxifen, regardless of PgR or ERBB2 status.

Crivellari D., Sun Z., Coates AS., Price KN., Thurlimann B., Mouridsen H., Mauriac L., Forbes JF., Paridaens RJ., Castiglione-Gertsch M., Gelber RD., Colleoni M., Lang I., Del ML., Gladiëff L., Rabaglio M., Smith IE., Chirgwin JH and Goldhirsch A (2008) Letrozole compared with tamoxifen for elderly patients with endocrine-responsive early breast cancer: the BIG 1-98 trial. *J Clin Oncol* **26**: 1972-1979

**Design:** RCT: sub-study of BIG1-98 trial

**Country:** International

**Aim:** To evaluate the differences in efficacy, treatment completion, and adverse events (AEs) in elderly women receiving adjuvant tamoxifen or letrozole for five years in the Breast International Group (BIG) 1-98 trial.

**Inclusion criteria**

postmenopausal women with hormone receptor-positive breast cancer

**Exclusion criteria**

**Population**

2,463 to letrozole group

2,459 to tamoxifen group

**Interventions**

Women were randomly assigned in a phase III, double-blind trial to one of the four following treatment regimens:

1. tamoxifen for 5 years,
  2. letrozole for 5 years,
  3. tamoxifen for 2 years followed by letrozole for 3 years,
  4. letrozole for 2 years followed by tamoxifen for 3 years.
- The current analysis focuses on the 4,922 patients randomly assigned to the two monotherapy arms.
  - The median follow-up was 40.4 months.

**Outcomes**

- disease-free survival (DFS): defined as the time from random assignment to the first of the following events ending DFS
- recurrence: at local, regional, or distant sites; a new invasive cancer in the contralateral breast; any second, non-breast cancer; or death without a prior cancer event.
- Subpopulation Treatment Effect Pattern Plot (STEPP) analysis was used to investigate the pattern of difference in 4-year DFS between treatment arms according to patient age at study entry.
- AEs were limited to the safety population (n=4,895) which excluded 27 patients who did not receive any trial treatment and included: any non-fracture AE, bone fractures, thromboembolic AEs, any cardiac AE, and ischemic cardiac events.

**Results**

**DFS:**

In the overall population, letrozole was more efficacious than tamoxifen (P =0.006), and this superiority was similar across the age spectrum and not significantly influenced by age (interaction of age and treatment, P=0.84).

**Adverse Events:**

The incidence of bone fractures, observed more often in the letrozole group, did not differ by age. In elderly patients, letrozole had a significantly higher incidence of any grade 3 to 5 protocol-specified non-fracture AE compared with tamoxifen ( $P = 0.002$ ), but differences were not significant for thromboembolic or cardiac AEs.

- There were no statistically significant differences between the two treatment groups for any of the risk factor categories.
- When the cumulative incidence of first non-fracture grade 3 to 5 adverse event with DFS as competing events, was evaluated it was found that there was a significantly earlier occurrence of grade 3 to 5 non-fracture AE in elderly patients (75 years and older) receiving letrozole ( $P = 0.002$ ).

**Fracture Rate:**

- Incidence of bone fractures was higher among patients treated with letrozole (8.0% let. group v 5.4% receiving tamoxifen;  $P < 0.001$ ).
- Risk factors for bone fractures (grade 1 to 5) during treatment were statistically significant for: smoking history ( $P = 0.006$ ) and prior bone fracture ( $P < 0.0001$ ).

**Cardiovascular AEs:**

- In the total population, thromboembolic events of any grade were less frequently reported in women treated with letrozole (2.0% in let. group v 3.8% receiving tamoxifen;  $P < 0.0001$ ).
- After adjusting for risk factors, the treatment difference in time to first thromboembolic event observed for the two younger age groups was less pronounced in the elderly groups
- Risk factors that were statistically significant for thromboembolic events during treatment were: higher Baseline BMI ( $P = 0.008$  for grade 1 to 5;  $P = 0.0005$  for grade 3 to 5) and prior thromboembolic events ( $P < 0.0001$  for grade 1 to 5 and for grade 3 to 5).
  
- The overall incidence of cardiac events (grade 1 to 5) was similar in the two treatment groups (letrozole 5.7% v tamoxifen 5.2%;  $P = 0.45$ ).
- After adjusting for risk factors, a significant difference favouring tamoxifen was observed in the older age group (65 to 74 years) but not in the elderly group ( $\geq 75$  yrs).
- A statistically significant difference was reported for risk factors for cardiac events during treatment included history of hypertension ( $P = 0.02$  for grade 3 to 5), and prior cardiac events ( $P < 0.0001$  for grade 1 to 5;  $P < 0.0001$  for grade 3 to 5).
  
- The overall incidence of ischemic heart events (grade 1 to 5) was similar in the two groups (letrozole, [2.2%] v tamoxifen, [1.8%];  $P = 0.42$ ).
  
- After adjusting for risk factors, a significant difference in time to first grade 3 to 5 ischemic heart event favouring tamoxifen was observed in the older age group (65 to 74 years) but not in the younger cohort ( $< 65$  years) or elderly group.
- Statistically significant risk factors for ischemic heart events during treatment included history of hypertension ( $P = 0.04$  for grade 1 to 5;  $P = 0.001$  for grade 3 to 5), and prior ischemic heart events ( $P < 0.0001$  for grade 1 to 5;  $P < 0.0001$  for grade 3 to 5)

Muss HB., Tu D., Ingle JN., Martino S., Robert NJ., Pater JL., Whelan TJ., Palmer MJ., Piccart MJ., Shepherd LE., Pritchard KI., He Z and Goss PE (2008) Efficacy, toxicity, and quality of life in older women with early-stage breast cancer treated with letrozole or placebo after 5 years of tamoxifen: NCIC CTG inter group trial MA.17. *J Clin Oncol* 26: 1956-1964

**Design:** RCT subset study, Evidence Level 1+

**Country:** Canada

**Aim:** To determine whether there were age-dependent differences in DFS, DDFS, and OS toxicity, or QOL among older and younger patients in the MA.17 RCT which tested the efficacy of letrozole compared to placebo in postmenopausal patients who were disease free after 5 years of tamoxifen.

**Inclusion criteria**

See original report of trial

**Exclusion criteria**

**Population**

5,169 randomly assigned patients were divided into three age groups:

1. younger than 60 years (n = 2,152)
2. 60 to 69 years (n = 1,694)
3. 70 years (n ≥ 1,323)

**Interventions**

letrozole (2.5 mg oral) or placebo for 5 years and stratified by hormone-receptor status, nodal involvement, and chemotherapy use.

**Outcomes**

- DFS
- distant-disease-free survival: DDFS
- OS
- Toxicity: QOL: Medical Outcomes Short Form 36-item general health questionnaire (SF-36), a multipurpose QOL measure.

**Results**

**Age outcomes:**

- There was no significant difference in DFS and DDFS between the three age groups.
- OS was significantly different between these three age groups due to an increased risk of non-breast cancer-related death with increasing age (with results remain the same after adjusting for other potential prognostic factors such as letrozole or placebo treatment, duration of prior tamoxifen, nodal status, and prior chemotherapy).

**Treatment outcomes:**

- Letrozole significantly improved both DFS and DDFS but only in women younger than 60 years of age (HR = 0.46; P = 0.0004)
- The interaction between age and treatment was not statistically significant for any of the outcomes (DFS, P =0.36; DDFS, 0.77, and OS, 0.98), indicating no evidence of a heterogeneous effect of letrozole among age groups (or a similar effect of letrozole among all age groups).
- Letrozole stats. significantly improved DFS compared with placebo for both node-negative and node-positive patients younger than 60 years (p=0.024) and for patients with negative

nodes  $\geq 70$  years old ( $p=0.021$ ).

- In node-positive patients: letrozole compared with placebo led to a significant improvement in DDFS in those age 60 to 69 years (HR = 0.39,  $P=0.009$ ) and a significant improvement in OS for those age  $\geq 70$  years (HR= 0.50,  $P= 0.038$ )

**QoL:**

- Women  $\geq 70$  years of age had significantly higher incidences of oedema, hypertension, fatigue, anorexia, constipation, diarrhoea, arthritis, dizziness, and dyspnoea but lower incidences of hot flushes, sweating, vaginal bleeding, high cholesterol, insomnia, headache, and vaginal dryness compared with younger women.
- Compared with placebo, women receiving letrozole who were younger than 60 years had a significantly lower incidence of vaginal bleeding ( $P=0.007$ ) and higher incidence of arthralgia ( $P<0.001$ )
- Women on letrozole 60 to 69 years had a statistically significantly higher incidence of hot flushes( $P=0.003$ ), insomnia ( $P=0.14$ ), arthralgia ( $P=0.005$ ), and alopecia ( $P=0.03$ ).
- Women  $\geq 70$  years had no significant difference in toxicities between the letrozole and placebo groups.
- There was no difference in toxicity or QOL at 24 months in the letrozole group and placebo group for patients  $\geq 70$  years age.

Author's recommend that "healthy patients age 70 years and older completing 5 years of tamoxifen should be considered for extended adjuvant therapy with letrozole."

Eisen, A., Trudeau, M., Shelley, W., Messersmith, H., Pritchard, K. (2008) Aromatase Inhibitors in adjuvant therapy for hormone receptor positive breast cancer: A systematic review. <i>Cancer Treatment Reviews</i> 34; 157-174
<b>Design:</b> Systematic Review
<b>Country:</b> Canada
<b>Aim:</b> To review the evidence for the use of third generation AI's as adjuvant therapy for post-menopausal women with early stage, hormone receptor-positive breast cancer.
<b>Inclusion criteria</b> Randomised trials or meta-analyses evaluating third generation aromatase inhibitors (AI's) as adjuvant therapy and including the primary outcomes disease/event/relapse-free survival and/or overall survival.
<b>Exclusion criteria</b> <ul style="list-style-type: none"> <li>• Non English language trials</li> <li>• Trials with no efficacy outcomes</li> </ul>
<b>Population</b> Nine randomised trials One systematic review
<b>Interventions:</b> AI's compared with Tamoxifen, placebo or Tamoxifen + AI's in sequence.
<b>Outcomes</b> <ul style="list-style-type: none"> <li>• AI's compared with Tamoxifen for five years in relation to clinical outcomes such as disease free or overall survival.</li> <li>• AI's in sequence with Tamoxifen for a total of five years compared with Tamoxifen alone outcomes such as disease free or overall survival.</li> <li>• AI's following five years Tamoxifen compared with placebo outcomes such as disease free or overall survival.</li> <li>• The harms associated with AI's compared with Tamoxifen or placebo</li> <li>• Do the relative efficacies of AI's compared with Tamoxifen depend on HER2/neu status?</li> </ul>
<b>Results</b> <u>Summary</u> Aromatase Inhibitors are consistently associated with longer disease free survival than treatment with Tamoxifen alone with only one of nine trials reviewed not reporting significantly longer disease free survival, an effect that appears to be independent of the way in which the aromatase inhibitor is administered (i.e. alone or in sequence with Tamoxifen). There is inconsistency in the effects of aromatase inhibitors on overall survival however with

some studies reporting a significant effect in favour of aromatase inhibitors and others reporting no differences. This may be due to a number of factors such as follow-up durations or possibly the trials do not have sufficient power to detect difference in overall survival. Across the majority of trials similar effects on lipid profile were observed with Tamoxifen associated with decreased total cholesterol and LDL cholesterol and increased triglycerides while upfront therapy with aromatase inhibitors was associated with no or minimum lipid changes.

Treatment with Tamoxifen is consistently associated with an increased rate of thromboembolic events and a greater incidence of endometrial cancer.

#### Aromatase Inhibitors alone versus Tamoxifen alone

Two trials reported on 5 year AI's versus Tamoxifen alone; **the ATAC trial** (anastrozole) and **the BIG 1-98 trial** (letrozole).

In the **ATAC trial** at 68 months follow-up intention-to-treat analysis showed significantly improved disease free survival (HR: 0.87; 95% CI: 0.78-0.97) , time to recurrence (HR: 0.79; 95% CI: 0.7-0.9) and time to distant recurrence (HR: 0.86; 95% CI: 0.74-0.99) for anastrozole over Tamoxifen. Overall survival was similar for both groups.

In the **BIG 1-98 trial** at 51 months follow-up disease free survival favoured letrozole over Tamoxifen (HR: 0.82; 95% CI: 0.71-0.95) but no significant benefit for overall survival. Time to recurrence (HR: 0.78; 95% CI: 0.66-0.93) and time to distant recurrence (HR: 0.81; 95% CI: 0.67-0.98) both favoured letrozole over Tamoxifen.

#### Aromatase Inhibitors after Tamoxifen versus Tamoxifen alone

In the **IES** study, women who have completed two or three years Tamoxifen were randomised to receive exemestane or further Tamoxifen for a total of five years. At 55.7 months follow-up there was an improvement in disease free survival (HR: 0.76; 95% CI: 0.66-0.88) but not in overall survival. Time to contralateral breast cancer (HR: 0.57; 95% CI: 0.33-0.98), time to recurrence (HR: 0.70; 95% CI: 0.58-0.83) and time to distant recurrence (HR: 0.83; 95% CI: 0.71-0.99) were significantly improved with exemestane.

In the **ITA trial**, women who had received two or more years of Tamoxifen were randomised to receive anastrozole or to continue Tamoxifen for a total of five years treatment. At 64 months median follow-up there were significant improvements in disease free survival (HR: 0.57; 95% CI: 0.38-0.85) in favour of anastrozole but no difference in overall survival.

The interim results of the **ABCSG-8** and **ARNO-95** trials were combined with survival analysis conducted beginning at completion of two years Tamoxifen. At 28 months median follow-up disease free survival was significantly better in women switching to anastrozole (HR: 0.60; 95% CI: 0.44-0.81) but again there was no difference in overall survival between the two groups.

Analysis of the **ARNO-95** trial data only at 30.1 months median follow-up reported that both disease free survival (HR: 0.66; 95% CI: 0.44-1.00, p=0.049) and overall survival (HR: 0.53; 95% CI: 0.28-0.99, p=0.045) were significantly improved in the Tamoxifen followed by anastrozole arm.

A meta analysis of three trials (**ITA, ABCSG-8 & ARNO-95**) found significant improvement in

disease free survival (HR: 0.59; 95% CI 0.48-0.74,  $p < 0.0001$ ), distant recurrence free survival (HR: 0.61; 95% CI: 0.45-0.83,  $p = 0.002$ ) and overall survival (HR: 0.71; 95% CI 0.52-0.98,  $p = 0.04$ ).

#### Aromatase Inhibitors after five years Tamoxifen

Three trials provided data on the effect of AI's versus placebo following five years Tamoxifen, the National Cancer Institute of Canada **MA 17 trial**, the **NSABP B-33** trial and the **ABCSG 6a** trial.

In the **MA 17** trial patients who had completed five years Tamoxifen were randomised to either five years letrozole or placebo. At 30 months median follow up, women in the letrozole arm reported significantly better disease free survival (HR: 0.58; 95% CI: 0.45-0.75) but not overall survival. In further analyzing the data, there was a significant trend in disease free survival ( $p < 0.0001$ ) and distant disease free survival ( $p < 0.0013$ ) out to 48 months duration in favour of letrozole.

Subgroup analysis showed that there was a significant improvement in overall survival for node-positive patients in the letrozole group (HR: 0.61; 95% CI: 0.38-0.98,  $p < 0.04$ ) at 30 months median follow-up. At 48 months a significant trend for increasing benefit of letrozole was observed for node-positive patients for disease free survival ( $p < 0.0004$ ), distant disease free survival ( $p = 0.0005$ ) and overall survival ( $p = 0.038$ ). In node-negative patients only disease free survival showed a significant trend towards improvement ( $p = 0.027$ ).

The **NSABP B-33 trial** originally intended to randomise women who had received five years Tamoxifen to two years of either exemestane or placebo but was later amended to five years exemestane or placebo. This trial was unblinded and placebo patients were offered exemestane; at 30 months median follow-up no significant difference was observed between the two groups in relation to disease free survival or overall survival, significantly longer relapse-free survival was reported in patients receiving exemestane (HR: 0.50,  $p = 0.03$ ).

The **ABCSG-6a** trial extended the ABCSG-6 trial from five years Tamoxifen versus five year Tamoxifen + aminoglutethimide to anastrozole versus no further treatment following five years Tamoxifen. At 60 months median follow-up the trial found a significant improvement in disease free survival in patients treated with anastrozole after five years Tamoxifen, with or without aminoglutethimide. The results were reported in abstract form and no p-values or point estimates were reported.

#### Harms associated with aromatase inhibitors

In the **ATAC trial** serious adverse events were defined as death, life threatening event, event causing extended hospitalisation, event causing disability or event needing intervention to prevent permanent impairment. Serious adverse events more frequently occurred with Tamoxifen (36%) than with anastrozole (33%,  $p = 0.03$ ). Treatment related adverse events were also more frequent in the Tamoxifen group (9% versus 5%,  $p < 0.0001$ ).

*Three trials and two Tamoxifen and Exemestane Adjuvant Multi-centre (TEAM) sub studies provided data on changes to lipid metabolism associated with aromatase inhibitors.*

In the **BIG 1-98 trial** patients receiving Tamoxifen had lower total cholesterol levels from

baseline while those in the letrozole arm had unchanged levels. 43.6% of the letrozole group had hypercholesterolemia reported at least once during the study as compared with 19.2% of the Tamoxifen group.

The rate of lipid metabolism disorders in the **ITA trial** was significantly lower in the Tamoxifen only group compared with the Tamoxifen followed by anastrozole group ( $p=0.04$ ).

A companion study to the **MA. 17 trial** found no significant difference in a number of lipid parameters between patients receiving letrozole and patients receiving placebo following Tamoxifen.

A lipid sub-study of the **TEAM trial** (currently still open to accrual) measured and compared baseline, three month and six month levels of total cholesterol, HDL cholesterol and LDL cholesterol and showed that at 12 months patients receiving exemestane experienced significantly less change in baseline cholesterol level from baseline than did patients receiving Tamoxifen (median percentage change -1.9% vs. -9.9%  $p=0.039$ ).

No significant differences were observed in HDL cholesterol at any time point for either group. There were significant differences in LDL cholesterol at three months (+4.8% vs. 9.2%,  $p=0.014$ ) and at six months (+8% vs. -9.1%  $p=0.001$ ) with those receiving exemestane having increased levels of LDL while those receiving Tamoxifen had decreased levels from baseline. Triglycerides were lower or unchanged in those receiving exemestane and higher in those receiving Tamoxifen at three months (+0.8% vs. +22.1%,  $p=0.018$ ), six months (-16% vs. +10%  $p=0.008$ ) and nine months (-7.9% vs. +32.6%  $p=0.009$ ); there was no significant difference at 12 months.

A separate **TEAM** sub study included five years anastrozole in addition to the main TEAM five year exemestane and Tamoxifen arms and observed that triglycerides were consistently increased above baseline with Tamoxifen, decreased with exemestane and remained unchanged with anastrozole.

*Bone-related toxicity*

Significantly higher fracture rates were observed for aromatase inhibitors compared with Tamoxifen in the **ATAC, BIG 1-98, IES and ABCSG-8/ARNO-95** studies.

<b>Trial</b>	<b>Treatment</b>	<b>Fractures</b>
ATAC	Anastrozole vs. Tamoxifen	11.0% vs. 7.7%, $p<0.0001$
BIG 1-98	Letrozole vs. Tamoxifen	8.6% vs. 5.8%, $p<0.001$
IES	Tamoxifen followed by exemestane vs. Tamoxifen	7.0% vs. 4.9%, $p=0.003$
ITA	Tamoxifen followed by Anastrozole vs. Tamoxifen	1.0% vs. 1.3%, $p=0.06$
ABCSG-8/ARNO-95	Tamoxifen followed by Anastrozole vs. Tamoxifen	2.0% vs. 1%, $p=0.015$
MA. 17	Tamoxifen followed by Letrozole vs. Tamoxifen followed by placebo	5.3% vs. 4.6%, $p=0.25$

NSABP-33	Tamoxifen followed by Exemestane vs. Tamoxifen followed by placebo	28 fractures vs. 20 fractures, p=0.33
----------	--	---------------------------------------

The **ATAC** study compared rate of fracture by site for anastrozole vs. Tamoxifen finding no significant difference in fracture rates for hip (1.2% vs. 1.0% p=0.5) or wrist/Colles (2.3% vs. 2.0% p=0.4) and significant differences in fracture rates for spine (1.5% vs. 0.9% p=0.03) and all other fractures (7.1% vs. 4.6% p<0.0001).

Two sub-studies from the **ATAC trial** reported in abstract form. The first sub study examined patterns of time to fracture between anastrozole and Tamoxifen in the ATAC trial up to five years and found that time to fracture was worse for women taking anastrozole compared with Tamoxifen.

The second study examined the impact of anastrozole vs. Tamoxifen on bone mineral density. Lumbar spine and total hip bone mineral density were measured and anastrozole was associated with decreases in both lumbar spine (percentage decrease in bone mineral density on anastrozole compared with Tamoxifen; -8.1% [95% CI -10.1% to -6.1%, p<0.0001]) and total hip (percentage decrease in bone mineral density on anastrozole compared with Tamoxifen; -7.4% [95% CI -9.6% to -5.3%, p<0.0001) bone mineral density loss at five years. No patient with normal baseline bone mineral density had osteoporosis at five years.

A sub-study associated with the MA.17 trial observed changes in baseline bone mineral density in patients treated with letrozole vs. placebo. Patients on letrozole had significantly greater decrease in total hip bone mineral density (-3.6% vs. -0.71%, p=0.008) and in lumbar spine bone mineral density (-5.35% vs. -0.70%, p=0.044) compared with those on placebo. No significant difference in the rate of osteoporosis was observed in lumbar spine or total hip. Post unblinding, more patients that crossed over to letrozole experienced new osteoporosis than those that did not cross over (~4.0% vs. ~1.5% p=0.007).

### Gynaecological Toxicity

Trial	Treatment	Gynaecological toxicity (including endometrial cancer)
ATAC	Anastrozole vs. Tamoxifen	<ul style="list-style-type: none"> <li>Vaginal bleeding: 5.4 vs. 10.2%, p&lt;0.0001</li> <li>Vaginal discharge: 3.5% vs. 13.2%, p&lt;0.0001</li> <li>Endometrial cancer: 0.2% vs. 0.8%, p=0.02</li> </ul>
BIG 1-98	Letrozole vs. Tamoxifen	<ul style="list-style-type: none"> <li>Vaginal bleeding: 3.8% vs. 8.3%, p&lt;0.001</li> <li>Endometrial biopsies: 2.3% vs. 9.1%, p&lt;0.001</li> <li>Invasive endometrial cancer: 0.1% vs. 0.3%, p=0.18</li> </ul>
IES	Tamoxifen followed by exemestane vs. Tamoxifen	<ul style="list-style-type: none"> <li>Serious gynaecological events: 7.0% vs. 10.6%, p=0.0001</li> <li>Vaginal bleeding: 5.2% vs. 7.6%, p=0.002</li> </ul>

		<ul style="list-style-type: none"> <li>• Vaginal discharge: 3.1% vs. 4.1%, p=0.06</li> <li>• Endometrial hyperplasia: 0.2% vs. 1.2%, p=0.0002</li> <li>• Uterine polyps/fibroids: 1.6% vs. 4.6%, p&lt;0.0001</li> <li>• Endometrial cancer: No significant difference</li> </ul>
ITA	Tamoxifen followed by Anastrozole vs. Tamoxifen	<ul style="list-style-type: none"> <li>• Gynaecological symptoms: 7.4% vs. 8.0%, p=0.5</li> <li>• Gynaecological changes (including endometrial carcinoma): 1.0% vs. 11.3%, p=0.0002</li> </ul>
ABCSG-8/ARNO-95	Tamoxifen followed by Anastrozole vs. Tamoxifen	<ul style="list-style-type: none"> <li>• Endometrial cancer: &lt;1% vs. &lt;1%, p=0.069</li> <li>• Vaginal bleeding/discharge (ABCSG-8 only): 18% vs. 17%, p=0.9348</li> </ul>
MA. 17	Tamoxifen followed by Letrozole vs. Tamoxifen followed by placebo	<ul style="list-style-type: none"> <li>• Vaginal bleeding: 6% vs. 8%, p=0.005</li> <li>• Endometrial cancer: 4 pts vs. 11 pts, p=0.12</li> </ul>

A sub-study of the ATAC trial (n=271), reporting in abstract form, observed that abnormalities in the anastrozole and Tamoxifen groups at six years were 27% and 44% respectively (OR: 0.52, 95% CI 0.20-1.32, p=0.17).

Median endometrial thickness was unchanged from baseline in the anastrozole group but had increased in the Tamoxifen group.

A second sub-study of the ATAC trial observed rates of endometrial cancer were lower than expected in the anastrozole group (standardised incidence rate ratio 0.73, 95% CI: 0.15-2.12) while in the Tamoxifen group they were higher than expected (standardised incidence rate ratio 2.68, 95% CI: 1.34-4.8).

### *Menopausal symptoms*

A number of menopausal symptoms were assessed across the trials; the table outlines the significant results from the different trials.

<b>Trial</b>	<b>Treatment</b>	<b>Menopausal Symptoms</b>
ATAC	Anastrozole vs. Tamoxifen	<ul style="list-style-type: none"> <li>• Hot flashes: 35.7% vs. 40.9%, p&lt;0.0001</li> <li>• Arthralgia: 35.6% vs. 29.4%, p&lt;0.0001</li> </ul>
BIG 1-98	Letrozole vs. Tamoxifen	<ul style="list-style-type: none"> <li>• Hot flashes: 32.8% vs. 37.4%, p&lt;0.001</li> <li>• Arthralgia: 20% vs. 13.5%, p&lt;0.001</li> </ul>
IES	Tamoxifen followed by exemestane vs. Tamoxifen	<ul style="list-style-type: none"> <li>• Insomnia: 20.8% vs. 18.2%, p&lt;0.03</li> <li>• Arthralgia: 20.8% vs. 15.1%, p&lt;0.0001</li> <li>• Arthritis: 17.5% vs. 14.6%, p=0.008</li> <li>• Muscle pain: 25.7% vs. 20.3%, p&lt;0.0001</li> </ul>
MA. 17	Tamoxifen followed by Letrozole vs. Tamoxifen followed by placebo	<ul style="list-style-type: none"> <li>• Hot flashes: 58% vs. 54%, p=0.003</li> <li>• Arthralgia: 25% vs. 21%, p&lt;0.001</li> <li>• Muscle pain: 15% vs. 12%, p=0.004</li> </ul>

In the **TEAM trial** menopausal symptoms were assessed during the first year of exemestane of Tamoxifen in 997 patients. Vaginal dryness ( $p=0.0004$ ), impaired word finding ( $p=0.0057$ ), bone/muscle aches ( $p<0.0001$ ), decreased libido ( $p=0.0343$ ) and difficulty sleeping ( $p=0.0346$ ) were worse in the exemestane group while vaginal discharge ( $p<0.0001$ ) and hot flashes ( $p=0.0253$ ) were worse in the Tamoxifen group.

#### *Quality of Life*

The **ATAC, MA.17, IES and NSAS BC 03 trials** and the **TEAM trial NSAS BC 04 sub study** reported on quality of life issues

In the **ATAC trial** 1021 patients were evaluated with quality of life measurements made at baseline, three months, six months and every six months thereafter. There was no significant difference in the Treatment Outcomes Score between anastrozole and Tamoxifen. All groups showed an improvement in the TOI scores at baseline and three months.

In the **MA.17 trial** 3582 patients were evaluated with measurements made at baseline, six months, twelve months and every twelve months thereafter. There was no significant difference in mean change scores between the letrozole and placebo groups.

No clinically meaningful differences were found between treatment arms in the **IES trial**.

The **NSAS BC 03** patients receiving Tamoxifen reported significantly better quality of life compared with those receiving anastrozole ( $p=0.012$ ).

The **TEAM sub study NSAS BC 04** showed no significant difference in quality of life issues between the three arms.

#### Effect of HER2/neu status

There was no evidence identified regarding the relative efficacy of any aromatase inhibitor compared with Tamoxifen when analysed by HER2/neu status.

#### **General comments**

All major trials under review were multi-centre trials with all but two reporting appropriate methods of randomisation.

All major trials, with the exception of three, reported double blinding; two trials were open label and one trial did not report on blinding.

All trials were sufficiently powered

#### Details of Coombes 2007

Coombes, L S Kilburn, C F Snowdon, R Paridaens, R E Coleman, S E Jones, J Jassem, C J H Van de Velde, T Delozier, I Alvarez, L Del Mastro, O Ortmann, K Diedrich, A S Coates, E Bajetta, S B Holmberg, D Dodwell, E Mickiewicz, J Andersen, P E Lønning, G Cocconi, J Forbes, M Castiglione, N Stuart, A Stewart, L J Fallowfield, G Bertelli, E Hall, R G Bogle, M Carpentieri, E Colajori, M Subar, E Ireland, J M Bliss, on behalf of the Intergroup Exemestane Study\* (2007) Survival and safety of exemestane versus tamoxifen after 2–3 years' tamoxifen treatment (Intergroup Exemestane Study): a randomised controlled trial. *Lancet*; 369: 559–70

#### **Disease-Free Survival**

Overall in the ITT group:

- unadjusted hazard ratio (HR) for disease-free survival = 0.76 (95% CI 0.66–0.88;  $p=0.0001$ ) - in favour of exemestane. Translating to a 3.3% (95% CI 1.6–4.9) absolute improvement in

disease-free survival at 2.5 years after randomisation, and a 3.4% (0.1–6.8) improvement 5 years after randomisation.

- Both node positive and node negative were in favour of exemestane with respect to improved disease-free survival
- ER+ and ER+PgR+ were in favour of exemestane
- ER+PgR– and ER unknown both did not have a significant difference b/n exe and tamoxifen
- Age 60–69 years favoured exemestane

In the oestrogen-receptor-positive and oestrogen-receptor-unknown group, very similar results were obtained, with a HR = 0.75 (95% CI 0.65–0.87; p=0.0001). For the oestrogen-receptor-positive and oestrogen-receptor unknown group, the absolute improvement at 2.5 years = 3.5% (95% CI 1.8–5.1) and at 5 years = 3.5% (0.1–6.9).

### **Overall survival**

Adjusting for potential confounders:

- ITT analysis: HR= 0.85 95% CI 0.71–1.01); p=0.07;
- Oestrogen-receptor-positive and oestrogen-receptor-unknown group: HR= 0.83, 0.69–0.99; p=0.04

### **Overall conclusions:**

Findings suggest that early improvements in disease-free survival noted in patients who switch to exemestane after 2–3 years on tamoxifen persist after treatment, and translate into a modest improvement in overall survival.

### 5.3 Is there an indication for the use of tamoxifen after excision of pure DCIS?

#### Short Summary

There is evidence from one placebo controlled RCT that in patients treated for DCIS with lumpectomy and adjuvant radiotherapy, adjuvant tamoxifen reduces the risk of ipsilateral local recurrence by 30% and contralateral breast cancer by 50%. The risk at 5 years of any breast cancer event in the tamoxifen arm was 8% and in the placebo arm, 13% (NSABP B-24 trial-Fisher *et al.* 1999). One subsequent RCT with a less rigorous design found no similar benefit arising from Tamoxifen (UKCCCR trial-Houghton *et al.* 2003).

The NSABP B-24 trial found that tamoxifen and radiotherapy improved disease free survival at 5 years (87%), compared to placebo and radiotherapy (83%), but with no difference between groups for overall survival.

The UKCCCR trial examined the use of tamoxifen versus no adjuvant therapy following complete local excision of DCIS (without radiotherapy) and found no benefit arising from Tamoxifen, except in terms of subsequent DCIS in either breast, this risk was reduced by 30%. The risk of any breast event in the Tamoxifen arm at 56 months was 12% (UKCCCR) and in the control arm, 15%.

#### PICO

Population	Intervention	Comparison	Outcome
Women who have had complete surgical excision of pure DCIS	Tamoxifen	No Tamoxifen Radiotherapy	<ul style="list-style-type: none"><li>• Local Control</li><li>• Reduction in contralateral primary tumors/recurrence</li></ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

#### Evidence Summary

The body of evidence for this question comes from high quality systematic reviews and RCTs, however they have limited applicability; a small number of observational studies were included but add little to the RCTs.

There is some variation in the study design of the RCTs though the studies are consistent with regard to their results: For outcomes where data exists from both studies, the confidence intervals overlap and the overall estimate of effect tends to favour Tamoxifen, although this finding is not always statistically significant.

There is evidence from one placebo controlled RCT that in patients treated for DCIS with lumpectomy and adjuvant radiotherapy, adjuvant Tamoxifen reduces the risk of ipsilateral local recurrence by 30% and contralateral breast cancer by 50%. The risk at 5 years of any breast cancer event in the tamoxifen arm was 8% and in the placebo arm, 13% (NSABP B-24). One subsequent RCT with a less rigorous design found no similar benefit arising from Tamoxifen (UKCCCR).

The NSABP B-24 trial found that tamoxifen and radiotherapy improved disease free survival at 5 years (87%), compared to placebo and radiotherapy (83%), but with no difference between groups for overall survival.

The UKCCCR trial examined the use of tamoxifen versus no adjuvant therapy following complete local excision of DCIS (without radiotherapy) and found no benefit arising from tamoxifen, except in terms of subsequent DCIS in either breast: this risk was reduced by 30%. The risk of any breast event in the Tamoxifen arm at 56 months was 12% (UKCCCR) and in the control arm, 15%.

### 1. Adjuvant Tamoxifen versus no adjuvant therapy

(Note: this data was also reported for Question 4)

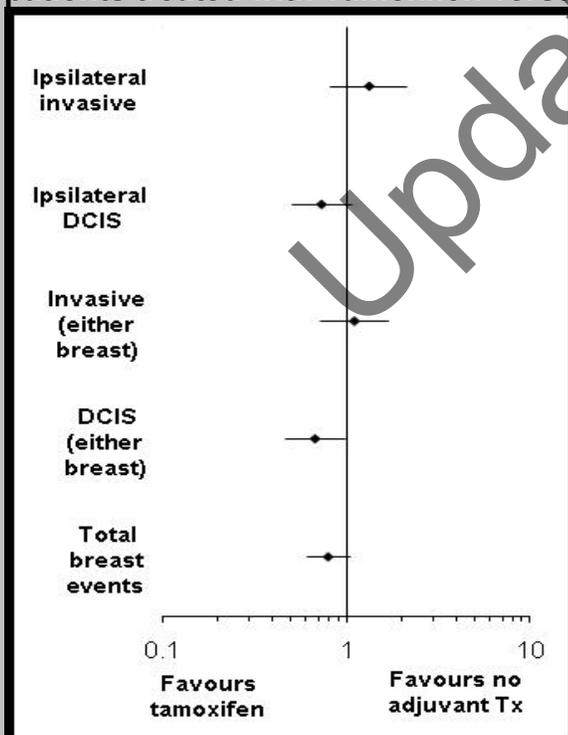

#### Local recurrence

One RCT provided a subgroup analysis of the effect of adjuvant Tamoxifen versus no adjuvant therapy in 1053 patients treated for DCIS with primary complete local excision, who did not receive radiotherapy (Houghton *et al.* 2003). Within this subgroup there was no difference between randomised arms in the incidence of ipsilateral invasive recurrence or ipsilateral DCIS (Figure 1).

#### Contralateral breast cancer

This study did not analyse the rate of contralateral breast events alone in this subgroup. Analysing events in either breast together, there was no difference in the incidence of total breast tumours (invasive plus DCIS) or invasive tumours alone. However there were statistically significantly fewer recurrent DCIS tumours in the Tamoxifen arm compared to the control arm (Figure 1). This study did not analyse survival.

**Figure 1: Data from UKCCCR trial subgroup analysis (n=1053): Breast recurrence in patients treated with Tamoxifen versus no adjuvant therapy (Fisher *et al.* 1999)**

Notes:

1. Method used to generate Forest plot: Clark O; Djulbegovic B. Forest plots in excel software (Data sheet). 2001. Available at [www.evidencias.com](http://www.evidencias.com)

## 2. Follow-up: 4.7 years

Breast event	Rate of breast event (%)		Hazard ratio: Tamoxifen:Control (95% CI)	p value
	Tamoxifen n	No adjuvant Tx		
Ipsilateral invasive recurrence	5	4	1.32 (0.81-2.14)	0.26
Ipsilateral DCIS	6	9	0.73 (0.51-1.06)	0.10
Total invasive tumours (either breast)	5	5	1.11 (0.72-1.72)	0.64
Total DCIS tumours (either breast)	6	10	0.68 (0.47-0.97)	0.03
Total breast events	12	15	0.80 (0.61-1.05)	0.11

## 2. Adjuvant Tamoxifen and radiotherapy

Two RCTs investigated disease related events in patients treated for DCIS with breast conserving surgery, who then received combinations of adjuvant Tamoxifen and radiotherapy (Fisher *et al.* 1999; Houghton *et al.* 2003);

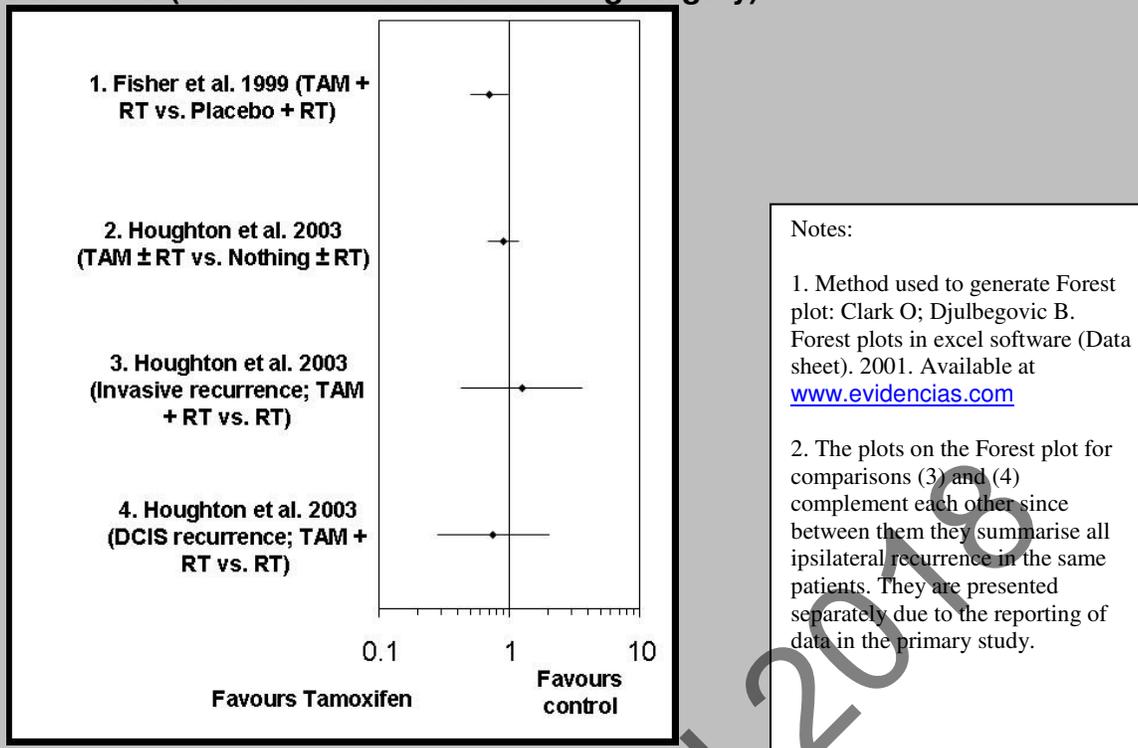

### Local recurrence

The NSABP-B24 trial randomised patients treated by lumpectomy for DCIS to radiotherapy plus Tamoxifen or radiotherapy plus placebo (Fisher *et al.* 1999). The rate of ipsilateral (invasive plus non-invasive) local recurrence at 5 years was statistically significantly lower in the Tamoxifen arm than in the control arm (Figure 2). This difference was also statistically significant for invasive recurrence alone but not for non-invasive recurrence alone. An update of the NSABP B-24 trial reporting data at 7 years follow-up reported a similar result (Fisher *et al.* 2001).

The UKCCCR trial used a 2x2 factorial design to examine the individual effects of Tamoxifen and radiotherapy following complete local excision of DCIS (Houghton *et al.* 2003). In the analysis of patients randomised to Tamoxifen or control, a proportion of patients received radiotherapy in addition (34.3% and 32.1% respectively). There was little difference in the rate of ipsilateral (invasive plus DCIS) local recurrence at a median follow-up period of 4.7 years between randomised arms (Figure 2), and also when considering only invasive recurrence or DCIS recurrence.

This study provided also a sub-group analysis for 523 patients randomised with regard to Tamoxifen, all of whom received radiotherapy. Data were presented for invasive recurrence and DCIS recurrence separately, and there was little difference in risk of ipsilateral recurrence between randomised arms (Figure 2).

**Figure 2: Ipsilateral local recurrence following adjuvant Tamoxifen and radiotherapy to treat DCIS (after initial breast conserving surgery)**

No.	Study	Ipsilateral event	Treatment in Tamoxifen arm	Treatment in control arm	Follow-up	Ratio	Value: Tamoxifen:Control (95% CI)
1	NSABP B-24 (Fisher <i>et al.</i> 1999)	Recurrence	Tamoxifen + RT	Placebo + RT	5 years	Rate ratio	0.70 (0.50-0.98)
2	UKCCCR (Houghton <i>et al.</i> 2003)	Recurrence	Tamoxifen (+ RT in 34.3% of patients)	No Tamoxifen (+ RT in 32.1% of patients)	4.7 years	Hazard ratio	0.90 (0.69-1.17)
3	UKCCCR (Houghton <i>et al.</i> 2003)	Invasive recurrence	Tamoxifen + RT	RT	4.7 years	Hazard ratio	1.25 (0.43-3.61)
4	UKCCCR (Houghton <i>et al.</i> 2003)	DCIS recurrence	Tamoxifen + RT	RT	4.7 years	Hazard ratio	0.75 (0.28-2.02)

### **Contralateral breast cancer**

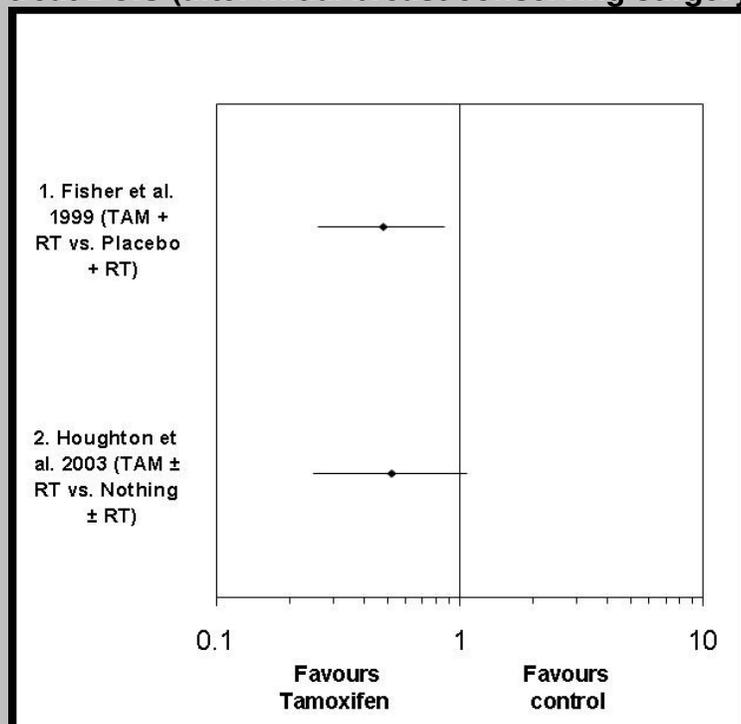

Data from the NSABP B-24 RCT demonstrates that tamoxifen reduces the occurrence of tumours in the contralateral breast in patients treated with lumpectomy and adjuvant radiotherapy (Fisher *et al.* 1999).

This trial randomised patients treated initially for DCIS with lumpectomy to either radiotherapy plus tamoxifen or radiotherapy plus placebo. At a median follow-up duration of 6.2 years there was a statistically significantly lower rate of contralateral (invasive + non-invasive) breast cancer events in the Tamoxifen arm compared to the control arm (Figure 3). A similar, statistically significant effect was observed for non-invasive contralateral breast events alone, but a similar trend for invasive contralateral breast events alone did not achieve statistical significance. Updated data at 7 years follow-up maintained these results with no marked changes (Fisher *et al.* 2001).

The UKCCCR trial (Houghton *et al.* 2003) provided within a 2X2 factorial design, a randomised comparison of tamoxifen versus control (no tamoxifen), where a proportion of patients in each arm received radiotherapy in addition (34.3% and 32.1% respectively). There was no statistically significant difference between tamoxifen and control for the incidence of contralateral (DCIS plus invasive ) breast events (Figure 3). There was also no statistically significant difference in incidence of contralateral invasive events alone, and the study did not analyse contralateral DCIS events alone. This study did not analyse contralateral breast events in the subgroup of patients randomised with regard to tamoxifen who received in addition radiotherapy. Although statistical significance was not always reached, in both of these RCTs the direction of the effect for all analyses of contralateral breast events was in favour of tamoxifen over control.

Updated 2018

**Figure 3: Contralateral breast events following adjuvant Tamoxifen and radiotherapy to treat DCIS (after initial breast conserving surgery)**

Method used to generate Forest plot: Clark O; Djulbegovic B. Forest plots in excel software (Data sheet). 2001. Available at [www.evidencias.com](http://www.evidencias.com)

No.	Study	Treatment in Tamoxifen arm	Treatment in control arm	Follow-up	Ratio	Value: Tamoxifen:Control (95% CI)
1	NSABP B-24 (Fisher <i>et al.</i> 1999)	Tamoxifen + RT	Placebo + RT	5 years	Rate ratio	0.48 (0.26-0.87)
2	UKCCCR (Houghton <i>et al.</i> 2003)	Tamoxifen (+ RT in 34.3% of patients)	No Tamoxifen (+ RT in 32.1% of patients)	4.7 years	Hazard ratio	0.52 (0.25-1.07)

### Disease-free survival

The NSABP B-24 trial randomised patients treated by lumpectomy for DCIS to radiotherapy plus Tamoxifen or radiotherapy plus placebo (Fisher *et al.* 1999). Estimated 5-year event-free survival (breast cancer and non breast cancer events) was statistically significantly higher in the Tamoxifen arm than in the control arm. The estimated 5-year cumulative incidence of all breast cancer events was statistically significantly lower in the Tamoxifen group compared to the control group. Updated disease-free survival data at 7 years follow-up was similar to that reported after 5 years (Fisher *et al.* 2001).

In the update study a comparative analysis of the NSABP B-24 and NSABP B-17 (lumpectomy alone vs. lumpectomy with radiation therapy) trials suggested that the use of Tamoxifen plus RT reduced the cumulative incidence of all breast cancer events (including regional and distant metastases) from that arising from lumpectomy alone by 66% at 7 years follow-up. For invasive cancer recurrence events the cumulative incidence reduction was 84% and for non-invasive events, 62% (Fisher *et al.* 2001). This finding rests on the assumption that the study samples are similar.

### **Overall survival**

The NSABP-B24 trial also analysed overall survival between randomised arms and found no difference in estimated 5-year overall survival between patients treated with Tamoxifen compared to those treated with placebo (Fisher *et al.* 1999). At 7 years follow-up there was also no difference in overall survival between the two groups (Fisher *et al.* 2001).

### **Observational studies**

Four small to moderate sized retrospective case series were identified and included in the evidence review (Freedman *et al.* 2005; Roka *et al.* 2004; Jha *et al.* 2001; Stallard *et al.* 2001). These studies are of very little value in the light of the RCTs. One retrospective case series reported that patients given adjuvant Tamoxifen therapy after breast conserving surgery in the absence of radiotherapy had significantly greater local recurrence (type not specified) compared to those who received RT in addition to Tamoxifen (Jha *et al.* 2001). The observational studies demonstrated no statistically significant effect of Tamoxifen in terms of recurrence.

Updated 2018

## **Further details**

### **1. Randomised Studies**

#### **(i) NSABP B-24**

The NSABP-B24 trial randomised 1804 patients treated by lumpectomy for DCIS to 50 Gy radiotherapy plus Tamoxifen for 5 years or 50 Gy radiotherapy plus placebo for 5 years (Fisher *et al.* 1999). The rate of ipsilateral (invasive plus non-invasive) local recurrence at 5 years was statistically significantly lower in the Tamoxifen arm than in the control arm: 13.75 per 1000 patients per year versus 19.62 per 1000 patients per year in the control arm; rate ratio Tamoxifen:control): 0.70 [95% CI 0.50-0.98],  $p=0.04$ . This difference was also statistically significant for invasive recurrence alone but not for non-invasive recurrence alone.

The estimated 5-year cumulative incidence of ipsilateral, invasive breast cancer events was 2.1% in the Tamoxifen arm versus 4.2% in the control arm, with respective rates per 1000 patients per year of 5.02 and 9.02; rate ratio (Tamoxifen:control): 0.56 [95% CI 0.32-0.95],  $p=0.03$ . The estimated 5-year cumulative incidence of ipsilateral, non-invasive breast cancer events was 3.9% in the Tamoxifen arm versus 5.1% in the control arm, with respective rates per 1000 patients per year of 8.73 and 10.60; rate ratio (Tamoxifen:control): 0.82 [95% CI 0.53-1.28],  $p=0.43$ .

Data from this trial also suggest that Tamoxifen has an effect in reducing the occurrence of tumours in the contralateral breast in patients treated with lumpectomy and adjuvant radiotherapy. At a median follow-up duration of 6.2 years there was a statistically significantly lower rate of contralateral (invasive + non-invasive) breast cancer events in the Tamoxifen arm (rate per 1000 patients per year = 3.93) compared to the control arm (rate per 1000 patients per year = 8.12); rate ratio (Tamoxifen:control): 0.48 [95% CI 0.26-0.87],  $p=0.01$ . A similar, statistically significant effect was observed for non-invasive contralateral breast events alone, but not for invasive contralateral breast events alone. The estimated 5-year cumulative incidence of non-invasive contralateral breast cancer events was 0.2% in the Tamoxifen arm versus 1.1% in the control arm, with respective rates per 1000 patients per year of 0.66 and 2.93; rate ratio (Tamoxifen:control): 0.22 [95% CI 0.04-0.81],  $p=0.02$ . The estimated 5-year cumulative incidence of invasive contralateral breast cancer events was 1.8% in the Tamoxifen arm versus 2.3% in the control arm, with respective rates per 1000 patients per year of 3.27 and 5.19; rate ratio (Tamoxifen:control): 0.63 [95% CI 0.31-1.26],  $p=0.22$ .

This trial provided evidence for an advantage arising from Tamoxifen in terms of event-free survival, but with little difference between randomised arms for overall survival. The estimated 5-year event-free survival (breast cancer and non breast cancer events) was statistically significantly higher in the Tamoxifen arm (87.4%) than in the control arm (83.3%): rate ratio (tamoxifen:control) 0.72 [95% CI 0.57-0.91],  $p=0.006$ . The estimated 5-year cumulative incidence of all breast cancer events was statistically significantly lower in the Tamoxifen group (8.2%) compared to the control group (13.4%): rate ratio (tamoxifen:control): 0.63 [95% CI 0.47-0.83],  $p=0.0009$ . Estimated 5-year overall survival in both randomised arms (Tamoxifen versus placebo) was 97%;  $p=0.74$ .

A subsequent comparative analysis of the NSABP B-24 and NSABP B-17 (lumpectomy alone vs. lumpectomy with radiation therapy) trials demonstrated that the cumulative incidence of all breast cancer events (including regional and distant metastases) in the lumpectomy only arm of the B-17 trial was 30% after 7 years (Fisher *et al.* 2001). In the lumpectomy plus RT arm of the B-17 trial the cumulative incidence was 18% and the corresponding value in the B-24 trial was 17%. When Tamoxifen was given in the B-24 trial the cumulative incidence of all breast cancer events was further reduced to 10%, the benefit being attributed to reduced rates of local, contralateral and invasive cancer at regional and distant sites. Therefore Tamoxifen

therapy in combination with RT reduced the risk of any breast cancer event at 7 years by two thirds compared to no post-operative therapy. Similarly for invasive cancer recurrence events, the risk was reduced by 84% and for non-invasive events, 62%.

Updated disease-free survival data at 7 years follow-up was similar to that reported after 5 years (Fisher *et al.* 2001): in the Tamoxifen treatment arm the 7 year estimated event-free survival was 83%, compared to 77% in the control arm (RR = 0.72, P = 0.002). Covariate RR analysis revealed a significantly higher rate of ipsilateral recurrence in women younger than 49 years of age than women over 50 years. The reduction in IBT in women >50 yrs given Tamoxifen was 33% and in women <49 yrs the reduction was 30%.

## **(ii) UKCCCR**

The UKCCCR trial aimed to examine the individual effects of adjuvant RT and adjuvant Tamoxifen in 1694 patients with predominantly screen-detected DCIS, all of whom were treated initially with complete local excision (Houghton *et al.* 2003). The study analysed breast events but not survival.

The study had a 2X2 factorial design by which 912 patients chose to enter randomisation to one of four treatment combinations of RT, Tamoxifen, or neither, or both. A further 664 patients made a choice whether to undergo RT or forego RT and accepted randomisation to either Tamoxifen or no Tamoxifen. A further 118 patients made a choice whether to receive Tamoxifen or forego Tamoxifen and accepted randomisation to either RT or no RT.

### **a) Tamoxifen versus control**

In the analysis of patients randomised to Tamoxifen or control, a proportion of patients received radiotherapy in addition (34.3% and 32.1% respectively). The rate of ipsilateral (invasive plus DCIS) local recurrence at a median follow-up period of 4.7 years was not statistically significantly different between randomised arms, nor when considering only invasive recurrence or DCIS recurrence. The rate of all ipsilateral (DCIS + invasive) events was 13% in the Tamoxifen arm versus 15% in the control arm; hazard ratio 0.90 [95% CI 0.69-1.17], p=0.42, stratified log-rank test. The rate of new ipsilateral invasive events was 6% in the Tamoxifen arm versus 4% in the control arm; hazard ratio 1.31 [95% CI 0.84-2.03], p=0.23, stratified log-rank test. The rate of new ipsilateral DCIS events was 7% in the Tamoxifen arm versus 10% in the control arm; hazard ratio 0.74 [95% CI 0.52-1.04], p=0.08, stratified log-rank test.

In the same analysis there was no statistically significant difference between Tamoxifen and control for the incidence of contralateral breast events. The rate of all contralateral (DCIS + invasive) breast events was 1% in the Tamoxifen arm versus 3% in the control arm; hazard ratio 0.52 [95% CI 0.25-1.07], p=0.07, stratified log-rank test. There was also no statistically significant difference in incidence of contralateral invasive events alone, which was 1% in the Tamoxifen arm and 2% in the control arm; hazard ratio 0.66 [95% CI 0.30-1.46], p=0.30, stratified log-rank test. The study did not analyse contralateral DCIS events alone.

### **b) Tamoxifen in the patient subgroup that received radiotherapy**

This study provided also a sub-group analysis for 523 patients randomised with regard to Tamoxifen, all of whom received radiotherapy. Data were presented for invasive recurrence and DCIS recurrence separately, and there was no statistically significant difference in rates of ipsilateral recurrence for either outcome between randomised arms. The rate of ipsilateral invasive tumours was 1% in the Tamoxifen arm versus 1% in the control arm; hazard ratio 1.25 [95% CI 0.43-3.61], p=0.68, stratified log-rank test. The rate of ipsilateral DCIS was 1% in the Tamoxifen arm versus 1% in the control arm; hazard ratio 0.75 [95% CI 0.28-2.02], p=0.57, stratified log-rank test.

This study did not analyse contralateral breast events in the subgroup of patients randomised with regard to Tamoxifen who received in addition radiotherapy.

### c) Tamoxifen in the patient subgroup that did not receive radiotherapy

This trial also provided a subgroup analysis of new breast events in patients randomised to Tamoxifen or control, stratified by whether or not they received RT. In the subgroup of patients who did not receive RT there was no statistically significant difference between randomised arms in the incidence of ipsilateral invasive recurrence or ipsilateral DCIS. The rate of ipsilateral invasive breast events was 5% in the Tamoxifen arm versus 4% in the control arm; HR 1.32 [95% CI 0.81-2.14],  $p=0.26$ , stratified log-rank test. The rate of ipsilateral DCIS events was 6% in the Tamoxifen arm versus 9% in the control arm; HR 0.73 [95% CI 0.51-1.06],  $p=0.10$ , stratified log-rank test.

This study did not analyse the rate of contralateral breast events alone in the subgroup of patients who did not receive RT, but did analyse new breast events that occurred in either breast together in this subgroup: there was no statistically significant difference in the incidence of total breast tumours (invasive plus DCIS) or invasive tumours alone. The rate of total breast events (invasive + DCIS; ipsilateral + contralateral tumours) was 12 % in the Tamoxifen arm versus 15% in the control arm; HR 0.80 [95% CI 0.61-1.05],  $p=0.11$ , stratified log-rank test. The rate of total invasive (ipsilateral + contralateral tumours) was 5% in the Tamoxifen arm versus 5% in the control arm; HR 1.11 [95% CI 0.72-1.72],  $p=0.64$ , stratified log-rank test. However there were statistically significantly fewer recurrent DCIS tumours in the Tamoxifen arm compared to the control arm: respective rates were 6% versus 10%; HR 0.68 [95% CI 0.47-0.97],  $p=0.03$ , stratified log-rank test.

## 2. Systematic reviews

One high quality systematic review (Shelley *et al.* 2006) included articles required to meet the following criteria:

- i. Study designs for the management of DCIS were randomised control trials, or meta-analyses on non-randomised and/or randomised trials.
- ii. Outcomes included overall or disease-free survival, local recurrence (invasive or non-invasive), breast conservation, distant recurrence, toxicity, or quality of life.
- iii. Clinical trials results reported in full papers or abstracts.
- iv. Evidence-based clinical practice guidelines addressing the management of DCIS.

An additional section - intended as an aid to practitioners and outside the guideline recommendations - was included in which issues for the management of DCIS that were not covered by included RCTs were reviewed through appraisal of expert opinion and non-randomised evidence identified from a non-systematic search of the literature. Of relevance to the evaluation of adjuvant Tamoxifen therapy in the management of DCIS, important outcome measurements addressed in this review included:

- i. Local and distant disease recurrence for non-invasive and invasive events
- ii. Overall and disease-free survival
- iii. Effect of Tamoxifen in patients by age at randomisation (comparison between UKCCCR and NSABP B-24 trials)
- iv. Toxicity of Tamoxifen vs. placebo (data obtained from NSABP P-1 trial)

Data concerning these outcomes were reviewed from the two RCTs covered in this evidence summary (Fisher *et al.* 1999; Houghton *et al.* 2003).

In addition to the key findings of the two randomised control studies presented in this summary, this systematic review highlights a number of other issues for the management of DCIS

*Influence on recurrence of positive vs. negative resected margins:*

In NSABP B-24, sixteen percent of the patients had positive resected margins and 10% had unknown margins for DCIS, and others were known to have residual suspicious micro-calcifications. The absolute risk reduction was larger in Tamoxifen plus RT treated patients with positive margins (3.5%) than in those with negative margins (1.8%) but no statistical test of this finding was reported in the review.

*Influence of tumour estrogen receptor status on recurrence:*

Of the 1798 eligible patients estrogen receptor (ER) status of tumours was known in 628 (35%) (327 placebo, 301 Tamoxifen). Seventy seven percent of tumours were ER positive and the risk ratio (RR) of recurrent or new breast pathology in patients receiving Tamoxifen was 0.41 in the ER positive group (95% CI, 0.25-0.65, P=0.0002). In the ER-negative group the RR was 0.8 (P=0.5) although the number of events (n=36) was too small to exclude a clinically meaningful benefit (95% CI for RR, 0.41-1.56).

*Effect of Tamoxifen in patients by age at randomisation:*

In this study only 9.5% of recruited patients were under 50 years of age, compared with 33.5% of those in the NSABP B-24 study. This may have been due to the nature of patient recruitment in the former study in that they were recruited through the UK national breast screening program. Age-related data comparison between studies was possible only for local (IBT) recurrence; the benefit of Tamoxifen in both studies was more apparent in women  $\leq$  50 years of age although this failed to achieve statistical significance.

***Other considerations for the use of Tamoxifen in the management of DCIS***

*Tamoxifen toxicity:*

Both RCT studies included some data on toxicity associated with Tamoxifen treatment, but the NSABP P-1 study (Tamoxifen in the prevention of breast cancer in 13,388 women at increased risk) included a detailed analysis stratified by patient age. Significant toxicity events were; endometrial cancer, stroke, pulmonary embolism, and deep vein thrombosis. The largest difference in serious adverse events appears to be in women > 50 years of age, however the absolute number of adverse events is low as is the incremental risk.

*Contraindications for breast conserving surgery (BCS):*

The authors state that as with invasive breast cancer, there are also contraindications for performing BCS in the management of DCIS: large tumour size and small breasts may not yield satisfactory cosmetic results and may be better served by mastectomy coupled with the option of reconstructive surgery. As with other studies, only a small proportion (4%) of patients recruited to the NSABP B-24 trial had lesions >2 cm. Therefore local control rates reported may not be applicable to patients with larger lesions. Also, the detection of multiple tumours or extensive micro-calcifications are relative contraindications of BCS.

**3. Observational studies**

For further information on the four observational studies included in the evidence, refer to the evidence table.

## Evidence Tables

Fisher, Dignam, Wolmark, Wickerham, Fisher, Mamounas, Smith, Begovic, Dimitrov, Margolese, Kardinal, Kavanah, Fehrenbacher & Oishi . Tamoxifen in treatment of intraductal breast cancer: National Surgical Adjuvant Breast and Bowel Project B-24 randomised controlled trial. Lancet 353[9169], 1993-2000. 1999.

Design: Randomized controlled trial (therapy), evidence level: 1+  
Country: United States, setting: Secondary care

**Inclusion criteria** Women with DCIS with a life expectancy of  $\geq 10$  years including:

- those with DCIS + LCIS;
- those with one or more masses or clusters of masses that could be completely excised;
- those with microscopic margin involvement;
- those with scattered calcifications on mammograms that were indeterminate

16% of patients had positive resected margins after surgery.

33.5% of patients were under 50 years of age

**Exclusion criteria** Time from surgery to randomisation  $>56$  days;

Previous diagnosis of cancer, excluding squamous cell carcinoma of the skin or carcinoma in situ of the cervix

**Population** number of patients = 1804.

**Interventions** Aim: to examine the effect of tamoxifen when given to patients with DCIS after treatment by lumpectomy and RT.

Tamoxifen group (n=902): received lumpectomy, 50 Gy breast RT and 10 mg BD tamoxifen for 5 years.

Control group (n=902): received lumpectomy, 50 Gy breast RT and placebo for 5 years.

**Outcomes** Occurrence of tumour in the ipsilateral or contralateral breast;  
Regional and distant metastases;  
Survival.

**Follow up** Physical examination every 6 months and mammography once a year.

Median duration 74 months (range 57-93 months).

**Results** Estimated 5-year overall survival:

Tamoxifen: 97% [95% CI 96%-98%]

Control: 97% [95% CI 96%-98%]; p=0.74

Estimated 5-year event-free survival (breast cancer and non breast cancer events):

Tamoxifen: 87.4% [95% CI 85.1%-89.6%]

Control: 83.3% [95% CI 80.8%-85.8%]  
Rate of all events per 1000 patients per year (breast cancer and non breast cancer events):  
Tamoxifen: 27.50  
Control: 38.12  
Rate ratio (tamoxifen:control): 0.72 [95% CI 0.57-0.91], p=0.006.

Estimated 5-year cumulative incidence of all breast cancer events:  
Tamoxifen: 8.2%  
Control: 13.4%  
Rate per 1000 patients per year:  
Tamoxifen: 18.33  
Control: 29.32  
Rate ratio (Tamoxifen:control): 0.63 [95% CI 0.47-0.83], p=0.0009.

All ipsilateral (invasive + non-invasive) local recurrence (rate per 1000 patients per year):  
Tamoxifen: 13.75  
Control: 19.62  
Rate ratio (Tamoxifen:control): 0.70 [95% CI 0.50-0.98], p=0.04

Estimated 5-year cumulative incidence of ipsilateral, invasive breast cancer events:  
Tamoxifen: 2.1%  
Control: 4.2%  
Rate per 1000 patients per year:  
Tamoxifen: 5.02  
Control: 9.02  
Rate ratio (Tamoxifen:control): 0.56 [95% CI 0.32-0.95], p=0.03

Estimated 5-year cumulative incidence of ipsilateral, non-invasive breast cancer events:  
Tamoxifen: 3.9%  
Control: 5.1%  
Rate per 1000 patients per year:  
Tamoxifen: 8.73  
Control: 10.60  
Rate ratio (Tamoxifen:control): 0.82 [95% CI 0.53-1.28], p=0.43

All contralateral (invasive + non-invasive) breast cancer events (rate per 1000 patients per year):  
Tamoxifen: 3.93  
Control: 8.12  
Rate ratio (Tamoxifen:control): 0.48 [95% CI 0.26-0.87], p=0.01

Estimated 5-year cumulative incidence of invasive contralateral breast cancer events:  
Tamoxifen: 1.8%  
Control: 2.3%  
Rate per 1000 patients per year:  
Tamoxifen: 3.27  
Control: 5.19  
Rate ratio (Tamoxifen:control): 0.63 [95% CI 0.31-1.26], p=0.22

Estimated 5-year cumulative incidence of non-invasive contralateral breast cancer events:

Tamoxifen: 0.2%

Control: 1.1%

Rate per 1000 patients per year:

Tamoxifen: 0.66

Control: 2.93

Rate ratio (Tamoxifen:control): 0.22 [95% CI 0.04-0.81], p=0.02

Combined regional and distant metastasis (rate per 1000 patients per year):

Tamoxifen: 0.66

Control: 1.58

Rate ratio (Tamoxifen:control): 0.42 [95% CI 0.07-1.82], p=0.32

Adverse events:

Proportion of patients with no recorded overall toxicity (duration of follow-up: different for each patient):

Tamoxifen: 57.1%

Control: 62.8%

Endometrial cancer (rate per 1000 patients per year):

Tamoxifen: 1.53

Control: 0.45

Rate ratio (tamoxifen:control): 3.39 [95% CI 0.64-33.42]; p=0.20

**General comments** Randomisation was stratified by age ( $\leq 49$  or  $> 49$  years) tumour type (DCIS or DCIS + LCIS) and method of detection (screening or symptomatic or both).

Power calculation performed.

29 patients became ineligible after randomisation (11: control, 18: tamoxifen). Of 1804 randomised patients 14 (0.8%) did not start randomised therapy. 564 (31.3%) patients did not complete randomised therapy (269: control; 295: tamoxifen). 6 patients were lost to follow-up (3: tamoxifen; 3: control). All randomised patients with follow-up data were included in the intention-to-treat analysis.

No analysis is made of adverse events between randomised groups. Reported 'overall toxicity' excludes alopecia, irregular menses, hot flushes, fluid retention, vaginal discharge, nadir grades and weight change.

Reporting of results is inconsistent; many instances of 'data not shown' in text.

Fisher, Land, Mamounas, Dignam, Fisher & Wolmark . Prevention of invasive breast cancer in women with ductal carcinoma in situ: an update of the national surgical adjuvant breast and bowel project experience. *Seminars in oncology* 28[4], 400-418. 2001.

Design: Randomized controlled trial (therapy), evidence level: 1+  
Country: United States, setting: Secondary care

**Inclusion criteria** 1798/1804 eligible and followed-up patients with pure DCIS. In addition to the NSABP B-17 trial (RT vs nothing) women with positive tumour specimen margins or with mammogram indicating an unlikely presence of invasive cancer were eligible for inclusion.

**Exclusion criteria** See Fisher et al *Lancet* 353, 1993-2000. 1999

**Population** number of patients = 1804.

**Interventions** Lumpectomy + XRT (50 Gy) + Tamoxifen n = 899  
Lumpectomy + XRT (50 Gy) + Placebo n = 899

**Outcomes** Event-free survival after 7 years

Overall survival after 7 years

Site, rate, RR, 95% CI and cumulative incidence of first events

Covariate RR (95% CI) for selected patient and tumour characteristics

**Follow up** Mean follow-up 82 months

Median follow-up 83 months

**Results** Ipsilateral breast cancer recurrence (IBT):

The rates of recurrence at 7 years follow-up for ipsilateral invasive plus non-invasive, invasive only, and non-invasive are reported to have maintained trends reported after 5 years follow-up. No significant changes in rate ratios (RR) are reported.

Contralateral breast cancer recurrence (CBT):

The rates of occurrence at 7 years follow-up for ipsilateral invasive plus non-invasive, invasive only, and non-invasive are reported to have maintained trends reported after 5 years follow-up. No significant changes in RRs are reported.

Survival:

Event-Free Survival after 7 years follow-up was similar to that reported after 5 years: in the Tamoxifen treatment arm the 7 year estimated event-free survival was 83.0% and 77.1% in the control arm of the trial, RR = 0.72 (95% CI, 0.59 - 0.89, P = 0.002).

There was no significant difference in Overall Survival between the 2 arms of the trial after 7 years, RR = 0.94 (95% CI, 0.62 - 1.44, P = 0.78)

Covariate RR analysis revealed a significantly higher rate of IBT in women younger than 49 years than women over 50 years. The reduction in IBT in women >50 yrs given Tamox was 32.7% and in women <49 yrs the reduction was 30.1%

This article reported updates for the NSABP B-17 and NSABP B-24 trials. The authors go on to examine the relationship between the two trials.

The cumulative incidence of all breast cancer events (IBT and CBT) in the lumpectomy only arm of the B-17 trial was 30.3% after 7 years. In the lumpectomy + RT arm of this trial the cumulative incidence was 18.0% and 16.9% in the B-24 trial. When Tamoxifen was given this was further reduced to 10.3%, the benefit being due to reduced rates of IBT, CBT and invasive cancer at regional and distant sites. Therefore Tamoxifen therapy in combination with RT led to a 66% lower cumulative incidence all breast cancer events at 7 years compared to women who had lumpectomy alone. For invasive cancer recurrence events the cumulative incidence reduction was 84% and 62% for non-invasive events.

-

**General comments** Update on results emerging from the NSABP B-24 RCT, Fisher et al Lancet 353, 1993-2000 (1999).

Extended survival and recurrence data plus analysis of the relationship between this trial and the earlier NSABP B-17 (BCS +/- RT) trial.

The calculation of reduction in cumulative incidence of all breast cancer events in the NSABP B-24 and NSABP B-17 (lumpectomy alone vs. lumpectomy with radiation therapy) trials crucially assumes that the two studies are similar; the NSABP B-24 trial included patients with positive surgical margins, which would serve to attenuate the difference.

Updated 2018

Houghton, George, Cuzick, Duggan, Fentiman, Spittle, UK Coordinating Committee on Cancer Research, Ductal Carcinoma in situ Working Party, DCIS trialists in the UK, Australia & and . Radiotherapy and tamoxifen in women with completely excised ductal carcinoma in situ of the breast in the UK, Australia, and New Zealand: randomised controlled trial. Lancet 362[9378], 95-102. 2003.

Design: Randomized controlled trial (therapy), evidence level: 1-  
Country: United Kingdom, Australia, New Zealand, setting: Secondary care

**Inclusion criteria** 1694 patients with unilateral or bilateral screen-detected or DCIS who were candidates for breast conserving surgery; including:  
-Symptomatic patients in whom DCIS was confirmed in the same way as in screening clinics;  
-Patients with microinvasion <1mm in diameter, provided histologically clear margins were obtained. This group comprised 59 patients (3%).

Age distribution largely reflects screened population: modal age group 50-54 years; 90% of patients were of age >50 years i.e. older than the other RCT populations

**Exclusion criteria** LCIS or atypical ductal hyperplasia;  
Doubtful histological margins;  
Paget's disease of the nipple;  
Patients with reduced life expectancy due to concomitant illness or malignancy;  
Patients considered unsuitable for any of the treatment options.

A total of 7 patients were excluded (from an original study size of 1701) after randomisation.

**Population** number of patients = 1694.

**Interventions** Aim: to investigate the individual effects of radiotherapy and tamoxifen as adjuvant treatment for DCIS following complete local excision.

All patients underwent complete local excision.

2X2 factorial design:

912 patients chose to enter randomisation to one of four treatments:

RT + tamoxifen:	242
Tamoxifen alone:	224
RT alone:	220
No treatment:	226

782 patients chose 2-way randomisation:

664 patients made a choice re: RT and were randomised to either tamoxifen or no tamoxifen:

RT + Tamoxifen:	30
Tamoxifen alone:	298
RT alone:	31
No treatment:	305

118 patients made a choice re: tamoxifen and were randomised to either RT or no RT:

RT + Tamoxifen: 44  
Tamoxifen alone: 45  
RT alone: 16  
No treatment: 13

Tamoxifen comprised 20mg daily for 5 years.  
RT comprised 50 Gy in 25 fractions over 5 weeks.

**Outcomes** Ipsilateral breast recurrence;  
Contralateral breast cancer;  
New cancer (non-breast);  
Death; breast cancer related or not.

Time-to-event analysis was by the life table method and the stratified log-rank test.

**Follow up** Yearly bilateral mammography for the first 7 years and every 2 years thereafter.

Median duration 56.2 months (range 2.4-118.3 months).

**Results** 1. Effect of tamoxifen (1576 patients in the randomised tamoxifen comparison)

New ipsilateral invasive events:

Tamoxifen: 45 (6%)

Control: 35 (4%)

HR 1.31 [95% CI 0.84-2.03], p=0.23, stratified log-rank test.

New ipsilateral DCIS events:

Tamoxifen: 57 (7%)

Control: 77 (10%)

HR 0.74 [95% CI 0.52-1.04], p=0.08, stratified log-rank test.

All ipsilateral (DCIS + invasive) events:

Tamoxifen: 102 (13%)

Control: 114 (15%)

HR 0.90 [95% CI 0.69-1.17], p=0.42, stratified log-rank test.

New contralateral invasive events:

Tamoxifen: 10 (1%)

Control: 15 (2%)

HR 0.66 [95% CI 0.30-1.46], p=0.30, stratified log-rank test.

New contralateral DCIS events: no data

All contralateral (DCIS + invasive) breast events:

Tamoxifen: 11 (1%)

Control: 21 (3%)

HR 0.52 [95% CI 0.25-1.07], p=0.07, stratified log-rank test.

All invasive (ipsilateral + contralateral) events:

Tamoxifen: 55 (7%)

Control: 50 (6%)

HR 1.11 [95% CI 0.76-1.63], p=0.59, stratified log-rank test.

All DCIS (ipsilateral + contralateral) events:

Tamoxifen: 58 (7%)

Control: 84 (11%)

HR 0.68 [95% CI 0.49-0.96], p=0.03, stratified log-rank test.

All events (invasive + DCIS; ipsilateral +contralateral):

Tamoxifen: 114 (14%)

Control: 137 (18%)

HR 0.83 [95% CI 0.64-1.06], p=0.13, stratified log-rank test.

## 2. Effect of RT (1030 patients in the randomised RT comparison)

New ipsilateral invasive events:

RT: 15 (3%)

Control: 30 (6%)

HR 0.45 [95% CI 0.24-0.85], p=0.01, stratified log-rank test.

New ipsilateral DCIS events:

RT: 14 (3%)

Control: 38 (7%)

HR 0.36 [95% CI 0.19-0.66], p=0.0004, stratified log-rank test.

All ipsilateral (DCIS + invasive) breast events:

RT: 29 (6%)

Control: 69 (14%)

HR 0.38 [95% CI 0.25-0.59], p<0.0001, stratified log-rank test.

New contralateral invasive events:

RT: 9 (2%)

Control: 6 (1%)

HR 1.50 [95% CI 0.53-4.22], p=0.44, stratified log-rank test.

New contralateral DCIS events: no data.

All contralateral (DCIS + invasive) breast events in patients in the RT comparison:

RT: 9 (2%)

Control: 11 (2%)

HR 0.82 [95% CI 0.34-1.18], p=0.65, stratified log-rank test.

All invasive (ipsilateral + contralateral) events:

RT: 24 (5%)

Control: 36 (7%)

HR 0.62 [95% CI 0.37-1.04], p=0.07, stratified log-rank test.

All DCIS (ipsilateral + contralateral) events:

RT: 14 (3%)

Control: 44 (9%)

HR 0.31 [95% CI 0.17-0.56], p<0.0001, stratified log-rank test.

All events (ipsilateral + contralateral; invasive + DCIS):

RT: 38 (7%)

Control: 82 (16%)

HR 0.43 [95% CI 0.29-0.63], p<0.0001, stratified log-rank test.

3. Subgroup analysis: New breast events in patients randomised to tamoxifen or control, stratified by whether or not they had RT

a) Patients not receiving RT (n=1053)

Ipsilateral invasive:

Tamoxifen: 37 (5%)

Control: 29 (4%)

HR 1.32 [95% CI 0.81-2.14], p=0.26, stratified log-rank test.

Ipsilateral DCIS:

Tamoxifen: 20 (6%)

Control: 68 (9%)

HR 0.73 [95% CI 0.51-1.06], p=0.10, stratified log-rank test.

Total invasive (ipsilateral + contralateral tumours):

Tamoxifen: 42 (5%)

Control: 39 (5%)

HR 1.11 [95% CI 0.72-1.72], p=0.64, stratified log-rank test.

Total DCIS (ipsilateral + contralateral tumours):

Tamoxifen: 51 (6%)

Control: 75 (10%)

HR 0.68 [95% CI 0.47-0.97], p=0.03, stratified log-rank test.

Total breast events (invasive + DCIS; ipsilateral + contralateral tumours):

Tamoxifen: 94 (12%)

Control: 117 (15%)

HR 0.80 [95% CI 0.61-1.05], p=0.11, stratified log-rank test.

b) Patients receiving RT (n=523)

Ipsilateral invasive tumours:

Tamoxifen: 8 (1%)

Control: 6 (1%)

HR 1.25 [95% CI 0.43-3.61], p=0.68, stratified log-rank test.

Ipsilateral DCIS:

Tamoxifen: 7 (1%)

Control: 9 (1%)

HR 0.75 [95% CI 0.28-2.02], p=0.57, stratified log-rank test.

Total invasive (ipsilateral + contralateral tumours):

Tamoxifen: 13 (2%)

Control: 11 (1%)

HR 1.11 [95% CI 0.50-2.48], p=0.80, stratified log-rank test.

Total DCIS (ipsilateral + contralateral tumours):

Tamoxifen: 7 (1%)

Control: 9 (1%)

HR 0.75 [95% CI 0.28-2.02], p=0.57, stratified log-rank test.

Total breast events (invasive + DCIS; ipsilateral + contralateral tumours):

Tamoxifen: 20 (3%)

Control: 20 (3%)

HR 0.95 [95% CI 0.51-1.77], p=0.88, stratified log-rank test.

-

**General comments** 'Complete excision': defined by radiology of the surgical specimen and free margins on histological examination. Re-excision was performed where necessary.

Randomisation was performed by each contributing centre, blocked in groups of four and stratified for screening assessment centre.

Power calculation performed; additional patients were recruited because patients/clinicians favoured the 2-way randomisation.

Analysis of the individual effect of tamoxifen included only patients randomised to tamoxifen (not those who chose tamoxifen). The analysis was repeated, stratified by whether RT was given in addition.

Analysis of the individual effect of RT included only patients randomised to RT (not those who chose RT). The analysis was repeated, stratified by whether tamoxifen was given in addition.

Of 794 patients randomised to tamoxifen, 86 (11%) did not fully comply with the regimen. Study does not measure adverse effects of tamoxifen or RT.

Survival was not analysed as there were few deaths (45 in total).

Study may be underpowered where sub groups are small; the largest subgroup arising through choice of treatment is patients who chose with their clinicians to not be randomised to radiotherapy or control (n=664).

## Retrospective case series

Freedman, Anderson, Hanlon, Eisenberg & Nicolaou . Pattern of local recurrence after conservative surgery and whole-breast irradiation. Int J Radiat.Oncol Biol.Phys. 61[5], 1328-1336. 2005.

### Design

Design: Retrospective case series (therapy), evidence level: 3  
Country: United States, setting: Secondary care

### Inclusion criteria

1990 women with stage T0 (DCIS), T1, or T2 breast cancer treated by breast conserving surgery and breast irradiation.  
237/1990 (12%) were stage T0, DCIS.

### Exclusion criteria

None specified

### Population

number of patients = 237, age range 22 to 93 years, median age = 57 years.

### Interventions

Breast conserving surgery  
All recieved post-operative whole breast RT

DCIS patients given Tamoxifen treatment = 16/237 (6.8%)  
Systemic chemotherapy (492, 25%)

### Outcomes

Ipsilateral breast cancer recurrence (Kaplan-Meier) - all cancers  
Crude local and regional/distant recurrence rates for DCIS +/- tamox (provided by personal communication, see results)

### Follow up

Median 81 months (range, 1 to 245 months)

### Results

16/237 (6.8%) received RT + Tamox  
221/237 (93.2%) received RT alone

True local (ipsilateral) events (all DCIS): 13/237 (5.5%)  
Contralateral events: 37/237 (15.6%)

Available results stratified by +/- Tamox treatment:

Local recurrence events:

DCIS +RT/-Tamox = 14/221 (6.3%)

DCIS +RT/+Tam = 1/16 (6.3%)

Contralateral recurrence events:

DCIS +RT/-Tamox = 30/221 (13.6%)

DCIS +RT/+Tam = 7/16 (43.8%) (see comments)

Comments from corresponding author (G. Freedman):

Only 16 patients had tamoxifen, apparently we were not using it very much in that time period before results of the NSABP B-24 became available.

There were 13 local only breast recurrences, 15 any local recurrence (perhaps with a regional), and 37 contralateral breast cancers reported in that paper. 1 of the patients out of the 15 total local failures had been on tamoxifen, she had a local and subsequent distant failure! (very rare for DCIS). And 7 of the 37 contralateral breast cancer patients had received tamoxifen, so 7 out of the 16 patients receiving tamoxifen had a contralateral breast cancer!

There must be some unusual bias against these women who had had tamoxifen. It was a retrospective study after all. My impression would be that if it was not our usual policy to give tamoxifen back in those years, there probably was something that worried the physicians about these 16 women to give them tamoxifen like a strong family history or LCIS or something.

#### **General comments**

Moderate retrospective case series study.

Corresponding author (G. Freedman) contacted and provided additional data for DCIS patients, specifically how many received Tamox and recurrence data for +/- Tamox in this treatment group.

The author made additional comments regarding the unexpectedly high rate of recurrence in the tamoxifen treatment group (see results).

Jha, Avlonitis, Griffith, Lennard, Wilson, McLean, Dawes & Shrimankar . Aggressive local treatment for screen-detected DCIS results in very low rates of recurrence. Eur J Surg Oncol 27[5], 454-458. 2001.

Design: Retrospective case series (therapy), evidence level: 3  
Country: United Kingdom, setting: Primary care

**Inclusion criteria** 304 women with mammographically-detected DCIS, confirmed by FNAC or FNAB. 12/304 not included in analysis

**Exclusion criteria** None stated but 12/304 (4%) originally treated but excluded from further analysis due to: (i) evidence of invasive disease (4/304); (ii) lost to follow-up (6/304); (iii) bilateral disease (2/304).

**Population** number of patients = 304, age range 51 to 65 years, median age = 59 years.

**Interventions** Simple mastectomy, 104/304 Patey's mastectomy, 72/304 (24%)  
Wide local excision + RT, 97 (32%)  
Wide local excision alone, 31 (10%)

RT was 50 Gy fractioned over 5 weeks.

Adjuvant Tamoxifen therapy given to 304/304 patients.  
5/304 (1.6%) withdrew from Tamoxifen treatment due to intolerable side-effects.

**Outcomes** Estimated local recurrence, Kaplan-Meier method (recurrence-free survival)

**Follow up** 88 months (range, 62 - 126 months)

**Results** Local Recurrence:  
Mastectomy (all): 0/176  
WLE + RT: 1/93 (1%)  
WLE - RT: 5/30 (16.7%) P = 0.0008 (log-rank test)

-

**General comments** Moderate sized retrospective case series. All patients received Tamoxifen and therefore this study really compares the added protective effect of receiving RT in addition to Tamoxifen following WLE. There were no recurrences in the mastectomy group.

Roka, Rudas, Taucher, Dubsky, Bachleitner-Hofmann, Kandioler, Gnant & Jakesz . High nuclear grade and negative estrogen receptor are significant risk factors for recurrence in DCIS. Eur J Surg Oncol 30[3], 243-247. 2004.

## Design

Design: Retrospective case series (therapy), evidence level: 3  
Country: Austria, setting: Secondary care

## Inclusion criteria

132 patients with DCIS treated surgically between 198 and 2001

## Exclusion criteria

History of breast cancer or any other cancer  
DCIS and histologically positive axillary lymph nodes

## Population

number of patients = 132, age range 32 to 85 years, median age = 56 years.

## Interventions

Breast conserving surgery, wide excision 132/190 (70%)  
Mastectomy 58/190 (30%)  
Post-operative RT, 50 Gy + 15 Gy to tumour bed

BCS alone	20/132
BCS +RT/-Tam	61/132
BCS +RT/+Tam	40/132
BCS -RT/+Tam	11/132

## Outcomes

Ipsilateral breast cancer recurrence after breast conserving surgery only  
statistical analysis used log-rank test for significance ( $P < 0.05$ )

## Follow up

median 61.6 months (range, 11.2 to 244.9 months)

## Results

Crude ipsilateral breast cancer recurrence rates:

BSC alone	3/20	15%	
BCS +RT/-Tam, or BCS -RT/+Tam	6/72	8.3%	
BCS +RT/+Tam	0/40	0%	$P = ns$
All BCS +Tam	1/51	1.9%	

All BCS -Tam	8/81	9.9%	$P = ns$
--------------	------	------	----------

Overall local recurrence rate = 6.1%

**General comments**

Small retrospective study in which the primary aim was to investigate the nuclear grade and estrogen receptor status as possible risk markers for recurrence following breast conserving surgery for DCIS. No significant differences found between interventions (+RT +/- Tamoxifen) but the small numbers included make the results susceptible to errors.

Updated 2018

Stallard, Hole, Purushotham, Hiew, Mehanna, Cordiner, Dobson, Mallon & George . Ductal carcinoma in situ of the breast -- among factors predicting for recurrence, distance from the nipple is important. Eur J Surg Oncol 27[4], 373-377. 2001.

Design: Retrospective case series (therapy), evidence level: 3  
Country: United Kingdom, setting: Secondary care

**Inclusion criteria** 220 patients with pure DCIS treated between 1986 and 1997  
Included patients with Paget's disease of the nipple, diffuse microcalcification on mammography, multifocal disease or involved margins with extensive DCIS, but these patients tended to be treated by mastectomy

**Exclusion criteria** None specified

**Population** number of patients = 220, age range 30 to 86 years, mean age = 58 years.

**Interventions** Breast conserving surgery 153/220 (70%): 99/153 (65%) had one procedure, 54/153 (35%) had a re-excision

Mastectomy 67/220 (30%)

BSC alone, 56/153 (37%)

BCS + Tamox, 54/153 (35%)

BCS + RT, 22/153 (14%)

BCS + Tamox + RT, 21/153 (14%)

22/78 (28%) of patients who did not have adjuvant Tamoxifen therapy received post-op RT

21/75 (28%) of patients who had adjuvant tamoxifen therapy received post-op RT

overall BCS patients given RT = 110/153

overall BCS patients not given RT = 43/153

52/153 were entered into the UK DCIS trial (est. 1991) and randomised to one of the 4 treatment modalities.

**Outcomes** Local recurrence following BCS:

Estimated 5 year freedom from local recurrence (Kaplan-Meier method)

Multivariate analysis of time to first recurrence (Cox's proportional hazards model) including factors either significant on univariate analysis or produced a large absolute difference in survival rates and were biologically plausible.

**Follow up** 60 months (60 month freedom from local recurrence estimate)

**Results**

Recurrence rates

<u>Intervention</u>	<u>No. events</u>	<u>Rate (%)</u>	<u>Type</u>
---------------------	-------------------	-----------------	-------------

Mastectomy	2/67	3	axillary
BCS - Tamoxifen	12/78	15.4	local
BCS + Tamoxifen	8/75	10.7	local
BCS - RT	18/110	16.4	local
BCS + RT	2/43	4.5	local

5 year actuarial recurrence-free survival

<b>Intervention</b>	<b>% disease-free</b>	<b>Univariate <i>P</i> value (log-rank test)</b>
BCS - Tamoxifen	75.4	
BCS + Tamoxifen	82.2	0.22
BCS - RT	75.4	
BCS + RT	94.2	0.14

Of all univariate analyses performed only two reached statistical significance: mammographically-measured nipple to lesion distance <40 mm vs >40 mm ( $P=0.007$ ), and nuclear grade ( $P=0.02$ )

Multivariate analysis included 3 factors from the univariate analysis and Relative Hazard Ratios were determined: (i) nipple to lesion distance RHR = 0.33 (95% CI, 0.11-0.95); (ii) nuclear grade (per unit change) RHR = 0.45 (95% CI, 0.21-0.98); and (iii) adjuvant RT (yes vs no) RHR = 0.43 (95% CI, 0.10-1.92)

-

**General comments** Moderate sized retrospective study. A proportion of patients in both the adjuvant Tamox group and the no adjuvant Tamox group received RT, 28% in each group. NO recurrence data for adjuvant Tamox alone or adjuvant RT alone.

## Systematic review of combined study designs

Shelley, McCready & Holloway . Management of ductal carcinoma in situ of the breast: A clinical practice guideline. Cancer Care Ontario . 2006.

Design: Systematic review of combined study designs (therapy), evidence level: 2+  
Country: Canada (federal state, Commonwealth Realm), setting: Secondary care

**Inclusion criteria** Included articles were required to meet the following criteria:

1. Study designs for the management of DCIS were randomised control trials, or meta-analyses on non-randomised and/or randomised trials.
2. Outcomes included overall or disease-free survival, local recurrence (invasive or non-invasive), breast conservation, distant recurrence, toxicity, or quality of life.
3. Clinical trials results reported in full papers or abstracts.
4. Evidence-based clinical practice guidelines addressing the management of DCIS.

An additional section - intended as an aid to practitioners and outside the guideline recommendations - was included in which issues for the management of DCIS that were not covered by included RCTs were reviewed through appraisal of expert opinion and non-randomised evidence identified from a non-systematic search of the literature.

**Exclusion criteria** Non English language publications  
Publications occurring before 1983

### Population -

**Interventions** Development of clinical practice guidelines for the management of ductal carcinoma in situ (DCIS) by Cancer Care Ontario's Program in Evidence-based care using the methods of the Practice Guidelines Development Cycle.

Literature search strategy:

MEDLINE search to March 2006 using a disease-specific MeSH terms ("carcinoma, intraductal, non-infiltrating") and treatment-specific Mesh terms (radiotherapy, mastectomy, Tamoxifen).

EMBASE searched to March 2006 using a disease-specific Excerpta Medica Tree (EMTREE) term("intraductal carcinoma") and the same treatment-specific EMTREE term as for MEDLINE.

Cochrane Library issue 5 (2004), the Physician Data Query database ([http://www.cancer.gov/search/clinical\\_trials/](http://www.cancer.gov/search/clinical_trials/))

Conference proceedings from the American Society of Clinical Oncology (1998 to 2005), American Society for Therapeutic Radiology and Oncology (1998 to 2005), San Antonio Breast Cancer Symposium (2001 to 2005).

Canadian Medical Association Infobase (<http://mdm.ca/cpgsnew/cpgs/index.asp>) and the

National Guidelines Clearinghouse (<http://www.guideline.gov/>) were searched for evidence-based practice guidelines.

Relevant articles and abstracts were selected and reviewed by three reviewers, and the reference lists from these sources were searched for additional trials, as were the reference lists from relevant review articles.

**Outcomes** Of relevance to the evaluation of adjuvant Tamoxifen therapy in the management of DCIS, important outcome measurements addressed in this review included:

1. Local and distant disease recurrence for non-invasive and invasive events
2. Overall and disease-free survival
3. Effect of Tamoxifen in patients by age at randomisation (comparison between UKCCCR and NSABP B-24 trials)
4. Toxicity of Tamoxifen vs. placebo (data obtained from NSABP P-1 trial)

Data concerning these outcomes were reviewed from the two RCTs covered in this evidence summary, NSABP B-24 and UKCCCR, and the NSABP P-1 study of Tamoxifen therapy in women of increased risk of developing breast cancer

**Follow up** Variable across included studies

## Results

In addition to the key findings of the two randomised control studies presented in this summary, this systematic review highlights a number of other issues for the management of DCIS

*Influence on recurrence of positive vs. negative resected margins (NSABP B-24 trial):*

Sixteen percent of the patients had positive resected margins and 10% had unknown margins for DCIS, and others were known to have residual suspicious micro-calcifications. The recurrence rate for those with negative margins was lower and the effect of Tamoxifen was less. The absolute recurrence risk for ipsilateral breast recurrence was 7.0% (Tamoxifen arm) vs. 8.8% (placebo arm) in the margin-negative group and 10.6% (Tamoxifen arm) vs. 14.1% (placebo arm) in the unknown/margin-positive group.

*Influence of tumour estrogen receptor status on recurrence (NSABP B-24 trial):*

Of the 1798 eligible patients estrogen receptor (ER) status of tumours was known in 628 (35%) (327 placebo, 301 Tamoxifen). Seventy seven percent of tumours were ER positive and the risk ratio (RR) of recurrent or new breast pathology in patients receiving Tamoxifen was 0.41 in the ER positive group (95% CI, 0.25-0.65, P=0.0002). In the ER-negative group the RR was 0.8 (P=0.5) although the number of events (n=36) was too small to exclude a clinically meaningful benefit (95% CI for RR, 0.41-1.56).

*Effect of Tamoxifen in patients by age at randomisation:*

In this study only 9.5% of recruited patients were under 50 years of age, compared with 33.5% of those in the NSABP B-24 study. This may have been due to the nature of patient recruitment in the former study in that they were recruited through the UK national breast screening programme. Age-related data comparison between studies was possible only for local (IBT) recurrence; the benefit of Tamoxifen in both studies was more apparent in

women  $\leq$  50 years of age although this failed to achieve statistical significance.

### **Other considerations for the use of Tamoxifen in the management of DCIS**

#### *Tamoxifen toxicity:*

Both RCT studies included some data on toxicity associated with Tamoxifen treatment, but the NSABP P-1 study (Tamoxifen in the prevention of breast cancer in 13,388 women at increased risk) included a detailed analysis stratified by patient age. Significant toxicity events were; endometrial cancer, stroke, pulmonary embolism, and deep vein thrombosis. The largest difference in serious adverse events appears to be in women  $>$  50 years of age, however the absolute number of adverse events is low as is the incremental risk.

#### *Contraindications for breast conserving surgery (BCS):*

The authors state that as with invasive breast cancer, there are also contraindications for performing BCS in the management of DCIS: large tumour size and small breasts may not yield satisfactory cosmetic results and may be better served by mastectomy coupled with the option of reconstructive surgery. As with other studies, only a small proportion (4%) of patients recruited to the NSABP B-24 trial had lesions  $>$ 2 cm. Therefore local control rates reported may not be applicable to patients with larger lesions. Also, the detection of multiple tumours or extensive micro-calcifications are relative contraindications of BCS.

Overall, for the purposes of developing a clinical guideline for DCIS management in Canada, the reviewers highlight data from the NSABP B-24 study which suggests that most of the benefit of receiving Tamoxifen is with younger women ( $<$  50 years) and those with positive or unknown resection margins. No significant benefit was shown in the UKCCCR study although this was possibly confounded by the fact that most of the women recruited were older than 50 years of age and with clear resection margins. The authors conclude that Tamoxifen may be an option in women less than 50 years with positive margins who refuse further surgery, and also to those who refused or are unable to undergo radiotherapy but wish to avoid mastectomy. It is also recommended that physicians and patients give due consideration to the potential toxicities of Tamoxifen as well as their possible benefits.

-

**General comments** Canadian systematic review of literature concerning the management of DCIS and development of an evidence-based care clinical guideline.

Systematic review of randomised studies of the efficacy of adjuvant tamoxifen therapy following breast conserving surgery with or without post-operative radiotherapy.

Non-systematic review of non-randomised observational studies concerning aspects of DCIS management that fell outside the scope of randomised studies.

The key points of six existing clinical practice guidelines are tabulated as part of this review. The authors point out the fact that tamoxifen recommendations/statements were made prior to the publication of the UKCCCR study is important to note.

#### **5.4.1 Update of NICE Technology Appraisal 109 – Docetaxel for the Adjuvant Treatment of Early Node-Positive Breast Cancer.**

#### **5.4.2 Update of NICE Technology Appraisal 108 – Paclitaxel for the Adjuvant Treatment of Early-Positive Breast Cancer**

##### **Short Summary**

There is a considerable volume of high quality evidence that evaluates the clinical and cost effectiveness of docetaxel and paclitaxel for the adjuvant treatment of early breast cancer. The evidence includes a Cochrane review (Ferguson *et al.* 2007); an HTA report (Ward *et al.* 2007); a meta-analysis (De Laurentiis *et al.* 2008); a pooled analysis (Bria *et al.* 2006); 2 RCTs (Kummel *et al.* 2006; Piedbois *et al.* 2007) and 1 RCT from an abstract (Ellis *et al.* 2007).

The studies which reported overall survival (Ferguson *et al.* 2007; Ward *et al.* 2007) showed improved overall survival with use of the taxanes. The meta-analysis and pooled analysis (De Laurentiis *et al.* 2008; Bria *et al.* 2006) also showed significant improvements in overall survival with the taxanes compared with the control treatments. The TACT (taxotere as adjuvant chemotherapy) abstract (Ellis *et al.* 2007) showed a non significant difference between those given docetaxel and the control chemotherapy arm.

Disease-free survival showed improvement with the taxanes (Ferguson *et al.* 2007; Ward *et al.* 2007). The meta-analysis and pooled analysis (De Laurentiis *et al.* 2008; Bria *et al.* 2006) also showed significant differences with the taxanes compared with the control treatments in disease-free survival. The TACT study (Ellis *et al.* 2007) found a non significant difference in disease-free survival with those in the docetaxel group and those in the control group.

Neutropenia and febrile neutropenia were identified as occurring more frequently in those in the docetaxel groups than in the control groups. Where quality of life was reported the reductions in QoL associated with treatment were higher with docetaxel than in the control groups, with paclitaxel there was no significant difference compared with controls.

The HTA report (Ward *et al.* 2007) noted that the comparators used in most trials restrict the generalisability of results as they do not conform to current standards of care in the UK for reasons such as too few cycles of chemotherapy or using doxorubicin instead of the more widely used epirubicin. One further study has been published which compared the efficacy of paclitaxel and docetaxel given weekly or every 3 weeks in the adjuvant treatment of breast cancer (Sparano *et al.* 2008). All received 4 cycles of IV doxorubicin and cyclophosphamide, with each of 4 groups then followed this with paclitaxel or docetaxel (175mg/m<sup>2</sup>) at 3-week intervals for 4 cycles, or at 1-week intervals for 12 cycles (80mg/m<sup>2</sup>). For disease-free survival, compared with those receiving paclitaxel every 3 weeks there was significantly

higher survival with weekly paclitaxel and with docetaxel every 3 weeks and no significant difference with weekly docetaxel.<sup>11</sup> For overall survival, compared with those receiving paclitaxel every 3 weeks there was significantly higher survival with weekly paclitaxel and no significant difference with weekly docetaxel or 3-weekly docetaxel. Those with HER2 negative disease who had weekly paclitaxel had improved disease-free survival and overall survival. No significant difference was seen with other groups.

## PICO

Patient	Intervention	Comparison	Outcomes
Patients with early node-positive breast cancer following initial surgery	Docetaxel given as part of a cytotoxic chemotherapy regimen for the adjuvant treatment of breast cancer	Other adjuvant chemotherapy regimens	<ul style="list-style-type: none"> <li>•Disease-free survival</li> <li>•Overall survival</li> <li>•Contralateral breast cancer</li> <li>•Quality of life</li> <li>•Adverse events</li> <li>•Drug interactions</li> <li>Cost effectiveness</li> </ul>
Patients with early node-positive breast cancer following initial surgery	Paclitaxel given as part of a cytotoxic chemotherapy regimen for the adjuvant treatment of breast cancer	Other adjuvant chemotherapy regimens	<ul style="list-style-type: none"> <li>•Disease-free survival</li> <li>•Overall survival</li> <li>•Contralateral breast cancer</li> <li>•Quality of life</li> <li>•Adverse events</li> <li>•Drug interactions</li> <li>•Cost effectiveness</li> </ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

## Evidence statement

The Cochrane review considered taxanes (paclitaxel or docetaxel) for adjuvant treatment of early breast cancer (Ferguson *et al.* 2007). This included any chemotherapy regimen that contained a taxane, compared with any chemotherapy regimen without a taxane. This review included 12 studies with 21,191 participants; docetaxel was included as a treatment in 7 studies and paclitaxel in 5 studies. Analysis was completed for taxanes as a combined group in this review with only disease-free survival and overall survival being analysed for the individual agents.

<sup>11</sup> Results were similar where the definition of end point did not include contralateral breast cancer or contralateral breast cancer and second nonbreast cancer

The HTA report considered the clinical and cost effectiveness of docetaxel and paclitaxel compared with non-taxane containing chemotherapy regimens including anthracycline agent, for the adjuvant treatment of women with early stage breast cancer (Ward *et al.* 2007). This report included 18 trials which comprised 11 trials including docetaxel and 7 including paclitaxel. Information on the outcomes included were reported for individual trials as the authors considered that the heterogeneity of interventions, comparators and populations precluded meta-analysis.

De Laurentiis *et al.* (2008) completed a meta-analysis of randomised trials on taxane-based combinations as adjuvant chemotherapy of early breast cancer. This included trials containing a taxane-anthracycline based regimen with an anthracycline based regimen. There were 13 trials included with 22,903 participants. Seven studies used docetaxel (N=13,001) and six studies used paclitaxel (N=9,902).<sup>12</sup>

Bria *et al.* (2005) completed a pooled analysis of 15,500 patients which included those who were randomised to receive chemotherapy either with or without sequential or concomitant taxanes, all trials were specifically designed to assess if chemotherapy with taxanes improved survival. There were 9 trials with 15,598 participants, 4 trials used docetaxel (N=7,395) and 5 trials used paclitaxel (N=8,203).

One RCT considered dose-dense chemotherapy in node-positive breast cancer with T/EC or EC/T vs. standard dose TEC with the aim of selecting a dose-dense regimen for further assessment in phase III studies (Peidbois *et al.* 2007). This study had a primary end point of grade 4 toxicity. The second RCT considered the survival benefit and safety of adjuvant dose-dense chemotherapy for node-positive breast cancer using a dose-dense regimen including paclitaxel (epirubicin and paclitaxel, then CMF) compared with a conventional schedule (epirubicin and cyclophosphamide, then CMF) (Kummel *et al.* 2006).

The TACT study considered N=2073 participants who were randomised to 4 cycles of FEC followed by 4 cycles of docetaxel, these were compared with N=2089 who randomised to either 8 cycles of FEC or 4 cycles of E-CMF, designed so that all participants would have eight cycles of treatment (Ellis *et al.* 2007).

## Overall survival

In the Cochrane review (Ferguson *et al.* 2007) overall survival for the taxanes was reported in 11 studies (18,304 participants), this identified a hazard ratio (HR) for taxane containing regimens vs. non-taxane containing regimens: 0.81 (0.75 to 0.88),  $p < 0.00001$ . Overall survival in the docetaxel studies (N=9377) identified a HR 0.76 (0.67 to 0.86),  $p < 0.0001$  and in the paclitaxel studies (N=8927), HR 0.85 (0.76 to 0.94),  $p < 0.001$ .

In the HTA report (Ward *et al.* 2007) overall survival with docetaxel (reported in 4 studies) identified:

- significant improvement with DAC6 vs. FAC6, HR 0.69 (0.52 to 0.90)

---

<sup>12</sup> This study reported both fixed effects and random effects, the fixed effects values are used in this evidence statement, there were no values reported which were significant for random effects that were not also significant for fixed effects

- improvement with FEC3-D3 vs. FEC6 (which had a 4% lower survival rate)
- NS difference with DC4 vs. AC4 and with DA4 vs. AC4

Overall survival paclitaxel (reported in 5 studies) identified:

- significant improvement with AC4-P4 vs. AC4, HR 0.82 (0.71 to 0.95)
- 3% higher survival rate with E3-P3-CMF4 vs. E4-CMF4
- NS difference with PA4-CMF4 vs. A4-CMF4; AC4-P4 vs. AC4; FEC4-P8 vs. FEC6

The meta-analysis (De Laurentiis *et al.* 2008), twelve studies (N=22,379 participants, N=3,329 deaths) showed a significant reduction in the risk of death for taxane-based treatment total HR 0.85 (0.79 to 0.91),  $p < 0.00001$ , with docetaxel this was a HR 0.87 (0.79 to 0.95),  $p = 0.003$ , and with paclitaxel this was a HR 0.83 (0.75 to 0.92),  $p = 0.0004$ .

The pooled analysis (Bria *et al.* 2006) showed significant differences in favour of the taxanes in overall survival for the:

- total (8 trials, N=15,074) with RR 0.87 (0.81 to 0.93),  $p < 0.0001$ , NNT 49
- docetaxel (4 trials, N=7,395) with RR 0.78 (0.68 to 0.90),  $p = 0.001$ , NNT 42
- paclitaxel (4 trials, N=7,679) with RR 0.90 (0.83 to 0.98),  $p = 0.013$ , NNT 50

This significant difference in favour of the taxanes was also seen with the node-positive group, sequential taxane and concomitant taxane administration.

One RCT considered overall survival as a secondary endpoint and at a median follow-up of 38.4 months 17% of participants had died, 14% in the dose-dense group and 20% in the conventional schedule group.

The TACT study reported overall survival of 82% in the docetaxel arm and 81.8% with FEC only, the HR of 0.98 was NS, there were N=291 breast cancer deaths with docetaxel and N=301 with FEC only (Ellis *et al.* 2007).

### **Disease-free survival**

In the Cochrane report (Ferguson *et al.* 2007) disease-free survival for the taxanes was also reported in 11 studies (19,943 participants), this identified a hazard ratio (HR) for taxane containing regimens vs. controls: 0.81 (0.77 to 0.86),  $p < 0.00001$ . Disease-free survival in the docetaxel studies (N=12,264) identified a HR 0.80 (0.74 to 0.87),  $p < 0.00001$  and in the paclitaxel studies (N=7679), HR 0.82 (0.76 to 0.89),  $p < 0.00001$ .

In the HTA report (Ward *et al.* 2007) disease-free survival with docetaxel (reported in 6 studies) identified significantly better disease-free survival for:

- DAC6 vs. FAC6, HR 0.71 (0.58 to 0.87),  $p < 0.001$
- DC4 vs. AC4, HR 0.67 (0.50 to 0.94),  $p = 0.015$
- FEC3-D3 vs. FEC3, HR 0.83 (0.69 to 0.99),  $p = 0.041$
- A3-D3-CMF3 vs. A4-CMF4 (for sequential docetaxel administration), HR 0.79 (0.64 to 0.98),  $p = 0.035$

There was NS difference in disease-free survival between: DA4 vs. AC4; DA4-CMF3 vs. A4-CMF3 (for concurrent docetaxel administration); E4-D4-CMF4 vs. E4-CMF4.

In the HTA report (Ward *et al.* 2007) disease-free survival with paclitaxel (reported in 5 studies) identified significant improvement with disease-free survival for:

- AC4-P4 vs. AC4, RR paclitaxel compared with control 0.83 (0.72 to 0.95),  $p = 0.006$
- FEC4-P8 vs. FEC6, HR 0.63,  $p = 0.0008$

There was NS difference in disease-free survival between: E3-P3-CMF3 vs. E4-CMF4.

In the meta-analysis (De Laurentiis *et al.* 2008) disease-free survival was reported in thirteen studies. The reduction in risk of recurrence was significant for those receiving taxane-based treatments, the total for taxanes was a HR 0.83 (0.79 to 0.87),  $p < 0.00001$ , with docetaxel this was a HR 0.86 (0.80 to 0.92),  $p < 0.00001$  and with paclitaxel HR 0.80 (0.74 to 0.86),  $p < 0.00001$ .

The pooled analysis (Bria *et al.* 2006) showed significant differences in favour of the taxanes in disease-free survival for the:

- total (9 trials, N=15,598) with RR 0.86 (0.81 to 0.93),  $p < 0.0001$ , NNT 30
- docetaxel (4 trials, N=7,395) with RR 0.83 (0.75 to 0.91),  $p < 0.0001$ , NNT 31
- paclitaxel (5 trials, N=8,203) with RR 0.87 (0.81 to 0.93),  $p < 0.001$ , NNT 28

This significant difference in favour of the taxanes was also seen with the node-positive group, sequential taxane and concomitant taxane administration.

One RCT considered overall survival as a secondary endpoint and at a median follow-up of 38.4 months 33% of participants had experienced a first event of relapse or death, 31% in the dose-dense group and 35% in the conventional schedule group (Kummel *et al.* 2006).

The TACT study reported disease-free survival of 74.7% with docetaxel and 73.9% with FEC only, a NS HR of 0.97 (Ellis *et al.* 2007).

## Locoregional or distant recurrence or contralateral breast cancer

The HTA report reported on recurrence and the two docetaxel studies that reported on recurrence identified NS difference for DAC6 vs. FAC 6 for locoregional, distant or contralateral recurrence, while for FEC3-D3 vs. FEC6 distant recurrence was 17.7% vs. 21.8%,  $p=0.023$  (NS difference for locoregional or contralateral recurrence)(Ward et al 2007).

In the HTA report two paclitaxel studies reported on recurrence, one study found contralateral recurrence for AC4-P4 vs. AC4 of 1.1% vs. 1.9% ( $p=0.039$ ) with NS difference for locoregional recurrence; for E3-P3-CMF3 vs. E4-CMF4 there was NS difference with contralateral recurrence (Ward et al 2007).

## Adverse events

In the Cochrane review (Ferguson *et al.* 2007), ten of the twelve studies provided data on toxicity (there was heterogeneity between studies with the use of different control regimens and varying doses and schedules of the taxane)

- febrile neutropenia; reported in 7 studies, identified an increase in the taxane arms OR 2.51 (1.11 to 5.66), the risk was highest with taxane and anthracycline concurrent administration OR 6.80(1.91 to 24.15).
- nausea; reported in 5 studies, identified a lower risk with the taxane arms OR 0.55 (0.39 to 0.77)
- cardiotoxicity (reported in 6 studies), fatigue (4 studies), stomatitis (5 studies); showed no difference between taxane and non-taxane containing regimens
- secondary malignancy (reported in 7 studies) showed N=48 cases of secondary leukaemia or myelodysplasia, there was NS difference in secondary malignancy between taxane and non-taxane regimens
- treatment related deaths (reported in 6 studies) showed N=14 deaths, there was NS difference between taxane and non-taxane regimens

In the HTA report (Ward *et al.* 2007) there were seventeen (total N=8829) treatment-related deaths in the taxane containing arms and eleven (total N=8819) in the control arms.

In the docetaxel studies, the docetaxel arm showed:

- significantly more febrile neutropenia/neutropenic fever for; DAC6 vs. FAC6; FEC3-D3 vs. FEC6; DC4 vs. AC4; DE6 vs. FEC6
- significantly less nausea and vomiting or high-grade nausea/vomiting for; DAC6 vs. FAC6; FEC3-D3 vs. FEC6; DC4 vs. AC4; DA4 vs. AC4; DE6 vs. FEC6
- significantly more stomatitis for; DAC6 vs. FAC6; FEC3-D3 vs. FEC6

- significantly more mucositis or high-grade mucositis for; DAC6 (without G-CSF) vs. FAC6; DA4 vs. AC4
- significantly more diarrhoea or high-grade diarrhoea for: DAC6 vs. FAC6; DAC6 (without G-CSF) vs. FAC6; DA4 vs. AC4

In the paclitaxel studies there were few significant values for reported adverse events, though there was significantly more peripheral neuropathy and hypersensitivity reactions with E3-P3-CMF4 vs. E4-CMF4.

The two RCTs reported primarily on adverse events. The RCT which compared two dose dense regimens (T/EC and EC/T) with a standard regimen TEC identified that neutropenia to be the most frequent toxicity; 34% with TEC, 63% with EC/T and 53% with T/EC, with NS between the groups (Piedbois et al 2007). The dose dense regimens had significantly more incidence of skin and nail disorders and hand-foot syndrome. Any grade 4 event showed NS difference between the groups (26% TEC; 40% EC/T; 18% T/EC), with any grade 3-4 event there was a significantly higher occurrence with EC/T (73%) vs. TEC (46%),  $p=0.043$ , T/EC (68%) vs. TEC was NS. There were higher levels of having at least one cycle delayed with the dose dense regimens (11% TEC; 53% EC/T; 38% T/EC).

The RCT which compared a dose-dense paclitaxel containing regimen with a conventional schedule identified that for haematological toxicity leukopenia and neutropenia occurred in both treatment groups at similar rates and that rate of discontinuation at 4% was the same in both groups (Kummel et al 2006). For nonhaematological toxicity events that occurred more in the dose-dense group compared with the conventional schedule group were; peripheral nervous system toxicity (47 vs. 11%), bone pain (44% vs. 23%), arthralgia/myalgia (22% vs. 15%).

With the TACT study neutropenia and febrile neutropenia were significantly higher in the docetaxel arm ( $p=0.001$  for both), severe nonhaematological side effects were also significantly higher in the docetaxel arm ( $p=0.001$ ), including neuropathy and lethargy (Ellis et al 2007).

### Quality of life

In the Cochrane review (Ferguson *et al.* 2007) quality of life (QoL) was reported in N=2 studies, with one showing a transient reduction in both regimens which was greater with the taxane containing regimen, the second showed no different between the types of treatment groups

In the HTA report (Ward *et al.* 2007) in the docetaxel studies the QoL score worsened during treatment and recovered 3-4weeks after the last cycle of treatment for both arms in DAC6 vs. FAC6, with NS difference between the groups. The docetaxel arm showed significantly worse global QoL score with FEC4-D4 vs. FEC8 vs. E4-CMF4 ( $p=0.002$ ), this was also found for DAC6 (without G-CSF) vs. FAC6 ( $p=0.008$ ). With paclitaxel E3-P3-CMF4 showed NS difference vs. E4-CMF4 at baseline or at the end of treatment.

## Post-hoc analysis for the taxanes

The Cochrane review (Ferguson *et al.* 2007) included a post-hoc analysis and this identified that:

- sequential or concurrent taxane and anthracycline identified a significantly lower HR with taxane vs. sequential anthracycline and also for taxane and anthracycline concurrently in the experimental arm for both overall survival and disease-free survival;
- lymph node status identified a HR favouring taxane for both overall survival and disease-free survival for both studies which included those with positive axillary node metastasis and studies which allowed the inclusion of those without lymph node metastases;
- duration of chemotherapy identified a HR favouring taxane for both overall survival and disease-free survival for both studies which had a taxane containing arm of longer duration than the control arm and studies which had taxane and control arms of the same duration'
- number of cycles of taxane containing chemotherapy identified a HR favouring taxane for both overall survival and disease-free survival for both studies which had 3 cycles of taxane in the experimental arm and those which had 4 or more cycles of chemotherapy in the experimental arm.

## Subgroup analysis

### HTA report – disease-free survival

Subgroup analysis was completed in the HTA report (Ward *et al.* 2007) and in the docetaxel studies identified:

- a significant benefit with DAC6 vs. FAC6; for those with 1-3 nodes, for those with a HR+ve and those with HR-ve hormone receptor status, for those with a HER2 +ve status and for those who were HER2-ve, and for those who were premenopausal
- a significant benefit with FEC3-D3 vs. FEC6; for those with 1-3 nodes, and for those aged 50+ years
- a significant benefit with DC4 vs. AC4 for those who were node positive
- a significant benefit with DA4 vs. AC4 for those with ER-PR+ve hormone receptor status

While subgroup analysis in the paclitaxel studies identified:

- a significant benefit with FEC4-P8 vs. FEC6; for those with  $\geq 4$ +ve nodes, for both those who were HR+ve and those who were HR-ve, for both HER2-ve and HER2+ve, and for those who were post menopausal
- a significant benefit with AC4-P4 vs. AC4 for those with HR+ve hormone receptor status

## Meta-analysis

Subgroup analysis was completed, for oestrogen receptor status, taxanes significantly reduced the risk of recurrence for both ER-positive and ER-negative whether docetaxel or paclitaxel was administered. The pooled HR for disease-free survival was similar for patients with 1-3 and for 4 or more positive lymph nodes. Taxanes also showed a significant risk reduction for both  $\leq 50$  years/premenopausal and  $> 50$  years/postmenopausal (De Laurentiis et al 2008).

One further study has been published which compared the efficacy of paclitaxel and docetaxel given weekly or every 3 weeks in the adjuvant treatment of breast cancer (Sparano *et al.*, 2008), with disease-free survival and overall survival as outcomes, with N=4950 participants. All received 4 cycles of IV doxorubicin and cyclophosphamide, with each of 4 groups then followed this with paclitaxel or docetaxel ( $175\text{mg}/\text{m}^2$ ) at 3-week intervals for 4 cycles, or at 1-week intervals for 12 cycles ( $80\text{mg}/\text{m}^2$ ).

With disease-free survival, compared with those receiving paclitaxel every 3 weeks there was significantly higher survival with weekly paclitaxel (OR 1.27,  $p=0.006$ , 95% CI 1.03 to 1.57) and with docetaxel every 3 weeks (OR 1.23,  $p=0.02$ , 95% CI 1.00 to 1.52), NS difference with weekly docetaxel.<sup>13</sup>

With overall survival, compared with those receiving paclitaxel every 3 weeks there was significantly higher survival with weekly paclitaxel (OR 1.32,  $p=0.01$ , 95% CI 1.02 to 1.72), NS difference with weekly docetaxel or 3-weekly docetaxel.

Those with HER2 negative disease who had weekly paclitaxel had improved disease-free survival (OR 1.33,  $p=0.009$ , 95% CI 1.07 to 1.64) and overall survival (OR 1.34,  $p=0.03$ , 95% CI 1.02 to 1.76). NS difference was seen with other groups.

28% of those in the weekly paclitaxel group had grade 3 or 4 toxic effects compared with 30% with 3-weekly paclitaxel (NS), 71% with 3-weekly docetaxel ( $p<0.001$ ) and 45% with weekly docetaxel ( $p<0.001$ ). 3-weekly docetaxel had a neutropenia rate of 46%, this was 4% or less in the other treatment groups. 20% grade 2, 3 or 4 neuropathy (paclitaxel 3-weekly), 27% (paclitaxel weekly), 16% (docetaxel 3-weekly and with docetaxel weekly), weekly paclitaxel was significantly higher than the other groups ( $p<0.001$ ).

---

<sup>13</sup> Results were similar where the definition of end point did not include contralateral breast cancer or contralateral breast cancer and second nonbreast cancer

## Evidence Tables

<b>Citation</b>
Sparano JA., Wang M., Martino S., Jones V., Perez EA., Saphner T., Wolff AC., Sledge GW, Jr., Wood WC and Davidson NE (2008) Weekly paclitaxel in the adjuvant treatment of breast cancer.[see comment][erratum appears in N Engl J Med. 2008 Apr 3;359(1):106]. <i>N Engl J Med</i> <b>358</b> : 1663-1671
<b>Design</b>
Design: RCT, Country: USA
<b>Inclusion criteria</b>
Inclusion: axillary lymph node-positive (tumour stage T1, T2, or T3 and nodal stage N1 or N2) or high-risk, lymph node-negative (T2 or T3, N0) breast cancer
<b>Exclusion criteria</b>
<b>Population</b>
N=4950 (98% who were eligible from the N=5052 enrolled between October 1999 and January 2002)  Median age 51yrs (range 19 to 84yrs), 12% no +ve lymph nodes, 56% 1 to 3 +ve nodes, 32% 4 or more +ve nodes Tumour +ve for estrogen receptor, progesterone receptor, or both in 70%; +ve for HER2 in 19% 60% had undergone mastectomy, 40% had undergone breast-sparing surgery
<b>Interventions</b>
All patients received 4 cycles of IV doxorubicin and cyclophosphamide at 3-week intervals; - then IV paclitaxel or docetaxel either 3-week intervals for 4 cycles (175mg/m <sup>2</sup> ) - or 1-week intervals for 12 cycles (80mg/m <sup>2</sup> )  Treatment groups were similar with regard to prognostic characteristics, median age 51yrs, 60% had undergone mastectomy
<b>Outcomes</b>
Primary: Disease-free survival; defined as the time from randomisation to disease recurrence (including death from recurrence if it was the first manifestation of recurrence), death without recurrence, or contralateral breast cancer  Primary comparisons: - paclitaxel with docetaxel, regardless of dosing schedule - weekly dosing with dosing every 3 weeks, regardless of taxane administered

<b>Follow up</b>
Interim analysis planned to begin every 2 yrs after initiation of the study
<b>Results (all CI 95%)</b>
<p><b>Taxane type and schedule:</b>  After median follow-up of 63.8mths, N=1048 had recurrence of breast cancer or cancer in the contralateral breast, N=668 had died</p> <p>NS difference in disease-free survival between paclitaxel and docetaxel groups or between those receiving weekly treatment or treatment of every 3 weeks</p> <p><b>Disease-free survival:</b></p> <ul style="list-style-type: none"> <li>- estimated 5-yr survival for the paclitaxel every 3wks group, 76.9%</li> <li>- estimated 5-yr survival for the weekly paclitaxel group, 81.5%</li> <li>- estimated 5-yr survival for the docetaxel every 3wks group, 81.2%</li> <li>- estimated 5-yr survival for the weekly docetaxel, 77.6%</li> </ul> <p>Compared with those receiving paclitaxel every 3 wks, disease-free survival was significantly better in those with weekly paclitaxel (OR 1.27, p=0.006, 1.03 to 1.57) and with docetaxel every 3 wks (OR 1.23, p=0.02, CI 1.00 to 1.52), NS difference with weekly docetaxel</p> <p>Results were similar where the definition of end point did not include contralateral breast cancer or contralateral breast cancer and second primary nonbreast cancer</p> <p><b>Overall survival:</b></p> <ul style="list-style-type: none"> <li>- estimated 5-yr overall survival for the paclitaxel every 3wks group, 86.5%</li> <li>- estimated 5-yr overall survival for the weekly paclitaxel group, 89.7%</li> <li>- estimated 5-yr overall survival for the docetaxel every 3wks group, 87.3%</li> <li>- estimated 5-yr overall survival for the weekly docetaxel, 86.2%</li> </ul> <p>Compared with those receiving paclitaxel every 3 wks, overall survival was significantly better in those with weekly paclitaxel (OR, 1.32, p=0.01, CI 1.02 to 1.72), NS difference with weekly docetaxel or those receiving docetaxel every 3 wks</p> <p><b>HER2:</b>  (analysis of hormone receptor status not prespecified when the study was initiated in 1999)</p> <p>Those with HER2 –ve disease who had weekly paclitaxel had improved disease-free survival (OR, 1.33, p=0.009, CI 1.07 to 1.64) and overall survival (OR, 1.34, p=0.03, CI 1.02 to 1.76). NS difference seen with other treatment groups</p> <p><b>Toxicity:</b>  Doxorubicin and cyclophosphamide, 40% had grade 2 toxic effects, 13% grade 3, 39% grade 4, percentages similar in the 4 treatment groups</p>

28% those in the weekly paclitaxel group had grade 3 or 4 toxic effects compared with 30% in those getting paclitaxel every 3 wks (NS difference), 71% of those receiving docetaxel every 3 wks ( $p < 0.001$ ) and 45% with weekly docetaxel ( $p < 0.001$ )

Docetaxel every 3 wks had a 46% neutropenia rate (4% or less with the other groups)

Grade 2, 3 or 4 neuropathy were 20% (paclitaxel 3 wks), 27% (paclitaxel weekly), 16% (docetaxel 3wks), 16% (docetaxel weekly); incidence with weekly paclitaxel significantly higher when compared with the other groups ( $p < 0.001$  for each comparison)

### General comments

The end point differs from the end point of disease-free survival used in other trials of paclitaxel sponsored by the National Cancer Institute

Power analysis completed

All those who underwent randomisation were included in efficacy analysis, all treated patients were included in AE analysis regardless of eligibility

### Citation

Bria et al (2008) Cardiotoxicity and incidence of brain metastases after adjuvant trastuzumab for early breast cancer: the dark side of the moon? A meta-analysis of the randomised trials. Breast Cancer Research treatment 109:231-239

### Design

Design: meta-analysis

Country: Italy

1

### Inclusion criteria

All phase III prospective and randomised trials published as full papers in peer-reviewed journals or presented at the American Society of Clinical Oncology (ASCO), European Cancer Conference (ECCO), European Society for Medical Oncology (ESMO) or San Antonio Breast Cancer Symposium (SABCS) meetings until December 2006

Patients with HER2 overexpressing early breast cancer, after definitive surgery, were randomised to receive either chemotherapy (control) or chemotherapy and trastuzumab (experimental arm), regardless of the schedule of administration (weekly or 3-weekly), treatment duration or timing of chemotherapy (concomitant and/or following)

### Exclusion criteria

### Population

N=5 trials identified, including NSABP B-31, NCCTG N9831, HERA, BCIRG 006, FinHer, N=11,186 randomised patients. FinHer subsequently excluded due to short administration (9wks) trastuzumab given prior to chemotherapy and the small size of the trial
<b>Interventions</b>
All RCTs provided data for safety and efficacy end points, except FinHer and BCIRG 006 which did not report data concerning the number of brain metastases
<b>Outcomes</b>
<p>Safety end-point:</p> <ul style="list-style-type: none"> <li>- the incidence of symptomatic cardiotoxicity, grade III-IV NYHA functional assessment</li> <li>- the incidence of non-symptomatic while significant (as defined in the trial) decline in L-FEV</li> <li>- the incidence of brain metastases, as first site of disease relapse</li> </ul> <p>Efficacy end-point:</p> <ul style="list-style-type: none"> <li>- disease-free survival event rate</li> <li>- distant-disease-free survival event rate</li> <li>- overall survival event rate</li> </ul>
<b>Follow up</b>
Median follow-up ranged from 24 to 36 months
<b>Results (all CI 95%)</b>
<p><b>Safety end-point:</b>  Core analysis (N=4 trials, N=10,995 patients)  Grade III-IV NYHA:  Arms in which trastuzumab was given for 1yr showed a significantly increased risk of grade III-IV CHF in the trastuzumab arm; RR 7.05 (3.88 to 12.83), <math>p &lt; 0.0001</math>. NS heterogeneity. Absolute difference (AD) 1.62% which gives a NNH of 62</p> <p>Asymptomatic L-FEV reduction:  A significantly increased risk of L-FEV reduction was found in the trastuzumab arm; RR 2.18 (1.45 to 3.27), <math>p &lt; 0.00015</math>. These studies had significant heterogeneity (<math>p = 0.00008</math>), AD 7.20% which gives a NNH of 14</p> <p>Incidence of brain metastases:  Incidence as first site of relapse was significantly higher in the trastuzumab arm; RR 1.57 (1.03 to 2.37), <math>p = 0.033</math>. NS heterogeneity. AD 0.62% which gives a NNH of 161</p> <p>(Overall population (N=5 trials, N=11,186 patients) showed increased risk in the trastuzumab arm for grade III-IV CHF of 1.43% and for asymptomatic L-FEV of 5.95%, these were significantly biased by heterogeneity)</p>
<p><b>Efficacy end-point:</b>  Core analysis (N=4 trials, N=9,974)  Disease-free survival:</p>

Significantly prolonged in the trastuzumab arm; RR 0.63 (0.51 to 0.77),  $p=0.00001$ .  
Significant heterogeneity  $p=0.038$ . AD 6.0% which gives a NNT of 16

Distant disease-free survival:

Significantly prolonged in the trastuzumab arm; RR 0.61 (0.54 to 0.70),  $p=0.00001$ . NS  
heterogeneity. AD 4.8% which gives a NNT of 21

Overall survival:

Significantly prolonged in the trastuzumab arm; RR 0.66 (0.55 to 0.78),  $p<0.00001$ . NS  
heterogeneity. AD 1.96% which gives a NNT of 51

(Overall population (N=5 trials, N=11,186 patients) showed increases of 6.10% (disease-free  
survival), 5% (distant disease-free survival) and 2% (overall survival), these were significantly  
biased by heterogeneity)

### General comments

All data were reviewed and separately computed by two different independent investigators

Cardiotoxicity was reported consistently in the trials using toxicity grading III-IV according to  
NYHA. The definition of an asymptomatic decline in L-FEV differed, defined as a decline of  
10% in some trials and 15% in others.

Author's discussion: the risk for developing brain metastases was significantly higher for  
those receiving trastuzumab, but overall low with >160 patients treated to see one event (how  
much as these 'confounded' by the advantage in gained deaths from trastuzumab? How  
many of the dead in the control arms would have developed brain metastases?)

<b>Citation</b>
De Laurentiis et al (2008) Taxane-based combinations as adjuvant chemotherapy of early breast cancer: a meta-analysis of randomized trials
<b>Design</b>
Meta-analysis 1++
<b>Inclusion criteria</b>
Inclusion: early breast cancer, adjuvant therapy, randomised trial comparing a taxane-anthracycline-based regimen with an anthracycline-based regimen
<b>Exclusion criteria</b>
Exclusion: if the retrieved paper was an earlier report of data updated in a subsequent article, abstract or presentation; if a taxane was used in substitution (not addition to) an anthracycline
<b>Population</b>
N=13 studies used in pooled analysis, N=22,903 patients N=7 studies docetaxel, N=13,001 patients N=6 studies paclitaxel, N=9,902 patients
<b>Interventions</b>
A meta-analysis of randomised trials to address questions about the efficacy of adjuvant taxane-based therapy, particularly in relevant subgroups of EBC patients
<b>Outcomes</b>
<b>Main outcomes</b> <ul style="list-style-type: none"> <li>• Overall survival</li> <li>• Disease-free survival (DFS events included second primary breast cancers, local or distant recurrences of the original cancer, or death – unless otherwise specified)</li> </ul>
<b>Follow up</b>
<b>Results</b> (all CI 95%)
<b>Risk of recurrence (disease-free survival)</b> DFS for N=13 studies, N=5,829 events Single-study HR ranged from 0.63 to 0.97, were statistically significant in N=7 studies (n=4 paclitaxel, N=3 docetaxel) The reduction of risk of recurrence was significant in those receiving taxane-based therapy: <ul style="list-style-type: none"> <li>- paclitaxel; HR: 0.80 (0.74 to 0.86), p&lt;0.00001 (fixed effect); HR: 0.80 (0.74 to 0.86), p&lt;0.00001 (random effect)</li> <li>- docetaxel; HR: 0.86 (0.80 to 0.92), p&lt;0.00001 (fixed effect); HR: 0.86 (0.80 to 0.92), p&lt;0.00001 (random effect)</li> <li>- total for taxanes; HR: 0.83 (0.79 to 0.87), p&lt;0.00001 (fixed effect); HR 0.83 (0.79 to 0.88), p&lt;0.00001 (random effect)</li> </ul>

There was no evidence of heterogeneity among trials, or publication bias. Sensitivity analysis shows that DFS was significantly improved even when the meta-analysis was restricted to trials of taxanes in combination regimens, or sequential regimens, or to studies of node-positive patients only

**Risk of death (overall survival)**

All RCTs provided data for safety and efficacy end points, except FinHer and BCIRG 006 which did not report data concerning the number of brain metastases
<b>Outcomes</b>
Safety end-point: - the incidence of symptomatic cardiotoxicity, grade III-IV NYHA functional assessment - the incidence of non-symptomatic while significant (as defined in the trial) decline in L-FEV - the incidence of brain metastases, as first site of disease relapse

**Efficacy end-point:**

- disease-free survival event rate
- distant-disease-free survival event rate
- overall survival event rate

**Follow up**

Median follow-up ranged from 24 to 36 months

**Results (all CI 95%)**

**Safety end-point:**

Core analysis (N=4 trials, N=10,995 patients)

Grade III-IV NYHA:

Arms in which trastuzumab was given for 1yr showed a significantly increased risk of grade III-IV CHF in the trastuzumab arm; RR 7.05 (3.88 to 12.83),  $p < 0.0001$ . NS heterogeneity. Absolute difference (AD) 1.62% which gives a NNH of 62

Asymptomatic L-FEV reduction:

A significantly increased risk of L-FEV reduction was found in the trastuzumab arm; RR 2.18 (1.45 to 3.27),  $p < 0.00015$ . These studies had significant heterogeneity ( $p = 0.00008$ ), AD 7.20% which gives a NNH of 14

Incidence of brain metastases:

Incidence as first site of relapse was significantly higher in the trastuzumab arm; RR 1.57 (1.03 to 2.37),  $p = 0.033$ . NS heterogeneity. AD 0.62% which gives a NNH of 161

(Overall population (N=5 trials, N=11,186 patients) showed increased risk in the trastuzumab arm for grade III-IV CHF of 1.43% and for asymptomatic L-FEV of 5.95%, these were significantly biased by heterogeneity)

**Efficacy end-point:**

Core analysis (N=4 trials, N=9,974)

Disease-free survival:

Significantly prolonged in the trastuzumab arm; RR 0.63 (0.51 to 0.77),  $p = 0.00001$ . Significant heterogeneity  $p = 0.038$ . AD 6.0% which gives a NNT of 16

Distant disease-free survival:

Significantly prolonged in the trastuzumab arm; RR 0.61 (0.54 to 0.70),  $p = 0.00001$ . NS heterogeneity. AD 4.8% which gives a NNT of 21

Overall survival:

Significantly prolonged in the trastuzumab arm; RR 0.66 (0.55 to 0.78),  $p < 0.00001$ . NS heterogeneity. AD 1.96% which gives a NNT of 51

(Overall population (N=5 trials, N=11,186 patients) showed increases of 6.10% (disease-free survival), 5% (distant disease-free survival) and 2% (overall survival), these were significantly biased by heterogeneity)

## General comments

All data were reviewed and separately computed by two different independent investigators

Cardiotoxicity was reported consistently in the trials using toxicity grading III-IV according to NYHA. The definition of an asymptomatic decline in L-FEV differed, defined as a decline of 10% in some trials and 15% in others.

Author's discussion: the risk for developing brain metastases was significantly higher for those receiving trastuzumab, but overall low with >160 patients treated to see one event (how much as these 'confounded' by the advantage in gained deaths from trastuzumab? How many of the dead in the control arms would have developed brain metastases?)

=12 studies, N=22,379 patients, N=3,329 deaths

Single-study HR ranged from 0.41 to 1.03, were statistically significant in N=4 studies (N=2 paclitaxel, N=2 docetaxel)

There was a reduction in the risk of death were significant for those receiving taxane-based therapy:

- paclitaxel; HR: 0.83 (0.75 to 0.92),  $p=0.0004$  (fixed effect); HR: 0.81 (0.70 to 0.94),  $p=0.005$  (random effect)
- docetaxel; HR: 0.87 (0.79 to 0.95),  $p=0.003$  (fixed effect); HR: 0.84 (0.73 to 0.96),  $p=0.010$  (random effect)
- total for taxanes; HR: 0.85 (0.79 to 0.91),  $p<0.00001$  (fixed effect); 0.83 (0.76 to 0.91),  $p=0.0001$  (random effect)

There was no statistical heterogeneity among studies or evidence of publication bias

Sensitivity analysis shows that overall survival was not significantly improved when the meta-analysis was restricted to studies of combination regimens

## Subgroups

### Oestrogen receptor (ER+ve vs. ER-ve)

N=10 studies, N=17,324 patients

Taxanes significantly reduced the risk of recurrence for both ER-positive and ER-negative

There was no statistically significant difference between the HRs in the two patient subgroups, this was independent of whether paclitaxel or docetaxel was administered

- ER+ve; HR: 0.83 (0.76 to 0.89),  $p<0.00001$  (fixed effect)
- ER-ve; HR: 0.79 (0.72 to 0.86),  $p<0.00001$  (fixed effect)
- total; HR: 0.81 (0.76 to 0.86),  $p<0.00001$  (fixed effect)

### Nodal status (N1 to 3 vs. N4+)

N=4 studies, N=6,170 patients

The pooled HR for DFS was similar for patients with one to three positive lymph nodes and for those with four or more positive lymph nodes

- N1-3; HR: 0.71 (0.61 to 0.84),  $p<0.0001$  (fixed effect)
- $N\geq 4$ ; HR: 0.75 (0.66 to 0.87),  $p=0.0001$  (fixed effect)
- total; HR: 0.74 (0.66 to 0.82),  $p<0.00001$  (fixed effect)

### Age ( $\leq 50$ vs. $>50$ years)

N=3 studies

<p><b>Menopausal status (pre vs. post)</b>  N=2 studies  As postmenopausal status usually arises around the age of 50yrs, the groups were analysed together  Taxanes showed a significant risk reduction for both ≤50 yrs/premenopausal and &gt;50yrs/postmenopausal  - ≤50 yrs/premenopausal; HR: 0.85 (0.76 to 0.96), p=0.006 (fixed effect)  - &gt;50yrs/postmenopausal; HR: 0.75 (0.67 to 0.87), p&lt;0.00001 (fixed effect)  - total; HR: 0.80 (0.74 to 0.87), p&lt;0.00001 (fixed effect)</p> <p><b>HER-2 expression</b>  N=2 studies  There was no interaction between HER-2 expression and taxane administration in terms of reduction of risk of recurrence</p>
<p><b>General comments</b></p> <p>Computerised search of PubMed (yrs 2000 to 2006) using the words; breast cancer and (paclitaxel or docetaxel); computerised search of appropriate abstracts and presentations; all review articles and cross-referenced manuscripts were screened from pertinent studies</p> <p>Data were independently extracted by two individuals who were blinded to each other. After review and comparison instances of disagreement were resolved by consultation</p> <p>All trials were based on the ITT principle, 95% CIs were calculated for each point estimate. Sensitivity analysis completed</p> <p>HR were extracted from relevant trials and performed a meta-analysis which aimed to: give the best estimate of the relative reduction of risk of recurrence and death; give the best estimate of the magnitude of benefit in terms of the risk of recurrence and death; verify whether or not such benefits remain consistent across some relevant subgroups of patients</p>
<p><b>Citation</b></p>
<p>Kummel et al (2006) Randomised trial: survival benefit and safety of adjuvant dose-dense chemotherapy for node-positive breast cancer</p>
<p><b>Design</b></p>
<p>Multicentre, randomised, open-label Phase 3  1+</p>
<p><b>Inclusion criteria</b></p> <p>Inclusion: primary resected, histologically confirmed breast cancer, stage I, II or III, surgical procedures performed ≤15days before randomisation (included R0 resection and axillary extirpation), patients had ≥4 positive axillary lymph nodes, no distant metastases, an Eastern Cooperative Oncology Group (ECOG) performance status &lt;2, adequate organ function, no previous chemotherapy or radiotherapy</p>

Ag 26 to 72yrs (mean age 53yrs), 60% post-menopausal
<b>Exclusion criteria</b>
Exclusion: leucocytes or platelets below specified levels (one patient with an ECOG performance status of 3 was admitted to the study in violation of the protocol, this patient was included in the analysis)
<b>Population</b>
N=231 (N=116 top dose-dense and N=115 to a conventional schedule) 30 centres in Germany between July 1996 and December 2000
<b>Interventions</b>
Evaluates a dose-dense sequential chemotherapy regimen administered after mastectomy or breast-conserving surgery  Dose-dense (DD): - epirubicin 90mg/m <sup>2</sup> plus paclitaxel 175mg/m <sup>2</sup> in four 14-day cycles, then CMF (600/40/600) in three 21-day cycles (plus filgrastim if required)  Conventional schedule (CS): - epirubicin 90mg/m <sup>2</sup> plus cyclophosphamide 600mg/m <sup>2</sup> in four 21-day cycles, then CMF (600/40/600) in three 21-day cycles (plus filgrastim if required)
<b>Outcomes</b>
<b>Primary end point</b> <ul style="list-style-type: none"> <li>• Rate of disease-free survival</li> </ul> <b>Secondary end point</b> <ul style="list-style-type: none"> <li>• Overall survival in the two groups</li> <li>• Incidence of chemotherapy postponement or dose reduction</li> <li>• Safety and tolerability of the regimen</li> </ul>
<b>Follow up</b>
Patients were followed for up to 5yrs after inclusion in the study with regularly scheduled visits
<b>Results</b> (all CI 95%)
N=15 excluded due to ineligibility (N=8 DD and N=7 conventional) N=4 discontinued in the each group  <b>Disease-free survival</b> At a median follow-up of 38.4mths N=71 (33%) experienced a first event of relapse or death; N=33 events (31%) in the DD group and N=38 events (35%) in the CS group  After 2yrs DFS was 81% (74-89%) in the DD group and 72% (64-81%) in the CS group After 4yrs DFS was 64% (55-76%) in the DD group and 58% (48-70%) in the CS group

The most common site of disease relapse was bone metastasis (31% of cases)

### **Overall survival**

At a median follow-up of 38.4mths N=37/216 (17%) had died; N=15 (14%) in the DD group and N=22 (20%) in the CS group

After 2yrs OS was 94% (89-99%) in the DD group and 92% (87-97%) in the CS group  
After 4yrs OS was 85% (78-94%) in the DD group and 75% (66-85%) in the CS group

### **Feasibility**

96% of patients in both groups received all 7 cycles of chemotherapy  
Doses were reduced in N=14/1477 evaluable cycles (1%)

### **Safety and tolerability**

Rate of discontinuation (4%) the same in both groups; N=2 (2%) DD group and N=1 (1%) CS group discontinued because of toxicity (included acute hypersensitivity reaction, febrile neutropenia, fatigue); N=3 (N=1 DD group, N=2 CS group) discontinued for other reasons (withdrawal of consent, uncontrolled diabetes, infection of a breast wound)

Haematological toxicity: leukopenia and neutropenia occurred in both treatment groups at similar rates; grade 3 leukopenia (DD group N=40, 37%; CS group N=46, 43%), grade 4 leukopenia (DD group N=8, 7%; CS group N=6, 6%), grade 3 neutropenia (DD group N=26, 34%; CS group N=23, 28%), grade 4 neutropenia (DD group N=22, 29%; CS group N=30, 37%)

Nonhaematologic toxicity:

Events that occurred more in the DD group than the CS group include peripheral nervous system toxicity (47 vs. 11%), bone pain (44 vs. 23%) and arthralgia/myalgia (22 vs. 15%)  
Cardiotoxicity; grade 3, N=1 in the CS group, N=0 in the DD group; grade 4 cardiotoxicity experienced by no patients

### **General comments**

Patients were randomised in permuted blocks, stratified by centre, using a computer-generated randomisation list

The trial was designed to detect a difference of 15% in the primary end point of DFS after 5yrs, with a risk of type-1 error of 5% (one-sided) and a power of approx 80% based on a sample size of 121 patients

### **Citation**

Piedbois et al (2007) Dose-dense adjuvant chemotherapy in node-positive breast cancer: docetaxel followed by epirubiin/cyclophosphamide (T/EC), or the reverse sequence (EC/T), every 2 weeks, versus docetaxel, epirubicin and cyclophosphamide (TEC) every 3 weeks. AERO B03 randomised phase II study. Annals of Oncology

### **Design**

Design: RCT Country: France 1+
<b>Inclusion criteria</b>
Female, >18yrs, Eastern Cooperative Oncology Group performance status 0-1, with histologically proven invasive breast adenocarcinoma, R0 resection of their tumour within 60days before randomisation and at least one histologically positive axillary lymph node among at least 6 resected nodes, adequate biological functions (blood counts, liver function, cardiac function) Study enrollment; 12 <sup>th</sup> December 2003 to 30 <sup>th</sup> September 2004 There were no evident imbalances in baseline characteristics
<b>Exclusion criteria</b>
T4, N2-3 or M1 stage, bilateral, second or inflammatory breast cancer, lymph node involvement determined by immunohistochemistry alone, ductal carcinoma in situ (DCIS), aminotransferases >1.5xUNL concomitant with ALP>2.5xUNL, sensory neuropathy of grade >2, prior history of cancer within 10yrs (except basal skin carcinoma or cervical CIS, lobular CIS or ipsilateral DCIS of the breast), previous or concomitant anticancer therapy including radiation and hormone therapy
<b>Population</b>
N=100 (Arm A, N=35; Arm B, N=31; Arm C, N=34), 12 <sup>th</sup> December 2003 to 30 <sup>th</sup> September 2004
<b>Interventions</b>
Primary objective: to select a dose-dense regimen for further assessment in phase III studies Secondary objective: a preliminary assessment of efficacy  Used two sequential dose-dense regimens (EC→T and T→EC) to select one of them as the experimental arm of further phase III studies, a control arm of a 3-drug regimen with conventional doses intervals was used  Arm A (TEC, docetaxel 75mg/m <sup>2</sup> , epirubicin 75mg/m <sup>2</sup> , cyclophosphamide 500mg/m <sup>2</sup> , every 3wks for 6 cycles) Arm B (EC→T, epirubicin 100mg/m <sup>2</sup> , cyclophosphamide 600mg/m <sup>2</sup> every 2wks for 4 cycles, followed by docetaxel 100mg/m <sup>2</sup> every 2wks for 4 cycles) Arm C (T→EC, the reverse sequence for EC→T)
<b>Outcomes</b>
Incidence of grade 4 toxicity Efficacy end points (OS and DFS) were only exploratory
<b>Follow up</b>
<b>Results</b>
The median number of examined nodes was 12 (range 4-24), median number of

pathologically involved nodes was 2 (range 1-20)

**Grade 4 toxicity:**

N=27 had grade 4 toxicity

- N=9 (26%) arm A

- N=12 (40%) arm B

- N=6 (18%) arm C

N=26/27 also had grade 4 neutropenia

- febrile neutropenia:

N=4 (arm A), N=3 (arm B), N=1 (arm C), despite G-CSF prophylaxis in N=7/8

- other:

N=2 fatigue, N=1 thrombocytopenia, N=1 nausea

Other:

Dose-dense regimens reported nail disorders, hand-foot syndrome, peripheral neuropathy and fluid retention of any grade and more grade 3 or 4 events (73% arm B and 68% arm C) compared with TEC (46%)

Overall incidence and grade 3-4 incidence showed no clear difference between the dose-dense regimens

Neutropenia and mucositis occurred more frequently with EC→T than with T→EC

One patient in arm B experienced grade 3 congestive heart failure with LVEF of 35 %

**Drop outs/incomplete treatment:**

N=5 patients prematurely discontinued study treatment due to toxicity:

- arm A, N=1 febrile neutropenia with grade 4 asthenia and vomiting (after 4<sup>th</sup> cycle of TEC)

- arm B, N=1 congestive heart failure (after 4<sup>th</sup> EC cycle), N=2 grade 3 peripheral neuropathy and nail disorder (N=1 at docetaxel cycle 1 and N=1 at cycle 3)

- arm C, N=1 withdrew with grade 3 hand-foot syndrome associated with nail and ocular toxicity after 3<sup>rd</sup> docetaxel cycle

- N=4 patients (N=1 arm A, N=2 arm B, N=1 arm C) refused to complete their treatment

- no toxic death occurred

**Exposure to treatment**

N=1 arm B did not receive treatment

N=2 (6%) TEC (arm A) did not receive the 6 planned cycles

N=5 (17%) arm B and N=3 (8%) arm C did not receive the 8 planned cycles

N=2 arm B didn't receive docetaxel, N=2 arm C didn't receive EC

N=4 (11%) TEC arm had at least one cycle delayed by >7days, compared with N=16 (53%) in the EC→T arm and N=13 (38%) in the T→EC arm

N=6 (17%) TEC arm had at least one dose reduction, compared with N=11 (37%) in the EC→T arm and N=11 (32%) in the T→EC arm

**General comments**

Toxicity was graded according to National Cancer Institute of Canada Common Toxicity Criteria version 3

N=33 patients per arm were considered necessary to correctly reject a toxic treatment (with >50% grade 4) and correctly accept a nontoxic treatment (with <25% grade 4) with a probability of 90%

If <11 grade 4 toxic events occurred, the treatment was to be considered tolerable; if >13 grade 4 toxic events occurred, the study was not conclusive

Trial was not powered to detect differences between treatment arms

A dose of pegfilgrastim was recommended in all patients on day 2 after each chemotherapy cycle, treatment could be resumed only when biological parameters returned to normal

<b>Citation</b>
Ferguson et al 2007 – Taxanes for adjuvant treatment of early breast cancer. Cochrane Database of Systematic Reviews
<b>Design</b>
Systematic review, meta-analysis 1++
<b>Inclusion criteria</b>
Unconfounded RCTs  Comparison of taxane (paclitaxel or docetaxel) containing adjuvant chemotherapy regimens with adjuvant regimens not containing a taxane in the management of women with operable early breast cancer
<b>Exclusion criteria</b>
Women who received neoadjuvant chemotherapy
<b>Population</b>
N=21,191 (N=12 included studies, N=5 paclitaxel, N=7 docetaxel)
<b>Types of participants</b>
women of any age with histologically confirmed operable breast cancer
<b>Interventions</b>
Any chemotherapy regimen that contained a taxane, compared with any chemotherapy regimen without a taxane: <ul style="list-style-type: none"><li>• Taxane containing regimen vs. the same regimen without a taxane</li><li>• Any taxane containing regimen vs. any regimen without a taxane</li><li>• Any taxane containing regimen vs. the same regimen with another drug or drugs that were substituted for the taxane</li><li>• Endocrine therapy was allowed if the same treatment was given to all groups</li></ul>
<b>Outcomes</b>

**Primary outcome**

- Overall survival

**Secondary outcome**

- Disease-free survival

post-hoc analysis

- Type of taxane
- Longer or same duration of chemotherapy
- Node positive only or node positive and negative
- Sequential or concurrent anthracycline and taxane
- Less than 4 or more cycles of taxane

Toxicity data

Quality of life

**Follow up**

Median follow-up ranged from 36mths to 60mths

Weighted average mean follow-up 60.4mths

**Results** (all CI 95%)**Overall survival**

N=18,304 (N=11 studies)

N=2483 deaths

Hazard Ratio (HR) taxane containing regimens vs. non-taxane containing regimens: 0.81 (0.75 to 0.88),  $p < 0.00001$

NS heterogeneity across trials

**Disease-free survival**

N=19,943 (N=11 studies)

N=4800 events reported

Taxane containing group vs. controls, HR: 0.81 (0.77 to 0.86),  $p < 0.00001$

NS heterogeneity across studies

**Type of Taxane**

Docetaxel N=7 studies

Pacitaxel N=5 studies

Overall survival:

- docetaxel N=9377, HR: 0.76 (0.67 to 0.86),  $p < 0.0001$

- pacitaxel N=8927, HR: 0.85 (0.76 to 0.94),  $p < 0.001$

Disease-free survival

- docetaxel N=12,264, HR: 0.80 (0.74 to 0.87),  $p < 0.00001$

- pacitaxel N=7679, HR: 0.82 (0.76 to 0.89),  $p < 0.00001$

**Sequential or concurrent taxane and anthracycline**

**Overall survival:**

N=12,004 (N=7 studies; 4 paclitaxel, 3 docetaxel) taxane and anthracycline administered sequentially

Taxane vs. sequential anthracycline, HR: 0.82 (0.75 to 0.90), p<0.0001

N=5284 (N=3 studies) taxane and anthracycline concurrently in the experimental arm

Taxane and anthracycline vs. non-experimental arm, HR: 0.79 (0.66 to 0.94), p=0.007

**Disease-free survival:**

N=10,756 (N=6 studies; 3 paclitaxel, 3 docetaxel) taxane and anthracycline administered sequentially

Taxane vs. sequential anthracycline, HR: 0.81 (0.76 to 0.88), p<0.00001

N=5284 (N=3 studies) taxane and anthracycline concurrently in the experimental arm

Taxane and anthracycline vs. non-experimental arm, HR: 0.79 (0.70 to 0.90), p=0.0003

**Lymph node status**

(variations in inclusion criteria between the studies may have impacted on the risk of recurrence)

**Overall survival:**

N=11,890, N=1903 deaths (N=6 studies; 3 paclitaxel, 3 docetaxel) required positive axillary node metastasis for eligibility

HR, favouring taxane: 0.81 (0.74 to 0.89), p<0.00001

N=6414, N=580 deaths (N=5 studies; 2 paclitaxel, 3 docetaxel) allowed inclusion of those without lymph node metastases

HR, favouring taxane: 0.81 (0.75 to 0.88), p<0.01

**Disease-free survival:**

N=13,529, N=3761 events (N=6 studies; 2 paclitaxel, 4 docetaxel) required positive axillary node metastasis for eligibility

HR, favouring taxane: 0.81 (0.76 to 0.87), p<0.00001

N=6414, N=580 events (N=5 studies; 2 paclitaxel, 3 docetaxel) allowed inclusion of those without lymph node metastases

HR, favouring taxane: 0.80 (0.71 to 0.91), p=0.0004

**Addition of a taxane/substitution of a taxane**

**Overall survival:**

N=8651 (N=5 studies; 4 paclitaxel, 1 docetaxel) experimental arm, taxane in addition to control chemotherapy

HR, favouring taxane: 0.84 (0.76 to 0.93), p<0.0008

N=9653 (N=6 studies) experimental arm, taxane substituted for one or more of the drugs in the control group

HR, favouring taxane: 0.76 (0.67 to 0.87), p<0.0001

**Disease-free survival:**

N=8651 (N=5 studies; 4 paclitaxel, 1 docetaxel) experimental arm, taxane in addition to control chemotherapy

HR, favouring taxane: 0.82 (0.76 to 0.89),  $p < 0.00001$

N=8405 (N=5 studies; all docetaxel) experimental arm, taxane substituted for one or more of the drugs in the control group

HR, favouring taxane: 0.78 (0.71 to 0.86),  $p < 0.0001$

### **Duration of chemotherapy**

Overall survival:

N=7747 (N=4 studies; 3 paclitaxel, 1 docetaxel) taxane containing experimental arm of longer duration than the control arm

HR, favouring taxane: 0.85 (0.77 to 0.94),  $p = 0.002$

N=10,557 (N=7 studies; 2 paclitaxel, 5 docetaxel) taxane containing experimental arm and control arm of the same duration

HR, favouring taxane: 0.76 (0.67 to 0.86),  $p < 0.0001$

Disease-free survival:

N=7747 (N=4 studies; 3 paclitaxel, 1 docetaxel) taxane containing experimental arm of longer duration than the control arm

HR, favouring taxane: 0.83 (0.77 to 0.94),  $p < 0.00001$

N=9309 (N=6 studies; 1 paclitaxel, 5 docetaxel) taxane containing experimental arm and control arm of the same duration

HR, favouring taxane: 0.77 (0.70 to 0.8),  $p < 0.0001$

### **Number of cycles of taxane containing chemotherapy**

Overall survival:

N=3604 (N=3 studies; 1 paclitaxel, 2 docetaxel) 3 cycles of taxane in the experimental arm

HR, favouring taxane: 0.74 (0.61 to 0.91),  $p = 0.004$

N=13,452 (N=7 studies; 3 paclitaxel, 4 docetaxel) 4 or more cycles of taxane in the experimental arm

HR, favouring taxane: 0.83 (0.76 to 0.90),  $p < 0.0001$

Disease-free survival:

N=3604 (N=3 studies; 1 paclitaxel, 2 docetaxel) 3 cycles of taxane in the experimental arm

HR, favouring taxane: 0.79 (0.68 to 0.91),  $p = 0.001$

N=13,452 (N=7 studies; 3 paclitaxel, 4 docetaxel) 4 or more cycles of taxane in the experimental arm

HR, favouring taxane: 0.81 (0.75 to 0.87),  $p < 0.00001$

### **Toxicity**

(there was heterogeneity between studies with the use of different control chemotherapies and varying doses and scheduling of the taxane drug)

N=10/12 provided data on toxicity

Cardiotoxicity:

N=6 studies: NS difference in the risk of developing cardiotoxicity between taxane containing

and non-taxane containing regimens

Febrile neutropenia:

N=7 studies: an increase in febrile neutropenia in the taxane containing arms: OR 2.51 (1.11 to 5.66), the risk was highest where the taxane was administered concurrently with an anthracycline: OR 6.80 (1.91 to 24.15) rather than sequentially (significant heterogeneity between the studies, chi-square=145, df=6, p<0.00001)

Nausea:

N=5 studies (grade 3 or 4 and/or vomiting): lower risk for those treated with a taxane: OR 0.55 (0.39 to 0.77)

Fatigue:

N=4 studies (grade 3 or 4 fatigue): NS increase in taxane containing regimens

Stomatitis:

N=5 studies (grade 3 or 4): no increase in taxane containing regimens

Other toxicities:

Grade 3 or 4 myalgia or arthralgia reported in N=3 studies, incidence low, more frequent in taxane containing arms (2% vs. 0.3%; 1% vs. <1%; 1.3% vs. 0.3%)

Nail changes in N=3 studies, more frequent in taxane containing arms (0.4% vs. 0.1%, 55% vs. 10%, 10.3% vs. 1%)

Grade 3 or 4 allergy reported in N=3 studies, more frequent in those receiving taxanes (3.7% vs. 0.3%, 1.3% vs. 0.1%, 2.2% vs. 0%)

Grade 3 or 4 oedema was an infrequent event

Neurotoxicity was inconsistently reported

### **Secondary malignancy**

N=7 studies (3 paclitaxel, 4 docetaxel) reported N=48 cases of secondary leukaemia or myelodysplasia – N=25 taxane containing regimens, N=23 control regimens, NS difference between the groups (NS heterogeneity)

### **Treatment-related deaths**

N=6 studies (3 paclitaxel, 3 docetaxel) reported N=14 treatment-related deaths, N=7 taxane containing regimens, N=7 control regimens, NS difference between the groups (NS heterogeneity)

### **Quality of life**

N=2 studies, one study (docetaxel) showed a transient reduction in both treatment arms, the reduction was greater in the taxane containing regimen, the second study (paclitaxel) showed no difference in QoL scores between the two treatment arms

### **General comments**

Search methods – Cochrane Breast Cancer Group Specialised Register searched between

August 2005 to January 2007, hand search included abstracts published from 1995 to 2006 for presentations at the American Society of Clinical Oncology Annual Scientific meeting and the San Antonio Breast Cancer Symposium

Selection criteria were applied to each trial publication or abstract independently by the two review authors who were masked to the study title, authors and results. Two review authors independently assessed each potential eligible trial for inclusion in the review, quality and analysis

All included studies had a time-to-event primary outcome, treatment groups were balanced in most studies, all seven full publications described ITT analysis, overall study quality was considered to be high

No studies were blinded to treatment, not considered to bias results as outcomes were uniformly measured by time to event and were not subject to observer or patient bias in interpretation

<b>Citation</b>
Ward et al (2007) Taxanes for the adjuvant treatment of early breast cancer: systematic review and economic evaluation. Health Technology Assessment
<b>Design</b>
Systematic review of RCTs 1++
<b>Inclusion criteria</b>
Women who have had surgery for early-stage breast cancer (stages I, II and IIIa)
<b>Exclusion criteria</b>
Neoadjuvant therapy, advanced-stage breast cancer, where the comparator is not anthracycline-containing chemotherapy, taxanes in both/all study arms
<b>Population</b>
Women who have had surgery for early-stage breast cancer (stages I, II and IIIa) Subgroups: age, nodal status, ER+ vs. ER- and PR+ vs. PR-; HER2 positivity prognostic status
<b>Interventions</b>
Any docetaxel and paclitaxel clinically and cost effective compared with non-taxane-containing chemotherapy regimens including anthracycline agent, for the adjuvant treatment of women with early stage breast cancer <ul style="list-style-type: none"><li>• Sequential paclitaxel therapy (paclitaxel following anthracycline therapy) vs. anthracycline-based non-taxane therapy</li><li>• Combination docetaxel therapy vs. anthracycline-based non-taxane therapy</li></ul>

<b>Outcomes</b>
<ul style="list-style-type: none"> <li>• Overall survival (defined as the hazard of death from any cause after a given follow-up period, or time from randomisation to death from any cause)</li> <li>• Disease-free survival (defined as the hazard of disease recurrence, second cancer or death from any cause after a given follow-up period, or time from randomisation to first of these events)</li> <li>• Local and distant recurrence (contralateral breast cancer, distant recurrence or local/regional recurrence)</li> <li>• Adverse events (AEs)/toxicity (any reported, however defined)</li> <li>• Health-related quality of life (HRQoL) (measured using any validated HRQoL instrument)</li> </ul>
<b>Follow up</b>
Median follow-up for studies ranged from 43 to 69 months
<b>Results</b> (all CI 95%)
<p><b>Overall survival</b></p> <p><i>Docetaxel</i>  HR 0.69 (0.52 to 0.90), significant improvement with DAC6 compared with FAC6 (BCIRG 001)  Improvement for FEC3-D3 compared with FEC6 which had a 4% lower survival rate (PAC 01)  NS difference: DC4 and AC4 (USO 9735), DA4 and AC4 (ECOG),  USO 9735 reported deaths from breast cancer at 36mths, docetaxel group had N=17 (3.4%)  from breast cancer, control group N=15 (2.9%) – no other studies reported deaths from breast cancer</p> <p><i>Paclitaxel</i>  HR 0.82 (0.71 to 0.95), significant improvement with AC4-P4 vs. AC4 (CALGB 9344)  3% higher survival rate for E3-P3-CMF4 vs. E4-CMF4 (HCOG)  NS difference: PA4-CMF4 and A4-CMF4(ECTO), AC4-P4 and AC4(NSABP B28), FEC4-P4  and FEC6 (GEICAM 9906)</p> <p><b>Disease-free survival</b></p> <p><i>Docetaxel</i>  Significantly better for:  - DAC6 vs. FAC6; HR: 0.71 (0.58 to 0.87), p&lt;0.001 (BCIRG 001)  - DC4 vs. AC4; HR: 0.67 (0.50 to 0.94), p=0.015 (USO 9735)  - FEC3-D3 vs. FEC3; HR: 0.83 (0.69 to 0.99), p=0.041 (PAC 01)  A3-D3-CMF3 vs. A4-CMF3 (sequential docetaxel); HR: 0.79 (0.64 to 0.98), p=0.035 (BIG 2-98)  NS difference: DA4 and AC4 (ECOG), DA4-CMF3 and A4-CMF3 (concurrent docetaxel, BIG 2-98), E4-D4-CMF4 and E4-CMF4 (Taxit 216)</p>

### *Paclitaxel*

Significant improvement AC4-P4 vs. AC4, with a 4% lower rate (NSABP B28)  
FEC4-P8 vs. FEC6; HR: 0.63, p=0.0008 (GEICAM 9906)  
NS difference: E3-P3-CMF3 and E4-CMF4 (HCOG)

TTR (time to relapse or recurrence – check?) was reported in 2 paclitaxel studies:  
significantly improved for AC4-P4 vs. AC4; HR: 0.83 (0.73 to 0.94) and NS difference for DA4  
and AC4 (ECOG)

FFP (freedom from progression – check?) was reported in 1 paclitaxel study: significantly  
improved for PA4-CMF4 vs. A4-CMF4; HR 0.65 (ECTO)

### **Locoregional or distant recurrence or contralateral breast cancer**

#### *Docetaxel*

- DAC6 vs. FAC6 (BCIRG 001) – NS for locoregional recurrence, distant recurrence and contralateral recurrence
- FEC3-D3 vs. FEC6 (PACS 01) – NS difference locoregional recurrence and contralateral recurrence; for distant recurrence FEC3-D3 vs. FEC6, 17.7% vs. 21.8%, p=0.023

#### *Paclitaxel*

- AC4-P4 vs. AC4 (NSABP B28) – NS for locoregional recurrence and distant recurrence; for contralateral recurrence AC4-P4 vs. AC4, 1.1% vs. 1.9%, p=0.039
- E3-P3-CMF3 vs. E4-CMF4 – NS difference contralateral recurrence

### **Disease-free survival – subgroup analysis**

#### *Docetaxel*

##### *Nodal status*

- DAC6 vs. FAC6 (BCIRG 001), 1-3nodes, HR 0.61 (0.46 to 0.82), 4+ nodes NS difference
- FEC3-D3 vs. FEC6 (PACS 01), 1-3nodes, HR 0.76 (0.58 to 1.00), 4+ nodes NS difference
- DC4 vs. AC4 (USO 9735), N+ve, HR 0.67 (0.45 to 0.98), N-ve NS difference

##### *Hormone receptor status*

- DAC6 vs. FAC6 (BCIRG 001), HR+ 0.72 (0.56 to 0.92), HR- 0.69 (0.49 to 0.97)
- DA4 vs. AC4 (ECOG 2197), ER-PR+, HR 0.30 (0.10 to 0.95), all other HR status NS difference
- DC4 vs. AC4 (USO 9735), NS difference

##### *HER2 status*

- DAC6 vs. FAC6 (BCIRG 001), HER2+ HR 0.60 (0.41 to 0.88); HER2- HR 0.76 (0.59 to 1.00); HER2 unknown, NS difference

##### *Disease-free survival by menopausal status or age*

- DAC6 vs. FAC6 (BCIRG 001), premenopausal HR 0.66 (0.50 to 0.86), post menopausal NS difference
- FEC3-D3 vs. FEC6 (PACS 01), aged 50+yrs, HR 0.67 (0.51 to 0.88), aged <50yrs NS difference
- DC4 vs. AC4 (USO 9735), aged 50+yrs and aged <50yrs, NS difference
- DA4 and AC4 (ECOG), NS difference according to age or menopausal status

### *Paclitaxel*

#### *Nodal status*

- FEC4-P8 vs. FEC6 (GEICAM 9906),  $\geq 4+$  nodes significant benefit, 1-3 nodes NS difference

#### *Hormone receptor status*

- AC4-P4 vs. AC4 (NSABP B28), HR+(ER+ and/or PR+), relative RR 0.77 (0.65 to 0.92),  $p=0.004$ ; HR-, NS difference

- FEC4-P8 vs. FEC6 (GEICAM 9906), significant improvement for both HR+ and HR- subgroups

- E3-P3-CMF4 vs. E4-CMF4 (HCOG) stated that the treatment effect on the hazard of disease progression was not different according to hormonal receptor status

#### *HER2 status*

- FEC4-P8 vs. FEC6 (GEICAM 9906), significant improvement for both HER2 -ve to 2+, and also for HER2 3+

#### *Disease-free survival by menopausal status*

- FEC4-P8 vs. FEC6 (GEICAM 9906), significant improvement for post menopausal; pre menopausal NS difference

#### *Time to recurrence*

- AC4-P4 vs. AC4 (CALGB 9344), significant improvement for HR- (unplanned analysis)

### **Adverse events**

#### *Treatment-related deaths*

Treatment-related deaths ranged from 0 to 0.4% (excluding the DA4 vs. AC4, RAPP 01 trial). Overall deaths from toxicity in the taxane-containing arms (N=17/8829), compared with the control arms (N=11/8819); neutropenia caused N=3 deaths in those taking docetaxel, hypersensitivity reaction to paclitaxel caused one death

#### *Docetaxel*

- Febrile neutropenia/neutropenic fever;

Docetaxel associated with significantly more: DAC6 vs. FAC6 (BCIRG 001), FEC3-D3 vs. FEC6 (PACS 01), DC4 and AC4 (USO 9735), DE6 vs. FEC6 (PACS 04) – although there was less low-grade neutropenia in the docetaxel groups in BCIRG 001 and PACS 01).

- Nausea and vomitin or high-grade nausea/vomiting;

Docetaxel associated with significantly less: DAC6 vs. FAC6 (BCIRG 001), FEC3-D3 vs. FEC6 (PACS 01), DC4 and AC4 (USO 9735), DA4 vs. AC4 (RAPP 01), DE6 vs. FEC6 (PACS 04)

- Stomatitis;

Docetaxel associated with significantly more: DAC6 vs. FAC6 (BCIRG 001), FEC3-D3 vs. FEC6 (PACS 01)

- Mucositis or high-grade mucositis;

Docetaxel associated with significantly more: DAC6 without G-CSF vs. FAC6 (GEICAM

9805), DA4 vs. AC4 (RAPP 01)

- Diarrhoea or high-grade diarrhoea

Docetaxel associated with significantly more: DAC6 vs. FAC6 (BCIRG 001), DAC6 without G-CSF vs. FAC6 (GEICAM 9805), DA4 vs. AC4 (RAPP 01)

- Other

- Significantly more neurosensory effects, significantly more mild to severe congestive heart failure more prevalent nail disorders, significantly more skin toxicity, significantly more chemotherapy-related amenorrhoea, significantly more arthralgia, myalgia or asthenia, more common oedema, significantly more allergy, infection and grade 3/4 severe non-haematological AEs - DAC6 vs. FAC6 (BCIRG 001)
- Significantly less cardiotoxicity, oedema more common, FEC3-D3 vs. FEC6 (PACS 01)
- Significantly more chemotherapy-related amenorrhoea, DA4 vs. AC4 (RAPP 01)
- Significantly more arthralgia, myalgia or asthenia, DC4 and AC4 (USO 9735), DAC6 without G-CSF vs. FAC6 (GEICAM 9805)
- Oedema more common, more total serious AEs, DA4 vs. AC4 (RAPP 01)

#### *Paclitaxel*

Few significant values were reported for AEs in the paclitaxel trials;

- Significantly more peripheral neuropathy and hypersensitivity reaction, older patients (65yrs+) had significantly higher rate of severe toxicities, E3-P3-CMF4 vs. E4-CMF4 (HCOG)

#### **Health related QOL**

##### *Docetaxel*

- DAC6 vs. FAC6 (BCIRG 001), balanced at baseline, worsened during treatment , (significantly larger decline with DAC6 on Global Health Status and Physical Functioning), NS difference between the groups with both recovering by 3-4wks after last cycle of treatment
- FEC4-D4 vs. FEC8 vs. E4-CMF4 (TACT) global QoL significantly worse (p=0.002), NS vs. E4-CMF4
- DAC6 without G-CSF vs. FAC6 (GEICAM 9805) significantly worse QoL score (p=0.008), NS difference for DAC6 with G-CSF vs. FAC

##### *Paclitaxel*

- E3-P3-CMF4 vs. E4-CMF4 (HCOG), NS difference at baseline or at the end of chemotherapy (comparison of baseline and end of chemotherapy identified - social functioning significantly worsened in the paclitaxel group, p=0.003; only the control group showed significant improvement in emotional functioning (p=0.031) and pain (p=0.007)

#### **General comments**

MEDLINE, EMBASE, CINAHL, BIOSIS, CDSR, CCTR, DARE, NHS EED, HTA, NRR, the Current Controlled Trials register, US NIH website ClinicalTrials.gov, systematic review were hand searched, searches were not restricted by language, date or publication type. Searches conducted between October 2005 and February 2006

Study selection was made by one reviewer, with involvement of a second reviewer when necessary

With one exception, all studies were Phase 3, multi-centre RCTs

None of the trials were blinded (authors note that this would be difficult for patients and clinicians however, there was no indication that outcome assessors were blinded)

Randomisation was reported and adequate in 3 docetaxel and 3 paclitaxel trials

Allocation concealment was reported and adequate in 1 docetaxel and 2 paclitaxel trials

There was a high rate of compliance with therapy and few withdrawals reported

ITT or analyses including 80% or more of the randomized population were available in all trials reporting effectiveness data

Subgroups were based on small sample size

Heterogeneity of interventions, comparators and populations precluded meta-analysis

One docetaxel (BCIRG 001) and two paclitaxel trials (CALGB 9344, Elling Phase 2) used taxanes in accordance with current UK marketing authorisation

Two additional paclitaxel trials (NSABP B28, GEICAM 9906) used paclitaxel in line with the licensed regimen but at different dose and/or frequency from those recommended in marketing authorisation.

Comparators used by most of the trials restrict the generalisability of results as they do not conform to current standards of care in the UK, either through too few cycles of chemotherapy or using doxorubicin instead of the more widely employed epirubicin

Only one trial GEICAM 9906 (FEC4-P8 vs. FEC6) could be said to have an adequate comparator for UK practice and be broadly in line with UK marketing authorisation

## Health Economic Summary

### Full Summary

The volume of economic evidence found since the publication of technology assessments 108 and 109 on taxanes for early breast cancer (EBC) is limited. Only 37 references were obtained from the review of the literature and of these only two were full economic evaluations. A further study published after the search was carried out was identified and included in the review. A summary table of the economic evaluations is presented in

Table 2 below. A full description of all these studies has been presented in the accompanying document containing the health economic evidence tables. Only the indirect comparison and subsequent analysis by Ward et al (2007) addressed the question of the cost-effectiveness of taxanes against UK relevant comparators. This seems to be mainly due to the lack of clinical evidence of the effectiveness of taxanes against standard UK clinical practice.

The question addressed by Limwattananon et al (2006) is similar to the analysis presented in the technology assessment on paclitaxel (TA 108) except that it was carried out in a Thai health care setting. A Markov model was constructed to estimate the incremental cost per quality adjusted life year (QALY) of paclitaxel following anthracycline regimen doxorubicin, plus cyclophosphamide (AC) versus AC alone. The authors mention that the baseline data used to populate the model was taken from Randomised Controlled Trials although only the CALGB9344 trial is mentioned. The resource utilisation and unit cost costs reflect the Thai health care setting although the reporting of resource use is limited. The authors used the CALGB9344 trial even though it is not specific to the Thai health care setting. This was justified by the reliable estimates based on the large sample size and long-term follow up. The results of the analysis concluded that subsequent use of paclitaxel is not a cost effective option according to the WHO criterion for cost effectiveness (approximate incremental cost effectiveness ratio (ICER) of 304,800 Bhat) at an ICER of 738,111 Bhat per QALY. The results of the sensitivity analysis showed that the cost effectiveness results were sensitive to changes in the relative efficacy and unit price of paclitaxel.

Ward et al (2007) was a full clinical and economic evaluation of docetaxel and paclitaxel for adjuvant treatment of EBC. Three analysis were undertaken: docetaxel, doxorubicin and cyclophosphamide (TAC) was compared with fluorouracil, doxorubicin and cyclophosphamide (FAC) based on the BCIRG 001 trial and paclitaxel following AC was compared with AC alone in two analyses based on the NSABP-B28 and CALGB9344 trials. The results of the analysis concluded that the ICER for the docetaxel containing regimen was £12,418 per QALY. The results for paclitaxel containing regimens were £39,332 based on the CALGB9344 trial and £42,672 based on the NSABP-B28 trial. This was a well conducted economic evaluation and all limitations were discussed by the authors. The extrapolation of data over time is a key issue. Restriction of the length of the analysis had a considerable effect on the ICER for both docetaxel and paclitaxel. An indirect comparison and a cost effectiveness analysis using the results of the indirect comparison were carried out by the authors. The authors state that the analysis showed considerable uncertainty in the benefits of taxane containing regimens when compared with standard regimens used in the UK.

Wolowacz et al (2008) was a full cost utility analysis examining the cost of effectiveness TAC compared with FAC based on the BCIRG 001 trial. The model in this study was used to support submissions to NICE and the SMC by the manufacturer of docetaxel. The results of the analysis concluded that the ICER was £18,188 when taking a 10 year timeframe into account. This was a well conducted economic evaluation and most of the limitations were discussed by the authors. The authors also considered the use of G-CSF as prophylaxis for febrile neutropenia which has been found to occur at a higher rate in the TAC regimen than the FAC regimen. When patients received lenograstim or filgrastim as primary prophylaxis the resulting ICER was £20,432 per QALY. If patients received pegfilgrastim the resulting ICER was £57,320. The extrapolation of disease free survival was tested in sensitivity analysis and this had the largest effect on the ICER.

**Table 2: Summary of included economic evaluations (cost-utility analyses)**

Summary Table of Economic Evaluations							
Study	Interventions	Quality	Applicability	Cost results (all 2005)	Effectiveness results	ICER (£/QALY)	Uncertainty
Limwattananon et al (2006)	AC* and AC->P	Minor limitations – incomplete reporting of data inputs.	Non UK data. Comparators not standard UK practice.	Incremental costs with paclitaxel 221,433 Baht.	Incremental QALYs with paclitaxel. 0.30 QALYs	Base case 738,111 Baht per QALY. Negative oestrogen receptor 393,984 Baht per QALY.	The ICER of paclitaxel varied considerably with changes in the relative efficacy and unit price of paclitaxel.
Ward et al (2007)	Docetaxel: TAC and FAC Paclitaxel: AC and AC->P	Minor limitations – mainly due to assumptions made in the absence of clinical data	Comparators are not standard UK practice, although an indirect comparison was carried out.	Incremental costs with docetaxel £6,961 Incremental costs with paclitaxel (CALGB 9344 study) £6,961 Incremental costs with paclitaxel (NSABP B28 study) £5,889	Incremental QALYs with docetaxel 0.56 QALYs Incremental QALYs with paclitaxel (based on CALGB 9344 study) 0.11 QALYs Incremental QALYs with paclitaxel (based on NSABP B28 study) 0.14 QALYs	Docetaxel base case £12,418 per QALY Paclitaxel base case (based on CALGB 9344 study) £39,332 per QALY Paclitaxel base case (based on NSABP B28 study) £42,672 per QALY	The ICER of docetaxel and paclitaxel varied considerably if risk of recurrence being the same in both arms is carried on beyond the time frame of the trial (from 5 to 10 years)  Decreasing the annual rate of recurrence after the follow up period also had an effect on the cost effectiveness estimates.
Wolowacz et al (2008)	TAC and FAC	Minor limitations – mainly minor issues around the probabilistic analysis	Comparators are not standard UK practice.	Incremental costs with TAC £5,759	Incremental QALYs with TAC 0.317	Base case £18,188 per QALY  Varying methods of extrapolation beyond trial follow up: Pooled loglogistic (common long-term risk) £28,782 Loglogistic (treatment specific long-term risk) £12,588 Natural history data (common long term risk) £20,483	Sensitivity analysis on the timeframe of the analysis. 5 year timeframe = £58,201/QALY 40 year timeframe = £9865/QALY.  When patients received lenograstim or filgrastim as primary prophylaxis for febrile neutropenia the ICER was £20,432 per QALY. If pegfilgrastim was given as primary prophylaxis for febrile neutropenia the ICER was £57,320.

## Table of regimens

Abbreviation	Regimen
TAC	Docetaxel, Doxorubicin, Cyclophosphamide
FAC	5-Fluorouracil, Doxorubicin, Cyclophosphamide
AC	Doxorubicin, Cyclophosphamide
FEC	5-Fluorouracil, Epirubicin, Cyclophosphamide
E-CMF	Epirubicin, Cyclophosphamide, Methotrexate, Fluorouracil

## Evidence Tables

### Economic Evaluations

#### Paclitaxel

Limwattananon, S., et al., Cost effectiveness analysis of sequential paclitaxel adjuvant chemotherapy for patients with Node Positive primary breast cancer. J Med Assoc Thai 2006; 89 (5): 690-8.

#### **Design:**

##### Type of economic evaluation:

Cost-utility analysis using modelling (i.e. Markov model in DATA 3.5).

##### Clinical effectiveness:

Randomised Controlled Trials (RCTs) (CALGB9344) and published oncology literature, assumptions, estimates of utilities from a survey of oncology nurses.

##### Cost estimation:

Cost of adjuvant medication, cost of treatment for adverse drug events, routine follow up care, treatment for the disease recurrence, and care at the end of the patient's life. Direct health care costs only, taken from a third party payer perspective such as a health insurance scheme. Costs are from 2005 and reported in Thai Baht.

**Country:** Thailand, **setting:** Hospital

#### **Inclusion criteria:**

Premenopausal women with Early Breast Cancer (EBC) who had axillary lymph nodes positive

#### **Exclusion criteria:**

Not stated.

#### **Population:**

Women with EBC.

#### **Interventions:**

Paclitaxel for four cycles following completion of four cycles of anthracycline regimen, doxorubicin plus cyclophosphamide (AC) versus four cycles of AC alone.

#### **Outcomes:**

Quality adjusted life years (QALYs), Life Years (LYs), costs and incremental cost effectiveness ratios (ICERs)

#### **Follow up:**

Time horizon = 15 years

#### **Data used to populate the model:**

##### Assumptions:

- Disease free survival rates past 7 years were estimated using a linear trend extrapolation.
- The ratio of 1:9 was assumed to both treatment arms for dividing total relapse into localized and metastatic diseases.
- Annual risks of death when in localized and metastatic states were assumed to decline gradually over time.

Health states: no disease, localized disease, metastatic disease, and death.

Data from prospective studies:

<b>Outcome of interest</b>	<b>Estimate</b>
Rates of Disease Free Survival (DFS) in the control group	-
DFS at year 1	92%
DFS at year 2	81%
DFS at year 4	70%
DFS at year 5	65%
DFS at year 7	58%
Annual risk of initial relapse in paclitaxel arm – hazard ratio (HR)	0.83
Best clinical efficacy of paclitaxel in negative oestrogen subgroup for sensitivity analysis (HR)	0.72
Worst clinical efficacy of paclitaxel in negative oestrogen subgroup for sensitivity analysis (HR)	0.94
Disease progression from localised disease to metastatic (probabilities from year 6 onwards)	0.38
Disease progression from localised disease to death	0.08
Disease progression from metastatic disease to death	0.22

Utilities: estimated by surveying oncology nurses, further details are not given.

<b>Health States</b>	<b>Utility</b>
No disease	0.85
Localised disease	0.65
Metastatic disease	0.62
Death	0
Chemotherapy use	0.72
3 months of AC alone (using CT use utility)	0.8175
3 months of AC followed by 6 months of paclitaxel (using CT use utility)	0.785

Health care resource utilisation and costs: Details of the extraction of resource utilisation is not clear however, for adverse events and terminal stage cancer costs are available from the author on request. Chemotherapy regimens were elicited through a panel of oncology experts.

<b>Unit costs</b>	<b>2005 Baht</b>
AC	52,595
AC with Paclitaxel	277,531
Disease recurrence in the AC alone arm	549,878
Disease recurrence in the paclitaxel with AC arm	487,936
Treatment cost per event of febrile neutropenia	14,406
Incurred care at terminal stage of cancer	32,544
Follow up care for state of no disease and localised and metastatic disease (cost per year for years 1-3)	2,800
Follow up care for state of no disease and localised and metastatic disease (cost per year for years 4-15)	2,300

## **Results**

<b>Outcome of interest</b>	<b>AC</b>	<b>Paclitaxel with AC</b>
15 year health care costs	134,892	356,325
Incremental cost	-	221,433
Overall survival rates	38.5%	54.0%
Life expectancy	10.14	10.61
QALYs	6.87	7.17
Incremental QALYs	-	0.3
Cost per QALY (not reported – calculated here)	19,635	49,697
Incremental cost effectiveness ratio (ICER)	-	738,111

#### Sensitivity analysis:

One way sensitivity analysis was carried on key uncertain parameters in the simulation model. The ICER of paclitaxel varied considerably with changes in the relative efficacy and unit price of paclitaxel. The results were robust to changes in the adverse event rates, treatment for recurrence, and cost of terminal care in this study.

When paclitaxel was assumed to reduce the disease relapse by 28% in women with negative estrogen receptors, the ICER was much lower than in the base case at 393,984 Baht per QALY. When the relative efficacy of paclitaxel was reduced to an HR of 0.94 the ICER rose to 2,426,246 Baht per QALY.

#### **Authors' conclusions:**

Overall, the additional benefit of subsequent use of paclitaxel on quality-adjusted life expectancy in all patients with axillary lymph node metastasis is not cost-effective according to the WHO criterion for cost effectiveness (approx ICER of 304,800 Bhat). The author's sensitivity analysis showed that in a subgroup of high-risk patients with estrogen receptor negative and axillary node metastasis, adjuvant paclitaxel comes close to the cost effectiveness threshold (393,984).

#### **General comments:**

There are some limitations regarding the source of clinical effectiveness data. Only the CALGB9344 trial is explicitly mentioned. There are also some limitations in the in the cost analysis due to lack of reporting the resource use required. The authors mentioned that there were no well designed trials examining paclitaxel in Thailand but that the trials used in the study provided reliable estimates based on the large sample size and long-term follow up. The impact of varying utility values was not examined in sensitivity analysis

### **Docetaxel**

Wolowacz, S., et al., Docetaxel in combination with doxorubicin and cyclophosphamide as adjuvant treatment for early node positive breast cancer: a cost-effectiveness and cost-utility analysis. Journal of clinical oncology 2008; 26 (6): 925-933.

The model used in this publication was used to support submissions by the manufacturer of docetaxel to NICE and the SMC.

#### **Design:**

##### Type of economic evaluation:

Cost-utility analysis using modelling (i.e. Markov model software not specified). A decision tree

was also used to estimate the costs of adjuvant chemotherapy and QALYs lost as a consequence of adverse events.

**Clinical effectiveness:**

RCTs (BCIRG 001) and published oncology literature, assumptions, estimates of utilities were also taken from the BCIRG 001 trial and from published literature.

**Cost estimation:**

Cost of adjuvant chemotherapy and support, granulocyte colony-stimulating factor (G-CSF), adverse events, the costs of monitoring and care post-relapse were included. Costs were from 2005 and reported in GBP.

**Country:** UK, **setting:** Hospital

**Inclusion criteria:**

Not stated.

**Exclusion criteria:**

Not stated.

**Population:**

Women with node positive early breast cancer. Median age 49 years, 55% premenopausal, 76% oestrogen or progesterone receptor positive.

**Interventions:**

(docetaxel, doxorubicin and cyclophosphamide (TAC) versus Fluorouracil, doxorubicin and cyclophosphamide (FAC), both with and without primary prophylaxis with G-CSF.

**Outcomes:**

QALYs, Life Years (LYs), costs and ICERs

**Follow up:**

Time horizon = 10 years in the base case (up to 40 years in sensitivity analysis) with a cycle length of 1 month.

**Data used to populate the model:**

**Assumptions:**

- Survival modelling using data from the BCIRG 001 trial was performed to estimate probabilities of events beyond trial follow-up.
- The authors state that simple survival functions did not provide an accurate fit to the data therefore a partitioned function of superimposed loglogistic and exponential functions, after an event-free lag-period was used.
- Long-term disease free survival was dominated by an exponential function. The disease free survival curves merge beyond the trial end. This assumed that treatment effect does not continue in the long term.
- The extrapolation of disease free survival was tested in sensitivity analysis.
- Survival after relapse was estimated from patient level data in the BCIRG 001 trial.
- Probability of death from other causes was taken from national age specific mortality rates for women.

**Health states:** remission, locoregional recurrence, distant recurrence, and death.

**Data from prospective studies:**

Outcome of interest	Estimate
Survival postrelapse estimates (years)	-

-if first relapse is locoregional	2.49
-if first relapse is distant	1.59
Probability of receiving primary G-CSF prophylaxis (TAC)	0.070
Probability of receiving primary G-CSF prophylaxis (FAC)	0.077
Incidence of febrile neutropenia for TAC	0.367
Incidence of febrile neutropenia for FAC	0.087
Probability of discontinuing chemotherapy because of adverse events (TAC)	0.060
Probability of discontinuing chemotherapy because of adverse events (FAC)	0.011

**Utilities:** The estimate of utility for remission was taken from data collected during the BCIRG 001 trial which was converted into utilities using a published algorithm. Other utilities were taken from the published literature:

Health States	Utility
Remission	0.79
First locoregional recurrence, under treatment	0.70
First locoregional recurrence, after treatment (assumed equivalent to remission)	0.79
Second locoregional recurrence	0.50
Third locoregional recurrence	0.50
Distant disease	0.50
Terminal illness	0.50

**Health care resource utilisation and costs:** Details of drug usage was taken from the BCIRG 001 trial. Other resource use estimations were taken from the published literature and expert opinion. Full details of costs and resource use were presented.

Unit costs	2005 £
Total cost per cycle of TAC plus administration	1247
Total cost per cycle of FAC plus administration	214
Monitoring for patients in remission	732
Hospital care costs postrelapse (first relapse is locoregional)	14,137
Hospital care costs postrelapse (first relapse is distant)	13,576
Primary care costs postrelapse (cost per month)	
-stable distant disease	310
-early progressive disease	310
-late progressive disease	487
-terminal illness	692

## Results

Outcome of interest	FAC	TAC
Mean total costs	£9828	£15,587
Incremental cost	-	£5759
Overall survival rates with no disease recurrence	50.3	56.2

Mean life years	6.821	7.194
Incremental life years	-	0.374
Incremental cost per life year gained	-	<b>£15,418</b>
QALYs	5.201	5.517
Incremental QALYs	-	0.317
Incremental cost per QALY	-	<b>£18,188</b>

**Sensitivity analysis:**

- Probabilistic sensitivity analysis was carried out. Only key model parameters were assigned distributions.
- It seems that only the mean incremental cost per QALY and per LYG with 95% confidence limits are presented (£18,247 per QALY, CI: £14,161 to £32,422).
- Results of the sensitivity analysis were that varying the timeframe of the analysis had the biggest impact on the ICER. A 5 year timeframe resulted in an ICER of £58,201 per QALY and a 40 year timeframe resulted in an ICER of £9865 per QALY.
- The extrapolation of disease free survival was tested in sensitivity analysis. The results were as follows:

<b>Method of extraction beyond trial follow up</b>	<b>ICER</b>
Pooled loglogistic (common long-term risk)	£28,782
Loglogistic (treatment specific long-term risk)	£12,588
Natural history data (common long term risk)	£20,483

- When patients received lenograstim or filgrastim as primary prophylaxis for febrile neutropenia the resulting ICER was £20,432 per QALY. If pegfilgrastim was given as primary prophylaxis for febrile neutropenia the resulting ICER was £57,320.
- Subgroup analysis suggested that TAC may be more cost effective in patients who are younger, oestrogen-receptor-negative and who have fewer positive nodes and lower tumour grades.

**Authors' conclusions:**

Overall, the authors conclude that adjuvant TAC is cost effective compared with FAC in the UK. The authors state that although FAC is rarely used in the UK it could be considered a reasonable surrogate for FEC (the most common regimen in the UK) and studies in the metastatic setting have also shown equivalence between the two regimens. The authors also conclude that TAC supported by primary G-CSF prophylaxis is also cost effective.

**General comments:**

This was a well conducted study. It would have been useful to see the results of the probabilistic analysis diagrammatically or by the conventional method of probability of cost effectiveness at various willingness to pay thresholds. The authors also conclude that TAC supported by primary G-CSF prophylaxis is also cost effective, however, it may be reasonable to suggest that this would only be cost effective if lenograstim or filgrastim were used but not pegfilgratim.

## Docetaxel and paclitaxel

Ward, S. et al., Taxanes for the adjuvant treatment of EBC: systematic review and economic evaluation, 2007. Health Technology Assessment, 11(40): 1-144.

Note that only the cost effectiveness section of this paper is reviewed here (see clinical evidence tables for review of the clinical effectiveness study).

### **Design:**

#### Type of economic evaluation:

Cost-utility analysis using modelling (i.e. probabilistic state-transition model).

#### Clinical effectiveness:

RCTs (BCIRG 001, NSABP-B28 and CALGB9344), assumptions, published literature, estimates of utilities from published sources.

#### Cost estimation:

Cost of medication, costs of diagnosis and treatment of recurrence/contralateral disease, cost of remission, cost of treatment of distant recurrence, routine follow up care, care at the end of the patient's life and cost of treatment for adverse drug events. Direct medical costs only, taken from the UK health service perspective. All costs were adjusted to 2005-6 and reported in GBP.

**Country:** UK, **setting:** Hospital

#### **Inclusion criteria:**

Not stated.

#### **Exclusion criteria:**

Not stated.

#### **Population:**

Women with EBC eligible to receive anthracycline based chemotherapy with or without taxanes.

#### **Interventions:**

BCIRG001 trial – six 3-weekly cycles of DAC (docetaxel, doxorubicin and cyclophosphamide), with six 3-weekly cycles of FAC (Fluorouracil, doxorubicin and cyclophosphamide).

NSABP B28 and CALGB 9344 – both trials compare four 3-weekly cycles of AC (doxorubicin and cyclophosphamide) followed by four 3-weekly cycles of P (paclitaxel) with four 3-weekly cycles of AC alone.

#### **Outcomes:**

QALYs, costs and ICERs

#### **Follow up:**

Time horizon = 35 years

#### **Data used to populate the model:**

Assumptions: (see pages 35&36 of the report for a full explanation and justification of the assumptions)

- The hazard ratio for recurrence during the duration of the trial period was assumed to be constant.
- In the base-case analysis, the risk of recurrence was assumed equal in the taxane and comparator arms after the trial period.
- Long-term risk of recurrence was extrapolated from the available trial data using a parametric survival model.
- Following contralateral disease or locoregional relapse, patients cannot experience further

locoregional relapse, they can only experience metastatic relapse.

- The survival of patients who relapse was assumed to be independent of the time of relapse.
- The survival of patients with metastatic relapse was equivalent to that of patients who are initially diagnosed with metastatic disease (i.e. patients who have not previously received adjuvant chemotherapy for early disease).
- Patients who had experienced an episode of EBC but are in remission after 15 years are assumed to be cured.
- Death from breast cancer could only occur in the metastatic state.
- Death rates for non-breast cancer causes were based on UK mortality statistics and applied across all health states.

Health states: Disease-free survival (DFS), contralateral disease, locoregional relapse, metastatic relapse, remission, death from breast cancer and death from other causes.

Data from RCTs:

<b>Outcome of interest*</b>	<b>Estimate</b>
HR for DFS	0.71
Relative risk (RR) from Cox proportional hazards model	0.82
HR for recurrence	0.83
Annual probability of metastatic disease in patients with locoregional or contralateral recurrence	-
Year 1	0.18
Year 2	0.19
Year 3	0.12
Year 4	0.09
Year 5 and beyond	0.12
Annual probability of death in patients with metastatic disease	0.37

\*Type of recurrence in each arm (i.e. Local, Contralateral or Distant for taxanes and comparators) was also reported, for full details of all key clinical parameters from trials used in the economic evaluation see Appendix AA5 of the study.

Utilities: From published literature, full details given in table 34 of the study.

<b>Health States</b>	<b>Utility</b>
Chemotherapy treatment	0.74
Disease-free	0.94
Contralateral	0.74
Locoregional recurrence	0.74
Distant metastases	0.5
Remission (following contralateral recurrence and locoregional recurrence)	0.85

Health care resource utilisation and costs: All health care resource utilisation and costs were presented in detail (see tables 26-33 of the study).

<b>Unit costs</b>	<b>2005-6 GBP</b>
-------------------	-----------------------

BCIRG 001 – FAC	1343.04
BCIRG 001 – DAC	7450.80
NSABP B28 – AC	1267.68
NSABP B28 – AC+P	7102.08
CALGB 9344 – AC	1267.68
CALGB 9344 – AC+P	5755.68
Average for hormonal therapy assuming 50% receive tamoxifen and 50% receive Aromatase inhibitors	525.83
Total cost of diagnosis of locoregional recurrence or contralateral disease	830.77
Average cost of surgery for locoregional recurrence or contralateral disease	2811
Neutropenia – Total initial cost to manage event	2155
Neutropenia – Total cost per subsequent cycle =	1067

## Results

### Cost per QALY for docetaxel based on BCIRG 100 study

Outcome of interest	DAC	FAC	Incremental
Cost of adjuvant chemotherapy (£)	8,516	2,254	6,262
Cost of AEs (£)	2,396	465	1,932
Cost of recurrence and death from breast cancer (£)	12,778	14,011	-1,233
Total cost (£)	23,690	16,730	6,961
QALYs	8.36	7.80	0.56
<b>Cost per QALY (£)</b>			<b>12,418</b>

### Cost per QALY for paclitaxel based on CALGB 9344 study

Outcome of interest	AC+P	AC	Incremental
Cost of adjuvant chemotherapy (£)	7,609	1,860	5,749
Cost of AEs (£)	257	215	42
Cost of recurrence and death from breast cancer (£)	13,472	14,820	-1,349
Total cost (£)	21,337	16,896	4,442
QALYs	8.35	8.24	0.11
<b>Cost per QALY (£)</b>			<b>39,332</b>

### Cost per QALY for paclitaxel based on NSABP B28 study

Outcome of interest	AC+P	AC	Incremental
Cost of adjuvant chemotherapy (£)	8,973	1,860	7,113
Cost of AEs (£)	257	215	42
Cost of recurrence and death from breast cancer (£)	12,080	13,345	-1,265
Total costs (£)	21,310	15,421	5,889
QALYs	9.05	8.91	0.14

Cost per QALY (£)			42,672
-------------------	--	--	--------

Sensitivity analysis:

- Results of the univariate sensitivity analysis were that varying utility values, costs of recurrence, costs of managing febrile neutropenia, duration of routine follow up, costs of treating metastatic disease had a minimal impact on the ICER.
- If the assumption that the trial based risk of recurrence is the same in both arms is carried on beyond the time frame of the trial (from 5 to 10 years) this lowered the ICERs to below £15,000 in all three analyses and therefore had a substantial effect on the cost effectiveness estimates. Decreasing the annual rate of recurrence after the follow up period also had a substantial effect on the cost effectiveness estimates.
- Results of the probabilistic analyses for docetaxel showed that with a cost-effectiveness threshold of £30,000 docetaxel has around 95% probability of being cost-effective when compared with non-taxane chemotherapy.
- Results of the probabilistic analysis for paclitaxel showed that with a cost effectiveness threshold of £30,000 paclitaxel containing regimens have around 30–40% probability of being cost-effective when compared with non-taxane chemotherapy.

**Authors' conclusions:**

Overall, the cost effectiveness of taxane containing chemotherapy regimens compared with non-taxane containing regimens varied depending on the taxane under consideration and the specific trial used to inform the analysis.

**General comments:**

The limitations of this study are addressed in the discussion. The length of the analysis in particular is mentioned as a key issue. Further long term clinical data is required in order to be able to address this issue. The issue of the comparators was also discussed. The trials available contained regimens which are not considered standard practice in the UK. This therefore restricts the generalisability of the results. An indirect comparison and a cost effectiveness analysis using the results of the indirect comparison were carried out by the authors. This analysis showed considerable uncertainty in the benefits of taxane containing regimens when compared with standard regimens used in the UK.

## **5.5 Update of Technology Appraisal 107 – Trastuzumab for the Adjuvant Treatment of Early Stage HER2- Positive Breast Cancer**

### **Short Summary**

Two papers reporting from the HERA trial (Herceptin Adjuvant) trial (Smith *et al* 2007, Suter *et al* 2007), one joint-analysis of the NSABP B-31 trial, National Surgical Adjuvant Breast and Bowel project) B-31 trial and the NCCTG N9831 trial, (North Central Cancer Treatment Group) trial (Romond *et al* 2005), two papers which considered cardiac dysfunction in the NSABP B-31 (Tan-Chiu *et al* 2005) and NCCTG N9831 (Perez *et al* 2008), a meta-analysis of cardiotoxicity and brain metastases with adjuvant trastuzumab (Bria *et al* 2008), a paper from the FinHer trial (Joensuu *et al* 2006) and an abstract from the E2198 trial (Budzar *et al* 2007) were identified which considered the adjuvant treatment of early breast cancer with trastuzumab. One small trial (Budzar *et al* 2007) was identified which considered the primary systemic treatment of early breast cancer with trastuzumab.

#### Sequential chemotherapy:

The HERA trial results at 1-year follow-up were included in the TA (NICE 2006a), the 2-year follow-up of those who received 1-year treatment with trastuzumab showed improved overall survival and distant recurrence event-free survival benefit for trastuzumab compared with the control group (Smith *et al* 2007). A further study considered the trastuzumab-associated cardiac adverse events from HERA, this identified a higher incidence of cardiac end points (severe congestive heart failure (CHF), symptomatic CHF and confirmed left ventricular ejection fraction (LVEF) drop) in the trastuzumab group compared with the control group.

#### Concurrent chemotherapy:

The joint analysis of the NSABP B-31 and NCCTG N9831 trials identified improved disease-free survival, overall survival and distant metastases as a first distant recurrence with trastuzumab compared with the control group. Cardiac dysfunction in the NSABP B-31 identified a higher relative risk of a cardiac event with trastuzumab compared with control, with no significant difference between the groups in the cumulative incidence of cardiac events (Tan-Chiu *et al* 2005).

#### Meta-analysis:

A safety and efficacy meta-analysis identified an increased risk of grade III-IV CHF, asymptomatic LVEF and brain metastases with trastuzumab compared with controls, along with prolonged disease-free survival, prolonged distant disease-free survival and prolonged overall survival with trastuzumab (Bria *et al* 2008).

#### Shorter duration:

The FinHer trial showed improvements in recurrence (or died without recurrence) and distant recurrence for the trastuzumab arm (9 week duration) compared with the control group. There was no significant difference between the groups for overall survival or in adverse events (Joensuu *et al* 2006).

The E2198 trial<sup>14</sup> did not identify a significant advantage for prolonged trastuzumab administration (10 weeks compared with 52 weeks).

### Primary Systemic Therapy

One small study identified improved disease-free survival with primary systemic 24-week chemotherapy and trastuzumab regimen compared with chemotherapy alone (Budzar *et al* 2007).

### PICO

Patient	Intervention	Comparison	Outcomes
Patients with early-stage HER2 positive breast cancer prior to and following intital surgery	Trastuzumab as treatment for breast cancer either alone, in sequence with or in combination with cytotoxic chemotherapy, given for 12 months according to the locensed indications.	Regimens including trastuzumab with different doses and duration. Regimens with and without trastuzumab.	<ul style="list-style-type: none"> <li>• Disease-free survival</li> <li>• Overall survival</li> <li>• Contralateral breast cancer</li> <li>• Quality of life</li> <li>• Adverse events (notably cardiac function changes)</li> <li>• Drug interactions</li> <li>• Cost effectiveness</li> </ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

### Evidence Summary

#### Sequential chemotherapy

##### HERA trial

The HERA trial, an RCT, compared 1 or 2 years of trastuzumab treatment (8mg/kg trastuzumab IV 90min infusion as a loading dose followed by 6mg/kg every 3 weeks for a year, or 2 years), with observation alone after standard chemotherapy in women with HER-2 positive node positive or high-risk node negative breast cancer. The results from this study at 1-year follow-up were included in the technology appraisal, this showed 87.1% in the control arm and 92.5% in the trastuzumab arm free from disease at 1 year follow-up (equating to a 46% relative reduction in risk of recurrence)

(<http://www.nice.org.uk/guidance/index.jsp?action=byID&o=11586>).

Overall survival was 97.6% (control arm) and 98.2% (trastuzumab) equating to a 24% relative reduction in mortality. The incidence of serious cardiac adverse events was 0.6% with trastuzumab and 0.1% in the control arm. The 2-year trastuzumab group remains blinded as the comparison of 1-year versus 2-years of trastuzumab is continuing to be monitored by the independent data monitoring committee (Untch et al 2008).

<sup>14</sup> Not designed or powered to test the question of trastuzumab duration

## **2-year follow-up**

Smith et al (2007) reported on a 2-year follow-up of the HERA trial of those with confirmed HER2-positive and included N=1698 in the observation group and N=1703 who received 1-year treatment with trastuzumab, with a median follow-up of 23.5 months.

*Overall survival:* there were N=149 deaths in the two groups, N=59/1703 in the trastuzumab group vs. N=90/1698 (5%) in the observation group, unadjusted HR 0.66 (0.45 to 0.87),  $p=0.0115$ .

*Distant metastases:* N=152/1703 (9%) trastuzumab group vs. N=233/1698 (14%), HR for time to distant recurrence 0.60 (0.49 to 0.73),  $p<0.0001$ . This corresponds to an absolute time to distant recurrence event-free survival benefit of 6.3% at 3 years (85.7% vs. 79.4%),  $p<0.0001$ .

*Adverse events:* N=190/1668 (11%) trastuzumab group vs. N=88/1442 (6%) observation group had one or more grade 3 or 4 adverse events,  $p<0.0001$ . One or more serious adverse events were N=156 (9%) with trastuzumab vs. N=97 (7%) with observation,  $p=0.0103$ . Fatal adverse events (N=9, 0.5% trastuzumab vs. N=3, 0.2% observation) were NS between the groups.

## **Trastuzumab-associated cardiac adverse events**

Suter et al (2007) considered the trastuzumab-associated cardiac adverse effects with data available for N=1693 assigned to 1-year of trastuzumab and N=1693 assigned to observation.

*Cardiac end points:* the incidence of cardiac end points was significantly higher in the trastuzumab group vs. the observation group for; severe CHF (0.60% vs. 0%, CI for difference in incidence 0.20% to 0.99%), for symptomatic CHF (2.15% vs. 0.12%, CI for difference in incidence 1.29% to 2.77%) and for confirmed LVEF drop (3.04% vs. 0.53%, CI for difference in incidence 1.59% to 3.43%).

*Recovery after a cardiac end point:* of those with severe CHF N=6/10 recovered their LVEF in a median of 124 days (range 36 to 409 days), for the N=24/36 of those with symptomatic CHF it was 151 days (range 26 to 831 days) and for the N=35/51 with confirmed significant LVEF drop it was 191 days (range 13 to 831 days).

## **Subgroups**

Untch et al (2008) considered the effect of trastuzumab within the patient subgroups defined by nodal and steroid hormone receptor status using the data included in the Smith et al (2007) analysis from the HERA trial. This analysis identified that for the relative risk reduction estimates for the overall cohort and for the subgroups results indicate consistent reductions in the risk of relapse, at 23.5 months median follow-up.

## **Concurrent chemotherapy**

### **NSABP B-31 and NCCTG N9831 trials Joint analysis**

A joint analysis was completed of two trials the NSABP B-31 and the NCCTG N9831<sup>15</sup>. These trials considered participants randomly assigned to 4 cycles of doxorubicin and cyclophosphamide followed by paclitaxel or the same regimen followed by 52 weeks of trastuzumab beginning on day 1 of the paclitaxel treatment (Romond et al 2005). In both studies trastuzumab began with a loading dose of 4mg/kg, followed by weekly doses of 2mg/kg for 51 weeks. N=1736/2043 in the B-31 trial had at least one follow-up evaluation, N=1615/1633 in the groups used in this analysis of N9831 had follow-up data.

*Disease-free survival:* HR for first event for trastuzumab vs. control was 0.48 (0.39 to 0.59),  $p < 0.0001$ . 87.1% of the trastuzumab group compared with 75.4% of the control group were alive and disease-free at 3 years, an absolute percentage point difference of 11.8 (8.1 to 15.4); at 4 years this was 85.3% for trastuzumab and 67.1% for the control group, an absolute percentage point difference of 18.2 (12.7 to 23.7).

*Overall survival:* there were N=62 deaths in the trastuzumab group compared with N=92 in the control group, HR 0.67 (0.48 to 0.93),  $p = 0.015$ . Absolute survival at 3 years was 94.3% with trastuzumab and 91.7% in the control arm, an absolute difference of 2.5 percentage points (0.1 to 5.0); at 4 years this was 91.4% for trastuzumab and 86.6% with control, an absolute difference of 4.8 percentage points (0.6 to 9.0)

*Distant metastases:* reported in N=96 trastuzumab group compared with N=193 control group, HR for a first distant recurrence 0.47 (0.37 to 0.61),  $p < 0.0001$ . At 3 years 90.4% trastuzumab group compared with 81.5% control group were free of distant recurrence, an absolute difference of 8.8 percentage points (5.5 to 12.1); at 4 years this was 89.7% trastuzumab compared with 73.7% control group, an absolute difference of 15.9 percentage points (11.1 to 20.8)

*Brain metastases:* the incidence of isolated brain metastases as first event was N=21 with trastuzumab vs. N=11 with control (NSABP B-31) and N=12 with trastuzumab vs. N=4 with control (NCCTG N9831). Further analysis in the NSABP B-31 trial identified the difference in brain metastases as first events as attributed to earlier failures at other distant sites in the control group.

*Adverse cardiac events:* in the NSABP B-31 trial the cumulative incidence of congestive heart failure or death from cardiac causes was N=31 (4.1%) with CHF in the trastuzumab group and N=5 (0.8%) in the control group (N=4 with CHF, N=1 death from cardiac causes). In the N9831 trial the 3-year cumulative incidence of congestive heart failure or death from cardiac causes was 2.9% in the trastuzumab group (N=20 had CHF and N=1 died of cardiomyopathy) and 0% in the control group.

<sup>16</sup>

---

<sup>15</sup> This study included a further group which considered trastuzumab administered after completion of chemotherapy, this group was excluded from this joint analysis

<sup>16</sup> Cases of interstitial pneumonitis were reported that in some cases appeared to be related to trastuzumab, N=4 in B-31 and N=5 in N9831

## Cardiac dysfunction

The assessment of cardiac dysfunction in the NSABP B-31 trial was reported with N=1664 in the trastuzumab group and N=814 in the observation group analysed (Tan-Chiu et al 2005).

*Cumulative incidence of cardiac events:* 3 years after day 1 of cycle 5 was 4.1% (2.9% to 5.8%) with trastuzumab compared with 0.8% (0.3% to 1.9%) for control, NS difference between the groups. The RR of a cardiac event for trastuzumab compared with the control 5.9 (2.3 to 15.3),  $p < 0.0001$

*Recovery of cardiac function:* N=26/27 of those followed for more than 6 months were without symptoms (N=18 using cardiac medications).

The cardiac safety of the NCCTG N9831 trial was reported for N=1,944 who had satisfactory or no LVEF evaluation who proceeded to post-AC therapy (Perez et al 2008), this included the arm of the trial with sequential trastuzumab administration which was excluded from the combined NSABP B-31 and NCCTG N9831 analysis (Romond et al 2005).

*Clinically significant cardiac events in those who proceeded post-AC therapy:* for the control group cumulative incidence at 1-year (0.0%), 2-year (0.2%) and 3-year (0.3%); for the sequential trastuzumab group cumulative incidence at 1-year (1.6%), 2-year (2.7%) and 3-year (2.8%); for the concurrent trastuzumab group cumulative incidence at 1-year (3.3%), at 2-year (3.3%) and 3-year (3.3%).

*Risk factors for cardiac events:* in those receiving trastuzumab univariate analysis identified factors associated with an increased risk of a cardiac event within 3-years of starting a trastuzumab-containing regimen included; age  $\geq 60$  years ( $p=0.003$ ), prior/current use of antihypertensive medication ( $p=0.005$ ), and registration LVEF less than 55% but above lower limit of normal ( $p=0.033$ ). BMI and post-AC LVEF level were NS.

## Shorter duration treatment

### FinHer trial

The FinHer trial, a multicentre open-label RCT, compared docetaxel with vinorelbine for the adjuvant treatment of early breast cancer, women (N=232) with tumours that overexpressed HER2/neu were also randomised to receive concomitant treatment with trastuzumab or without trastuzumab (Joensuu et al 2006). The N=116 who received trastuzumab had nine infusions at 1-week intervals, the first infusion was given on day 1 of the first docetaxel or vinorelbine cycle (the docetaxel/vinorelbine was followed by FEC, no trastuzumab was given during FEC administration). The first dose of trastuzumab was 4mg/kg, subsequent doses were 2mg/kg, the full dose of trastuzumab was administered in 99.1% of cycles.

*Recurrence or died without recurrence:* N=12/115 trastuzumab vs. N=27/116 in the control group, HR 0.42 (0.21 to 0.83),  $p=0.01$  (this HR remained similar when adjustment was made according to type of chemotherapy, centre, and number of positive nodes).

*Distant recurrence:* N=8/115 trastuzumab vs. N=26/116 control, HR 0.29 (0.13 to 0.64),  $p=0.002$ .

*Overall survival:* N=6/115 trastuzumab vs. N=14/116 died, NS difference between the groups.

Adverse events: trastuzumab did not significantly increase the frequency of adverse events related to vinorelbine or docetaxel. LVEF were preserved in women who received trastuzumab, N=4 trastuzumab and N=7 control had one or more measurements of ejection fraction more than 15 percentage points less than pretreatment value (a decrease by more

than 10 percentage points, resulting in an ejection fraction of less than 50% occurred in N=3 none of whom had trastuzumab).

### **E2198 trial**

The E2198 is an adjuvant RCT looking at cardiac safety endpoints, this used two arms, the short duration arm included paclitaxel followed by weekly trastuzumab for 10 weeks (loading dose 4mg/kg followed by doses of 2mg/kg), plus doxorubicin plus cyclophosphamide (AC), the long duration arm had the same regimen followed by trastuzumab for a further 52 weeks (dose 2mg/kg), this study is currently only published in abstract form (Sledge et al 2006). N=234 HER-2 positive participants were randomised between the treatments. This study was designed to consider a primary end point of evaluating the rate of clinical CHF with these treatments. The authors concluded that although this study was not designed or powered to test the question of trastuzumab duration, a significant advantage (disease-free survival or overall survival) for prolonged trastuzumab administration was not observed in E2198.

### **Meta-analysis**

The included meta-analysis included phase III prospective and randomised trials and identified 5 trials appropriate for inclusion (NSABP B-31, NCCTG N9831, HERA, BCIFG006, FinHer) and considered safety and efficacy endpoints (Bria et al 2008). For the safety analysis it was found that for trastuzumab given for 1 year compared with the control groups (4 trials, N=10,995 patients) there was a significant increase in risk of grade III to IV CHF (RR 7.05, CI 3.88 to 12.83,  $p<0.0001$ , NNH 62, NS heterogeneity) and asymptomatic L-FEV reduction (RR 2.18, CI 1.45 to 3.27,  $p<0.00015$ , NNH 14, significant heterogeneity  $p=0.00008$ ). The incidence of brain metastases was significantly higher in the trastuzumab compared with the control arm, RR 1.57 (CI 1.03 to 2.37,  $p=0.033$ , NS heterogeneity). For the efficacy analysis the trastuzumab compared with the control groups showed prolonged disease-free survival (RR 0.63, CI 0.51 to 0.77,  $p=0.00001$ , NNT 16, significant heterogeneity  $p=0.038$ ), prolonged distant disease-free survival (RR 0.61, CI 0.54 to 0.78,  $p<0.00001$ , NNT 21, NS heterogeneity) and prolonged overall survival (RR 0.66, CI 0.55 to 0.78,  $p<0.00001$ , NNT 51, NS heterogeneity).

### **Neoadjuvant**

The search identified one small study for the neoadjuvant use of trastuzumab in early breast cancer, this study considered N= 42 participants randomised to paclitaxel followed by 5-fluorouracil, epirubicin and cyclophosphamide (FEC) alone or the same regimen with concomitant trastuzumab (first dose 4mg/kg then 2mg/kg) weekly for 24 weeks (Budzar et al 2007). This study aimed to estimate the efficacy of the chemotherapy and trastuzumab regimen.

*Safety data:* median LVEF for chemotherapy alone was 65% (range 55 to 76%), for chemotherapy and trastuzumab 65% (range 50 to 71%). At 6 months this was 65% (range 55 to 70%) for chemotherapy alone and 60% (range 52 to 70%) for chemotherapy and trastuzumab. None of the patients treated with trastuzumab and chemotherapy experienced clinical cardiac dysfunction, there were no cardiac deaths in this study.

*Disease-free survival:* at 1-year for chemotherapy alone 94.7% (85.2 to 100%), for chemotherapy and trastuzumab 100% (85.2 to 100%); at 3-year for chemotherapy 85.3%

(67.6 to 100%), for chemotherapy and trastuzumab 100%. Chemotherapy alone vs. chemotherapy and trastuzumab,  $p=0.041$ .

## Evidence Tables

<b>Citation</b>
Buzdar AU, Valero V, Ibrahim NK, Francis D, Broglio KR, Theriault RL <i>et al.</i> Neoadjuvant therapy with paclitaxel followed by 5-fluorouracil, epirubicin, and cyclophosphamide chemotherapy and concurrent trastuzumab in human epidermal growth factor receptor 2-positive operable breast cancer: an update of the initial randomized study population and data of additional patients treated with the same regimen. <i>Clinical cancer research : an official journal of the American Association for Cancer Research</i> 2007; <b>13</b> :228-33.
<b>Design</b>
Design: initial RCT (scoend cohrt data also reported in this study, not included here)
<b>Inclusion criteria</b>
<p>Patients with histologically confirmed stage II to IIIA invasive but non-inflammatory carcinomas of the breast, all tumours were shown to be HER2/neu-positive by immunohistochemical or fluorescence in situ hybridization methods</p> <p>Randomisation between June 2001 and October 2003</p> <p>Patient distribution in both groups was similar with respect to age, tumour size, and nodal status between the groups</p>
<b>Exclusion criteria</b>
Patients with a history of uncompensated heart failure or of a cardiac ejection fraction of <45% were excluded
<b>Population</b>
N=42
<b>Interventions</b>
<p>Primary objective (of the revised study, following protocol amendment to add an additional N=21 to the chemotherapy and trastuzumab arm) was to estimate the efficacy of the chemotherapy and trastuzumab regimen</p> <p>Patients were randomised to receive either chemotherapy alone (paclitaxel followed by FEC) or the same chemotherapy concurrent with trastuzumab weekly for 24weeks</p> <p>Trastuzumab is given 4mg/kg trastuzumab IV over 90min on day 1 of the first cycle of paclitaxel, patients received 2mg/kg trastuzumab weekly IV over 30min during the 24wks of chemotherapy</p>
<b>Outcomes</b>
Pathologic complete remission, CR (CR defined as no evidence of clinical invasive cancer in either the breast or axilla)
<b>Follow up</b>
Median follow-up 36.1mths (range 12.30-54.8)

**Results** (all CI 95%)**Clinical response**

Clinical response assessed by physical examination of the breasts and nodes

**Safety data**

Median left ventricular ejection fraction chemotherapy alone 65% (range 55-76%); chemotherapy and trastuzumab 65% (50-71%). After 6mths these were 65% (range 55-70%) and 60% (range 52-70%) respectively

None of the patients treated with trastuzumab and chemotherapy experienced clinical cardiac dysfunction, and there were no cardiac deaths in this study

**Disease-free survival**

Chemotherapy alone group DFS at 1yr 94.7% (85.2 to100%), at 3yrs 85.3% (67.6 to100%)

There was no recurrent disease in the chemotherapy and trastuzumab group, DFS at 1 and 3yrs 100% (85.2 to 100%)

Chemotherapy alone vs. chemotherapy and trastuzumab p=0.041

**General comments**

At the completion of the original study, the protocol was amended to discontinue the chemotherapy alone arm and to add an additional patients to the chemotherapy and trastuzumab arm – not reporting additional cohorts here, the second cohort was treated between June 2001 and October 2003

**Citation**

Joensuu Heikki, Kellokumpu-Lehtinen PL, Bono P, Alanko T, Kataja V, Asola R *et al.* Adjuvant docetaxel or vinorelbine with or without trastuzumab for breast cancer. *The New England journal of medicine* 2006;**354**:809-20.

**Design**

Design: phase 3, randomized, open-label, multicentre trial

**Inclusion criteria**

Women with axillary-node-positive or high-risk node-negative cancer; less than 66years, WHO performance status of 0 or 1, breast surgery with axillary-node dissection or sentinel-node biopsy for invasive breast carcinoma; steroid hormone-receptor status and HER2 expression by immunohistochemistry, according to the guidelines of each institution

**Exclusion criteria**

Distant metastases, pregnancy, severe hypertension, cardiac disease (including cardiac failure of any degree, arrhythmia requiring regular medication, and myocardial infarction within the previous 12months), serum bilirubin level, an alanine or aspartate aminotransferase level, an alkaline phosphatase , a blood leukocyte count, a neutrophil count, or a platelet count outwith specified limits

**Population**

N=1010 N=232 whose tumours had an amplified HER2/neu gene, N=116 received trastuzumab and N=116 did not

Baseline characteristics of the groups were balanced (axillary nodal metastases tended to be more frequent in the trastuzumab group than the no trastuzumab group)

### **Interventions**

Docetaxel or vinorelbine treatment followed by three cycles of fluorouracil, epirubicin and cyclophosphamide (FEC), those whose tumour had an amplified HER2/neu gene were further assigned to receive or not to receive nine weekly trastuzumab infusions

Nine trastuzumab infusions at one-week intervals, the first infusion was given on day 1 of the first docetaxel or vinorelbine cycle, no trastuzumab was given during FEC administration, first dose was 4mg/kg, subsequent doses were 2mg/kg

The most common reasons for a reduction in the dose of docetaxel were neutropenia/neutropenic infections, for vinorelbine it was neutropenia. The full dose of trastuzumab was administered in 99.1% of cycles (93.6% docetaxel and 96.6% vinorelbine)

### **Outcomes**

Primary end point: recurrence-free survival (defined as the time from the date of randomisation to the date of detection of local, distant, or contralateral invasive breast cancer or death, whichever occurred first)

Secondary end point: adverse events, the effect of the treatment of LVEF, time to distant recurrence, overall survival (defined as time from randomisation to death from any cause)

### **Follow up**

Scheduled follow-up for a minimum of 5 years, median follow-up 37mths (trastuzumab) and 35mths (no trastuzumab) groups

### **Results (CI 95%)**

#### **Recurrence or died without recurrence**

N=12/115 trastuzumab had a recurrence of breast cancer or died without recurrence vs.

N=27/116 in the control group

HR for trastuzumab vs. control 0.42 (0.21 to 0.83), p=0.01

The HR remained similar when adjustment was made according to the type of chemotherapy given (0.41, 0.21 to 0.82), centre (0.42, 0.21 to 0.83), number of positive nodes (0.39, 0.20 to 0.77)

#### **Distant recurrences**

N=8/115 trastuzumab had distant recurrences vs. N=26/116 in the control group

HR for trastuzumab vs. control 0.29 (0.13 to 0.64), p=0.002

#### **Overall survival**

N=6/115 trastuzumab vs. N=14/116 in the control group died, NS difference between groups

**Adverse events**

Trastuzumab NS increase in the frequency of adverse events related to vinorelbine  
Left ventricular ejection fractions were preserved in women who received trastuzumab

**General comments**

Randomisation central with computer-assisted blinding, to a study group within 12 weeks after surgery, permuted blocks used to randomly assign treatments

Those with HER2-positive cancer were randomly assigned to receive or not receive trastuzumab

Trastuzumab was administered at full doses regardless of blood-cell counts, but infusions were deferred whenever vinorelbine or docetaxel infusions were postponed because of adverse events

Power analysis completed

No patient was lost to follow-up

**Citation**

erez EA, Suman VJ, Davidson NE, Sledge GW, Kaufman PA, Hudis CA *et al.* Cardiac safety analysis of doxorubicin and cyclophosphamide followed by paclitaxel with or without trastuzumab in the North Central Cancer Treatment Group N9831 adjuvant breast cancer trial. *J.Clin.Oncol.* 2008;**26**:1231-8

**Design**

NCCTG N9831 trial – a three-armed phase III randomised study  
details of design in Romond et al evidence table

**Inclusion criteria****Exclusion criteria****Population**

N=3,129 began AC treatment, N=1,944 began post AC treatment either having post AC LVEF level that allowed trastuzumab to be administered (N=1876) or no LVEF evaluation (N=68)

Demographics were similar across all arms

**Interventions**

Control arm – AC followed by paclitaxel

Sequential arm – AC followed by paclitaxel, followed by trastuzumab (4mg/kg loading dose, then 2mg/kg for 52 weeks)

Concurrent arm – AC followed by paclitaxel plus trastuzumab followed by trastuzumab alone

**Outcomes**

Cardiac events or cardiac death, 3-year cumulative incidence
<b>Follow up</b>
LVEF was measured at 6,9 and 8 to 21 months post registration
<b>Results</b>
<p><b>Range of LVEF at each evaluation point</b> Pre-trastuzumab 4.0 to 5.1%, during trastuzumab administration 7.8% to 10.4%, and following trastuzumab (sequential arm month 21, concurrent arm month 18) 5.4% to 5.8%</p> <p><b>Clinically significant cardiac events</b> during post-AC treatment among patients not precluded from receiving trastuzumab 1-year cumulative incidence rate for cardiac events: 0.0% (control), 1.6% (sequential) and 3.3% (concurrent) 2-year cumulative incidence rate for cardiac events: 0.2% (control), 2.7% (sequential) and 3.3% (concurrent) 3-year cumulative incidence rate for cardiac events: 0.3% (control), 2.8% (sequential) and 3.3% (concurrent)</p> <p><b>Risk factors for cardiac events in those receiving trastuzumab</b> Univariate factors associated with an increased risk of a cardiac event within 3 yrs of starting of post-AC treatment with a trastuzumab-containing regimen included age <math>\geq 60</math> yrs (<math>p=0.003</math>), prior/current use of antihypertensive medication (<math>p=0.005</math>), and registration LVEF less than 55% but above lower limit of normal (<math>p=0.033</math>). BMI and post-AC LVEF level were NS risk factors</p>
<b>General comments</b>
The accrual to the concurrent arm was suspended for 9 months of the trial due to concerns regarding cardiotoxicity, following review by an independent cardiac safety monitoring

<b>Citation</b>
Romond EH, Perez EA, Bryant J, Suman VJ, Geyer CE, Davidson NE <i>et al.</i> Trastuzumab plus adjuvant chemotherapy for operable HER2-positive breast cancer. <i>The New England journal of medicine</i> 2005; <b>353</b> :1673-84.
<b>Design</b>
Design: joint-analysis of two RCTs (The National Surgical Adjuvant Breast and Bowel Project Trials (NSABP) B-31 and the North Central Cancer Treatment Group Trial (NCCTG) N9831)
<b>Inclusion criteria</b>
Pathologic diagnosis of adenocarcinoma of the breast, both trials required patients to have histologically proven, node-positive disease (some patients with high-risk node-negative disease were eligible for N9831); adequate haemopoietic, hepatic and renal function and a LVEF that met or exceeded the lower limit of normal; complete resection of the primary tumour and axillary-node dissection were required

(In both trials those treated with lumpectomy were to receive whole-breast radiotherapy with an optimal boost to the tumour bed)

### **Exclusion criteria**

Clinical or radiological evidence of metastatic disease; angina pectoris or arrhythmia requiring medication; clinically significant valvular disease, cardiomegaly, left ventricular hypertrophy (B-31 only), poorly controlled hypertension, clinically significant pericardial effusion (N9831 only), history of MI, congestive heart failure or cardiomyopathy

### **Population**

N=1736/2043 of NSABP B-31 as of February 2005 had at least one follow-up evaluation

N=1614/1633 of NCCTG N9831 had follow-up data submitted by March 2005

### **Interventions**

NSABP B-31; 4 cycles of doxorubicin and cyclophosphamide followed by paclitaxel (group I), same regimen plus 52weeks of trastuzumab beginning on day 1 of paclitaxel therapy (group II). Trastuzumab beginning with a loading dose of 4mg/kg, followed by weekly doses of 2mg/kg for 51weeks

NCCTG N9831; 4 cycles doxorubicin and cyclophosphamide followed by paclitaxel for 12weeks (group A – control group), same regimen followed by 52weeks of trastuzumab beginning on day 1 of paclitaxel therapy (group C – trastuzumab group). (this study also included a group B which was excluded from this analysis because the protocol required trastuzumab to be administered after the completion of chemotherapy)

Trastuzumab beginning with a loading dose of 4mg/kg, followed by weekly doses of 2mg/kg for 51weeks

LVEF was assessed before entry, after completion of doxorubicin and cyclophosphamide therapy, and at 6, 9 and 18months after randomisation

The groups from each study were similar

### **Outcomes**

Primary: Disease-free survival (events determining were local, regional and distant recurrence; contralateral breast cancer including DIS; other second primary cancers; death before recurrence or a second primary cancer)

Other end points: overall survival, time to distant recurrence, death from breast cancer, contralateral breast cancer, and other second primary cancer

### **Follow up**

The median follow-up was 2.0 years (2.4 years in B-31 and 1.5 years in N9831)

### **Results (95% CI)**

#### **Disease-free survival**

First event trastuzumab vs. control 0.48 (0.39 to 0.59),  $p < 0.0001$

Percentages of patients alive and disease-free at 3 years were 87.1% (trastuzumab group) and

75.4% (control group), absolute percentage point difference 11.8 (8.1 to 15.4); at 4 years this was 85.3% trastuzumab and 67.1% control group, absolute percentage point difference 18.2 (12.7 to 23.7)

### **Overall survival**

N=62 deaths in the trastuzumab group, N=92 in the control group, HR 0.67 (0.48 to 0.93), p=0.015

Absolute survival rate at 3 years was 94.3% trastuzumab group vs. 91.7% control group, absolute percentage point difference 2.5 (0.1 to 5.0); at 4 years this was 91.4% trastuzumab and 86.6% control, absolute percentage point difference 4.8 (0.6 to 9.0)

### **Distant metastases**

Reported in N=96 trastuzumab group, N=193 control group

Trastuzumab vs. control for a first distant recurrence HR 0.47 (0.37 to 0.61), p<0.0001

At 3 years 90.4% trastuzumab group were free of distant recurrence vs. 81.5% control group, absolute percentage point difference 8.8 (5.5 to 12.1); at 4 years 89.7% trastuzumab and 73.7% control, absolute percentage point difference 15.9 (11.1 to 20.8)

### **Brain metastases**

In both trials the incidence of isolated brain metastases as first events was higher in the trastuzumab group than in the control group (21 vs. 11 in B-31 and 12 vs. 4 in N9831). Those in B-31 were followed for additional occurrences beyond the first event, brain metastases as a first or subsequent event occurred in N=28 in the trastuzumab group and N=35 in the control group, HR NS, therefore the imbalance in brain metastases as first events can be attributed to earlier failures at other sites in the control group

### **Adjustment for additional characteristics**

Adjustment for treatment assignment, nodal status, pathologic tumour size, hormone-receptor status, age, tumour grade, histologic appearance of the tumour, and trial, minimally altered the effect of trastuzumab vs. control therapy, HR for a first time event 0.46 (0.37 to 0.46), p<0.001

The number of positive nodes, pathologic tumour size, hormone-receptor status, and tumour grade were significant predictors of disease-free survival

There was no evidence that the benefit of trastuzumab differed significantly between the two studies

### **Adverse cardiac events**

In B-31 those who met the inclusion criteria for trastuzumab the cumulative incidence of congestive heart failure or death from cardiac causes was N=31 (4.1%) had congestive heart failure in the trastuzumab group N=5 (0.8%), (N=4 had congestive heart failure, N=1 died from cardiac causes) in the control group

In the N9831 trial the 3 year cumulative incidence of congestive heart failure or death from cardiac causes was 2.9% trastuzumab group and 0% control group

Rare cases of interstitial pneumonitis were reported that in some cases appeared to be related to trastuzumab, in B-31 N=4 had interstitial pneumonitis, in N9831 N=5 had grade 3+ pneumonitis

or pulmonary infiltrates
<b>General comments</b>
<p>The NCI and FDA approved the joint-analysis plan</p> <p>B-31 treatments assigned balanced according to nodal status, the planned hormonal therapy, the type of surgery, the intended radiotherapy, and the institution with the use of a biased-coin minimization algorithm</p> <p>N9831 used dynamic allocation that balanced the marginal distributions of nodal status and hormone-receptor status between groups</p> <p>Genentech provided trastuzumab and partial funding support but did not participate in the design of the studies or the collection of data</p> <p>Power analysis completed, sensitivity analysis was completed</p>

<b>Citation</b>
Sledge, G. W. Adjuvant trastuzumab: long term results of E2198. ASCO 2006 Poster Session II: Treatment Adjuvant Therapy. 15-12-2006.
<b>Design</b>
E2198, pilot adjuvant trial, RCT
<b>Inclusion criteria</b>
HER-2 positive patients, lymph node positive breast adenocarcinoma, no prior history of CHF or recent MI, resting LVEF >50%, adequate renal, hepatic and marrow function
<b>Exclusion criteria</b>
<b>Population</b>
N=234 HER2-positive stage II breast cancer patients
<b>Interventions</b>
<p>Paclitaxel IV over 3hrs immediately followed by trastuzumab IV over 30-90mins, paclitaxel every 3wks for 4 courses, trastuzumab weekly for 10 courses, 3 wks following this doxorubicin IV and cyclophosphamide over 1 hr every 3wks for 4 cycles ER and/or PR +ve receive tamoxifen for 5yrs</p> <p>As above with additional trastuzumab IV weekly beginning within 3wks following completion of chemotherapy for 1yr (tamoxifen may be concurrent with trastuzumab)</p>
<b>Outcomes</b>
Primary end point: to evaluate the rate of clinical CHF

Secondary endpoint: to evaluate a >10% decrease in LVEF from baseline
DFS and OS were not initial end points
<b>Follow up</b>
Every 3mths for 1 yr, every 6mths for 2 yrs, annually thereafter
<b>Results</b>
<b>Disease-free survival</b> At 5yrs equivalent for short duration (76%) and long duration (73%) arms
<b>Overall survival</b> At 5yrs equivalent for short duration (88%) and long duration (83%) arms
<b>Congestive heart failure</b> N=7 CHF events (N=3 short duration, N=4 long duration) No deaths due to CHF
<b>General comments</b>
Results from an abstract
This study was not designed or powered to test the question of trastuzumab duration
Stratified according to radiotherapy (none planned vs. planned to breast or chest wall)
Author's conclusion: optimum adjuvant trastuzumab duration remains to be established, also CHF events early N=4/7 within the first year and overall incidence is similar to other trials (N9831 and NSABP B-31)

<b>Citation</b>
Smith I, Procter M, Gelber RD, Guillaume S, Feyereislova A, Dowsett M <i>et al.</i> 2-year follow-up of trastuzumab after adjuvant chemotherapy in HER2-positive breast cancer: a randomised controlled trial. <i>Lancet</i> 2007; <b>369</b> :29-36
<b>Design</b>
Design: international, multicentre, open-label, randomized trial (HERA trial)
<b>Inclusion criteria</b>
Centrally confirmed HER2-positive (immunohistochemistry score 3 or FISH positive), early stage invasive breast cancer who had completed local regional therapy and a minimum of four courses of predefined standard adjuvant or neoadjuvant chemotherapy; node-positive disease or node-negative if the pathological tumour size was larger than 1cm
<b>Exclusion criteria</b>
Locally advanced disease including inflammatory breast cancers; LVEF of less than 55% after completion of chemotherapy and radiotherapy; congestive cardiac failure; other major cardiac

problems

**Population**

N=5102 recruited included N=1698 in the observation group, N=1703 who received 1 year treatment with trastuzumab

**Interventions**

Either observation only or 8mg/kg trastuzumab IV 90min infusion as a loading dose followed by 6mg/kg every 3wks for a year (or the same schedule for 2yrs not reported here)

**Outcomes**

Primary: Disease-free survival previously reported in the TA

Secondary: Overall survival reported in this paper (other secondary end points included time to recurrence, time to distant recurrence, and safety including cardiac safety)

**Follow up**

Median follow-up of 23.5 months (0-48 months)

**Results**

**Overall survival**

N=149 deaths occurred in the two groups

N=90/1698 (5%) observation group; N=59/1703 (3%) 1-year trastuzumab group

Unadjusted HR trastuzumab vs. observation alone 0.66 (0.45 to 0.87), p=0.0115, corresponds to an absolute overall survival benefit of 2.7% (92.4% vs. 89.7%) at 3 years

HR for OS by censored analysis 0.63 (0.45 to 0.87), p=0.0051

**Distant metastases**

Distant events N=233/1698 (14%) observation group; N=152 (9%) trastuzumab group

HR for time to distant recurrence trastuzumab vs. observation group 0.60 (0.49 to 0.73),

p<0.0001, corresponds to an absolute time to distant recurrence event-free survival benefit 6.3% at 3 years (85.7% vs. 79.4%), p<0.0001

**Adverse events**

Patients with one or more grade 3 or 4 adverse events N=88/1442 (6%) observation group vs. N=190/1668 (11%) trastuzumab group, p<0.0001

Patients with one or more serious adverse event N=97 (7%) observation group vs. N=156 (9%) trastuzumab group, p=0.0103

Fatal adverse events N=3 (0.2%) observation group vs. N=9 (0.5%) trastuzumab group, NS difference between groups

Severe congestive failure; observation vs. trastuzumab, N=0 vs. N=10 (0.6%), p<0.0001

Symptomatic congestive heart failure; observation vs. trastuzumab N=2 (0.1%) vs. N=36 (2%), p<0.0001

Confirmed significant LVEF drop; observation vs. trastuzumab N=9 (0.5%) vs. N=51 (3%), p<0.0001

**General comments**

Randomisation was done within 7 weeks from day 1 of the last chemotherapy cycle or 6 weeks from the end of radiotherapy or definitive surgery, whichever was last. Procedure stratified according to region of the world, age, nodal status, title of chemotherapy, and hormone receptor status together with intention to use endocrine therapy

Severe congestive heart failure, was defined as New York Heart Association grade III or IV functional class confirmed by a cardiologist and a decrease in LVEF of at least 10% below baseline and to less than 50%

Power analysis completed

Efficacy analysis done on ITT basis

Collection, analysis and interpretation of data were done entirely independently

Trial sponsored and funded by Roche

<b>Citation</b>

<b>Design</b>
HERA trial – details of design in Smith et al evidence table
<b>Inclusion criteria</b>
<b>Exclusion criteria</b>
<b>Population</b>
Data available on N=1,693 trastuzumab group and N=1,693 control group The demographic characteristics were balanced in both groups
<b>Interventions</b>
<b>Outcomes</b>
Primary end point; disease-free survival  Secondary end point; cardiac safety, overall survival, time to recurrence, time to distant recurrence
<b>Follow up</b>

## Results

### Cardiac end points

Incidence significantly higher in trastuzumab group vs. observation group, severe CHF (0.60% vs. 0%, CI for difference in incidence 0.20% to 0.99%), symptomatic CHF (2.15% vs. 0.12%, CI for difference in incidence 1.29% to 2.77%), confirmed significant LVEF drop (3.04% vs. 0.53%, CI for difference in incidence 1.59% to 3.43%)

### Recovery after a cardiac end point

N=6/10 with severe CHF recovered their LVEF in a median of 124 days (range 36 to 409 days)  
N=24/36 with symptomatic CHF recovered their LVEF in a median of 151 days (range 26 to 831 days)  
N=35/51 with a confirmed significant LVEF drop recovered their LVEF in a median of 191 days (range 13 to 831 days)

### Potential cardiac risk factors

The incidence of any type of cardiac end point among patients with the risk factor was compared with the incidence of any type of cardiac end point among patients without the risk factor for the trastuzumab group

Screening LVEF of  $55\% \leq \text{LVEF} < 60\%$  had a significantly higher incidence of cardiac end points vs. screening LVEF  $\geq 60\%$  (6.90% vs. 2.72%)

Screening LVEF of  $60\% \leq \text{LVEF} < 65\%$  had a significantly higher incidence of cardiac end points vs. screening LVEF  $\geq 65\%$  (3.89% vs. 1.88%)

High BMI ( $>25$ ) significantly higher incidence of cardiac end points vs. BMI in the normal range ( $20 \leq \text{BMI} \leq 25$ )

### **Design**

HERA trial – details of design in Smith et al evidence table  
This paper used the HERA dataset reported by Smith et al (2007)

### **Inclusion criteria**

### **Exclusion criteria**

### **Population**

Data available on N=1,693 trastuzumab group and N=1,693 control group  
The demographic characteristics were balanced in both groups

### **Interventions**

### **Outcomes**

Primary end point; disease-free survival (defined as time from randomisation to the first occurrence of any of the following events: recurrence of breast cancer at any site, the development of ipsilateral or contralateral breast cancer including DCIS but not lobular carcinoma in situ, second nonbreast malignant disease other than basal cell or squamous cell carcinoma of the skin or carcinoma in situ of the cervix, or death from any cause without documentation of a cancer related event)

Secondary end point; cardiac safety, overall survival, time to recurrence, time to distant recurrence

### **Follow up**

23.5 months median follow-up

### **Results**

At 23.5mths median follow-up, the relative risk reduction estimates for the overall cohort and for subgroups indicate consistent reductions in the risk of relapse

Excluding neo-adjuvant (small cohort) all groups showed an improvement in estimated 3-year DFS, though estimates of the magnitude of absolute improvement ranged widely

### **General comments**

The 2-year trastuzumab group remains blinded as the comparison of 1-year versus 2-years of

trastuzumab is continuing to be monitored by the independent data monitoring committee

The trial was sponsored and funded by Roche

All authors had access to all the data

## Health Economic Summary

### Full Summary

A large volume of economic evidence was found since the publication of technology assessment 107. Of the 148 initial hits from the search, 26 were requested for further review. Of these, seven studies were economic evaluations addressing the above question from a health economics point of view. Due to the number of studies identified, those that only examined costs of early breast cancer were excluded. Three further studies were included following the update search to account for studies published after the first search was carried out. Therefore ten studies were reviewed in detail. Five of the studies identified were full cost-utility analyses (Garrison et al. 2007, Kurian et al. 2007, Lidgren et al. 2007, Liberato et al. 2007 and Millar and Millward 2007) and the remaining five studies were cost-effectiveness analyses (Dedes et al. 2007, Neyt 2006, Neyt et al. 2008, Norum et al. 2007 and Shiroiwa et al. 2008). A summary of the results of these studies can be found below and in

Table 2 and a summary of their methods can be found in Table 4. A full description of these studies has been presented in the accompanying document containing health economics evidence tables.

## **Summary of cost utility modelling studies**

### Overall

The cost utility studies identified were of good or reasonable quality. There were two US studies, two European studies and one Australian study. Four of the studies were based on the 12 month trastuzumab regimen and one study considered both the 12 month and 9 week regimens. The majority of the studies based their efficacy data on the NSABP-B31 and NCCTG N983 trials (and subsequent joint analysis) and the HERA trial. One study based its effectiveness on the BCIRG 006 trial (descriptions of the main trials are given in Appendix AA2). The main comparison was AC->P with AC->PT (abbreviated regimens are explained in Appendix AA3). The studies varied as to whether or not they considered that trastuzumab may be given to patients who had progressed to metastatic cancer who had already received trastuzumab in the adjuvant stage. Most of the studies (4 of 5) examined this aspect in some way either as their base case analysis or in their sensitivity analysis. Two of the studies included the costs of HER2 testing in the model, the others did not.

### Model structures

All of the cost utility studies had similar structures and all of the models were Markov models. Three of the models were set up in TreeAge modelling software, one model was built in Excel and the other study did not specify the software used (Garrison *et al.* 2007). Each model had a well/disease free state, a recurrence state (some had more than one indicating the difference between local, contralateral and metastatic recurrence), three of five models included a cardio toxicity state and all models had a death state. All but one study had a lifetime horizon; Liberato *et al.* 2007 had a 15 year time horizon.

### Risk of recurrence and survival

The benefits of trastuzumab were accounted for in all models as the relative risk of recurrence. The majority of studies derived relative risks of recurrence from clinical trials. Three of the studies assumed that there was no added or diminished benefit due to trastuzumab following the trial duration and benefits were assumed to be the same over the lifetime of the patient. Two studies (Kurian *et al.* 2007 and Millar and Millward 2007) assumed that the benefit of trastuzumab would diminish over time. Kurian *et al.*, 2007 based recurrence rates for trastuzumab for the first two years on clinical trial data. Following this they assumed that the relative risk reduction for breast cancer would be reduced by one-third in years 2 to 4 and by an additional third in years 5 to 10 after which values were held constant. Millar and Millward (2007) assumed that the relative risk reported in the trials would remain for 5 years after which this would diminish over the following 3 years (by 25%, 50% and 75% of the initial RR respectively). Examining diminished benefit from trastuzumab may reflect a conservative assumption.

### Individual summaries

Garrison *et al.* (2007) was a well conducted cost-utility analysis conducted in the US on the cost effectiveness of AC->P compared with AC->PT trastuzumab with a dosing schedule for trastuzumab of 12 months. The main sources of efficacy data were taken from the NSABP-B31 and NCCTG N983 trials and the EBCTCG report. In order to extend the clinical trial data over a lifetime horizon the authors state that the first five years of distant free recurrence and survival estimates were based on empirically fitted observed distributions for the first four years of reported trial data (NSABP B-31 and NCCTG N983) and extrapolation of the trends to the fifth year. From 6 years onwards the transition probabilities to recurrence and death were assumed to be the same in both arms. All patients were assumed to have received trastuzumab treatment after distant recurrence and the efficacy of trastuzumab in this setting was included in the model. Costs were based on trials and other published literature and are likely to appropriately and accurately reflect the costs and resource use. Costs and resource use associated with HER2 testing was included in the model. The rate and cost of cardiac events were included in the model however no disutility was assumed. Some indirect costs were accounted for in a separate analysis from the (partial) societal perspective. The ICER of AC->PT compared with AC->P was reported to be US\$26,417 per QALY gained (2006 prices) and a 3% discount rate applied for costs and benefits. The analysis was also carried out for a shorter time period of 20 years, resulting in an ICER of US\$34,201 per QALY gained. In further sensitivity analysis the range of results was found to be US\$9104 to US\$69,340.

Kurian *et al.* (2007) used a Markov model to estimate the costs and efficacy associated with three adjuvant therapy options for women with HER2 positive breast cancer in the US. Conventional chemotherapy (AC->P) without trastuzumab; anthracycline-based regimens with trastuzumab (AC->PT); and a nonanthracycline regimen with trastuzumab (docetaxel plus carboplatin plus trastuzumab). The trastuzumab regimen was 12 months for each of the comparators. The main sources of efficacy were the NSABP B-31 and NCCTG N9831 trials and the HERA and BCIRG 006 trials. All patients with metastatic disease were assumed to have received trastuzumab treatment. The efficacy of trastuzumab in this setting was included in the model (the costs and efficacy of metastatic disease was varied in sensitivity analysis). Costs were based on trials and other published literature and are likely to appropriately and accurately reflect the costs and resource use. The cost of HER2 testing does not appear to have been included. Costs and utility of cardiac events was included in the model. The results showed that the ICER of AC->PT compared with AC->P was US\$39,892 per QALY gained for 2005 prices and a 3% discount rate for costs and benefits. The docetaxel, carboplatin and trastuzumab regimen was dominated by the AC->PT regimen (more costly and less effective). Recurrence rates were varied in sensitivity analysis and showed that when no benefit of trastuzumab is assumed after year 4 the ICER for AC->PT compared with AC->P was US\$142,516 per QALY gained and was US\$157,078 per QALY gained for the docetaxel regimen compared with AC->P. Probabilistic analysis was carried out however, the details of the methods used were unclear.

Lidgren *et al.* (2007) carried out a cost-utility analysis to examine strategies of testing for HER2 status and the subsequent treatment of patients with trastuzumab in the Swedish health care setting. All other studies examining testing for HER2 were excluded as they did not examine in detail how testing would affect subsequent treatment. Test and treatment strategies were compared with standard care defined as adjuvant chemotherapy with no additional adjuvant trastuzumab for all patients. Patients in the testing strategies received a 12 month course of trastuzumab dependent on the results of various testing strategies with IHC and FISH testing. All patients were assumed to have had adjuvant chemotherapy before

being tested. Estimates of the effectiveness of trastuzumab were taken from the HERA trial. The cost of trastuzumab in the metastatic setting is not included. Costs were based on trials and other published literature and are likely to appropriately and accurately reflect the costs and resource use. Indirect costs were also included. Costs and utility of cardiac events were included in the model. Results showed that standard care was the least expensive and least effective strategy. The strategy of IHC testing for all patients with FISH confirmation of 2+ and 3+ followed by 12 months adjuvant trastuzumab for FISH positive patients (strategy 4) had the lowest ICER after two strategies were ruled out by dominance. The ICER of this strategy was €36,000 per QALY gained compared with the standard care strategy in 2005 prices with a 3% discount rate. The strategy of FISH testing in all patients with 12 months adjuvant trastuzumab for FISH positive patients was the most effective strategy (strategy 5). Compared with strategy 4 the ICER for this strategy 5 was €41,500. Subgroup analysis was carried on age at the start of adjuvant trastuzumab treatment. The results of this analysis found that patients aged 35 had a lower cost per QALY, €26,700 and €30,100 for strategies 4 and 5 respectively. At age 65 the resulting ICERs were €56,200 and €64,700 for strategies 4 and 5 respectively. An increase of 30% in the hazard ratio of an event after 1 year of trastuzumab resulted in ICERs of €84,400 and €97,000 for strategies 4 and 5 respectively. Probabilistic analysis was also carried out. From the graph it can be estimated that at €40,900, the probability of strategy 4 being cost effective is approximately 65% and of strategy 5 being cost effective is approximately 50%.
