Liberato *et al.* (2007) used a Markov model to estimate the cost utility of AC->P compared with AC->PT with a dosing schedule for trastuzumab of 12 months. The main sources of efficacy data were taken from the NSABP-B31 and NCCTG N983 trials and the EBCTCG report. Patients were not assumed to have received trastuzumab treatment after distant recurrence if they had already been treated with trastuzumab for early breast cancer. The efficacy of trastuzumab in this setting was included in the model, however it is unclear whether the costs are also included. Costs were estimated from the perspective of the Italian and US health care systems and appear to accurately reflect costs in these settings. The costs of HER2 testing were not included. The costs and disutility of cardiac dysfunction were taken into account. The ICER of AC->PT compared with AC->P was reported to be US\$18,970 and €14,861 for the US and Italy respectively per QALY gained with a 3% discount rate for costs and benefits. No cost year was reported. The author's probabilistic analysis showed that the ICER ranged from €11,286 to €128,780 per QALY (US\$15,165 to US\$143,064 per QALY) when the time horizon is varied from 20 to 5 years respectively. Adjuvant trastuzumab was less cost effective in older women and in higher risk patients. A multiway analysis using the main characteristics of the HERA trial was performed. The resulting ICERs were €11,228 per QALY gained in the Italian setting and US\$16,199 per QALY gained in the US setting.

Millar and Millward (2007) conducted a cost utility analysis using a Markov model in the Australian setting. This was to estimate the cost effectiveness of treatment with a 12 month or 9 week course of trastuzumab. Details of the comparator treatment were not given. The main sources of efficacy data were taken from the NSABP-B31 and NCCTG N983 trials and the HERA trial. Transition probabilities for the 12 month course were also applied to the 9 week course model except for the probability of remission to metastatic disease. The costs and efficacy of treatment with trastuzumab in metastatic disease is explored. The effect of palliative trastuzumab was also examined. Costs were based on mainly on published literature and are likely to appropriately and accurately reflect the costs and resource use.

The costs of testing for HER2 status were omitted. The costs of diagnosing and treating heart failure as well as the utility of heart failure were included in the model. The ICER for 12 months of trastuzumab compared with no trastuzumab therapy was reported to be A\$ 22,793 per QALY gained. The ICER of 9 weeks of trastuzumab compared with no trastuzumab therapy was reported to be A\$1700 in 2005 prices with a 3% discount rate for costs and benefits. Univariate analysis on duration of effect showed that the ICER ranges from \$A18,444 per QALY for 10 years duration of effect to \$A 35,353 per QALY for 2 years duration of effect. Sensitivity analysis for the 9 week course showed that when the risk reduction for distant recurrence is varied (using 95% CI) the range of cost effectiveness is from \$A 1018 to \$A 5569 per QALY.

## **Summary of cost effectiveness modelling studies**

### Overall

Five cost effectiveness studies were identified. Four studies were European (one from Sweden, two from Belgium and one from Norway) and one study was carried out in Japan. Three of the studies were based on the 12 month trastuzumab regimen and two studies considered both the 12 month and 9 week regimens. The two trials that considered the 12 month and 9 week regimens based their efficacy data on the HERA and FinHer trials. One study based its efficacy data on the 2-year follow up of the HERA trial and the other studies based efficacy data on the NSABP-B31 and NCCTG N983 trials and the BCIRG 006 trial. All of the studies considered trastuzumab in patients who had progressed to metastatic cancer. However, in some of the studies it was unclear whether the efficacy of trastuzumab in this setting was taken into account. The costs of HER2 testing were included in some way in four out of the five studies.

### Model structures

Neyt *et al.* (2006) and Norum *et al.* (2007) used a treatment model and a decision analytic model respectively and a diagram of the structure of each of these models was presented. Neyt *et al.* (2008) used the same structure presented in Neyt *et al.* (2006) and therefore did not reproduce the schematic. Dedes *et al.* (2007) specifically stated that a Markov model was used but no structure was presented although the health states used were clearly outlined. Shiroywa *et al.* (2008) used a Markov model and a diagram was presented. A therapeutic strategy corresponding to the Markov states was also included.

### Risk of recurrence and survival

It is difficult to have a clear understanding of how risk of recurrence and survival is handled in these papers. Shiroywa *et al.* (2008) explain with relative clarity that three risk reduction strategies were considered: risk reduction continuing for two years, five years and for ten years. The assumed risk of recurrence during the first five years was higher than that during the next five years. Further explanation on how this was achieved would have been a useful addition to this study. Dedes *et al.* 2007 stated that the clinical benefit of trastuzumab was assumed to last for the first 5 years in the base case, thereafter the relative risk for recurrent and metastatic disease in the trastuzumab group assumed to be the same as in the observational group. Norum *et al.* 2007 stated that 10 year survival figures for CMF were adjusted for the regimens examined. A 5% absolute improvement in overall survival was

added for the FEC regimen and a 10% and 20% increase due to trastuzumab was estimated. Neyt *et al.* (2006) appears to only include hypothetical improvements due to trastuzumab. Neyt *et al.* (2008) states that the model was mainly based on the progression (or prevention of progression) of patients to metastatic disease. Life years were then calculated from the life expectancy of patients progressing and not progressing to metastatic disease.

### Individual summaries

Dedes *et al.* (2007) examined the cost effectiveness of adjuvant chemotherapy with or without trastuzumab in the Swiss health care setting using a Markov model. The 12 month and 9 week trastuzumab regimens were included. Further details of the comparator treatment were not given. Efficacy data was mainly derived from the HERA trial and the FinHer trial. In the base case analysis 50% of patients with metastatic disease were retreated with trastuzumab. Costs were mainly based on the HERA trial and published literature and are likely to accurately reflect the costs and resource use in the author's setting. The cost of HER2 testing was included. The costs and effect of cardiac toxicity was taken into account. Results were given for 5, 10 and 15 years. The cost per LYG of the 12 month trastuzumab group compared with the no trastuzumab group was €212,360, €40,505 and €19,673 for 5, 10 and 15 years respectively at 2006 prices and costs discounted at 3% (benefits not discounted). With both costs and benefits discounted at 3% the ICER was €27,094 per LYG (15 year result). With the clinical benefit of trastuzumab limited to 3 years the ICER was €37,630 (15 year result). For the 9 week regimen the trastuzumab group was more effective and less costly in each of the scenarios (5, 10 and 15 years).

The study by Neyt *et al.* (2006) was primarily a costing study from the Belgian health care perspective. The authors state they carried out a threshold analysis to examine the cost effectiveness of trastuzumab. However limited details were provided and therefore this study is difficult to review as a cost effectiveness analysis. The model aimed to examine the costs and resource use associated with two trastuzumab containing regimens, AC followed by docetaxel and trastuzumab (TH) and, docetaxel, carboplatin and trastuzumab. The efficacy of trastuzumab is primarily based on the BCIRG 006 trial and the SEER database, however, mortality and estimates of progression to metastatic disease were taken from US and Canadian databases respectively. Costs were based on trial data and published literature and seem to accurately reflect the costs and resource use in the author's setting. No cost year was reported making comparison of costs difficult. The costs of HER2 testing were included. Trastuzumab was considered for use in metastatic cancer although it is not clear if the effectiveness of trastuzumab in this setting has been included. It is likely that it has not been. The costs and effects of cardiac toxicity do not appear to have been included. The total costs for stage III breast cancer patients over 50 years were €16,787 for standard treatment, €21,523 for AC->TH and €21,827 for the docetaxel, carboplatin and trastuzumab regimen. The percentage point of cancers not becoming metastatic and the improvement in time to disease progression to metastatic cancers were plotted against an ICER. It is not clear whether this ICER is by LYG and this figure is not provided. This study cannot accurately provide cost effectiveness data for trastuzumab compared with standard treatment.

Neyt *et al.* (2008) examined the cost effectiveness of standard breast cancer treatment with and without trastuzumab in the Belgian health care setting. The comparator (standard breast cancer treatment) was not discussed in detail. The 12 month and 9 week trastuzumab regimens were included. Efficacy data were mainly derived from the HERA trial for the

12 month regimen and the FinHer trial for the 9 week regimen. National data and assumptions were also used. Metastatic treatment costs with and without trastuzumab were included. It is not clear how the efficacy of trastuzumab in this setting was taken into account. Costs were based mainly on the HERA and FinHer trials as well as published literature. Some of the cost data and efficacy data were taken from Dutch sources were no Belgian data were available. The cost of HER2 testing was included. The costs of heart failure were taken into account. Results were given for three stages of cancer. For stages I, II and III the 12 month regimen produced ICERs of €34,999, €16,026, and €5994 per LYG respectively assuming a discount rate of 3% for costs and 1.5% for benefits (no single cost year was reported). The 9 week regimen dominated standard care in all three cancer stages. Results were also given by age and showed that outcomes were better for younger patients. In probabilistic analysis (applying a threshold of €30,000 per LYG), early stage breast cancer treatment with trastuzumab for 12 months is not cost effective in 6 out of the 15 analysed groups (stage and age). For the 9 week regimen, trastuzumab is not cost effective in only 1 group.

Norum *et al.* (2007) examined the cost effectiveness of FEC followed by 12 months of trastuzumab versus FEC alone in the Norwegian health care setting. Efficacy data were mainly derived from the NSABP B-31 and NCCTG N983 trials as well as other published literature and assumptions. The authors state that survival benefit was reduced due to cardiac events and secondary malignancy. This reduction was arbitrary and therefore does not adequately take into account the effect of trastuzumab for metastatic disease and cardiac events. The costs of trastuzumab for metastatic disease and the cost of cardiac events were considered. The results in terms of costs per life year gained are unclear. The table is confusing and the numbers given do not appear to add up. The authors state that a quality of life figure of 0.8 QALYs was calculated and applied. However, the quality of life figure only refers to a previous paper. Its derivation is not fully explained in this study. The authors state that the cost per life year saved ranged between €8148 and €35,947. Withdrawing trastuzumab from use in the metastatic setting raised the upper figure to €39,383. The authors state that the cost per QALY ranged between €10,185 and €48,391 although they urge caution in the interpretation of these results. Due to the poor reporting of results, this study cannot accurately provide cost effectiveness data for trastuzumab compared with standard treatment.

Shiroiwa *et al.* (2008) examined the cost effectiveness of 1 year of adjuvant trastuzumab therapy compared with an observational group in the Japanese health care setting. Efficacy data were mainly derived from HERA trial as well as other published literature and assumptions. No cost year was reported which makes the comparison of costs difficult. The costs of trastuzumab for metastatic disease and the cost of cardiac events were considered. The cost of HER2 testing does not appear to have been taken into account. The cost and effectiveness of trastuzumab was considered for metastatic cancer in this analysis. Results were given for various weight categories of patients as this affects the amount and cost of trastuzumab used and for three risk reduction scenarios (risk reduction continuing constantly for 2, 5 and 10 years, representing conservative, standard and optimistic scenarios respectively). The authors state that the cost per life year gained in the base case (5 years efficacy and 50-60kg patient) was JPY 2,740,000 (€18,000) assuming a discount rate of 3% for both costs and benefits (no cost year was reported). In probabilistic analysis the probability of adjuvant trastuzumab therapy being below JPY 5,400,000 (€36,000) was 95%. This study is a useful addition to the review showing an evaluation that examines the 2-year

follow up data from the HERA trial where the other analyses have used the 1-year follow up data.

**Table 3 Summary Table of Economic Evaluations**

The following is a summary table of main results of the economic evaluations considered in the review. The table is separated into cost-utility, cost-effectiveness and regulatory body studies.

Study/ Study design	Interventions	Methodological quality	Cost results	Effectiveness results	ICER (£/QALY)	Uncertainty
Garrison et al., 2007 CUA	Trastuzumab plus adjuvant chemotherapy (AC->P+/-T)	Minor limitations	Incremental costs US\$44,923	Incremental QALYs 1.70	ICER US\$26,417	Scenarios Lifetime cost per QALY- US\$26,417 20 year horizon – US\$34,201 per QALY Societal perspective – US\$27,637 One way analysis Results sensitive to discount rate, price of trastuzumab and probability of metastases.
Kurian et al., 2007 CUA	Adjuvant chemo followed by paclitaxel plus/minus Trastuzumab (AC->P+/-T) and TCH	Minor limitations	Total costs Adjuvant chemo without trastuzumab US\$133,492 Adjuvant chemo with trastuzumab US\$190,092 Docetaxel plus chemo and trastuzumab US\$206,561	Total QALYs Adjuvant chemo without trastuzumab 9.35 Adjuvant chemo with trastuzumab 10.77 Docetaxel plus chemo and trastuzumab 10.61	ICER of AAT over NT US\$ 39,892  The AAT regimen dominated the NAT regimen. AAT regimen is less costly and more effective than the NAT regimen	Probabilistic analysis Full methods not clear One way analysis Results sensitive to the discount rate, the cost of AT, median survival after breast cancer recurrence, and the cost of treating metastatic breast cancer.
Lidgren et al. 2007 CUA of testing strategies	Trastuzumab after adjuvant chemotherapy (dependent on HER2 test) and Adjuvant chemo with no added trastuzumab	Minor limitations	Total costs ranged from €115,151 to €129,188	Total QALYs ranged from 11.020 to 11.304	5 testing strategies Strategy 1 = standard care (no testing and no trastuzumab). Strategy 2 and 3 dominated standard care (were more effective and less costly). Strategy 4 and 5 had an ICER of €35,975 and €41,471 respectively compared with Strategy 1.	One-way analysis Results were sensitive to relative risk reduction (hazard ratio) of an event arising from treatment with trastuzumab, duration of effect and inclusion of future costs were the parameters that affected the ICERs. Subgroups Increase in age of patients at start of treatment = increase in cost per QALY gained. Probabilistic analysis Only the CEAC was presented - From the graph it can estimated that at €40,900, the probability of strategy 4 being cost effective is approximately 65% and of strategy 5 being cost effective is approximately 50%.
Liberato et al., 2006 CUA	Trastuzumab plus adjuvant chemotherapy (AC->P+/-T)  Trastuzumab after adjuvant chemotherapy	Minor limitations	Total costs (Italian) No adjuvant trastuzumab €36,522 Adjuvant trastuzumab €54,058 Total costs (US) No adjuvant trastuzumab US\$55,526	Total QALYs (Italian and US) No adjuvant trastuzumab 8.03 Adjuvant trastuzumab 9.22	ICER (Italian) €14,861 ICER (US) US\$18,970  No cost year reported	Scenarios Results are sensitive to the time frame of the analysis and patients' age. Adjuvant trastuzumab was less cost effective in older women. A multiway analysis using the main characteristics of the HERA trial was performed. Adjuvant trastuzumab cost €11,228 per QALY for the Italian setting and \$16,199 per QALY for the US setting.

Study/ Study design	Interventions	Methodological quality	Cost results	Effectiveness results	ICER (£/QALY)	Uncertainty
			Adjuvant trastuzumab US\$77,947			
Millar and Millward, 2007 CUA	Trastuzumab (52 or 9 weeks) or no trastuzumab plus adjuvant chemotherapy	Moderate limitations	Total costs Trastuzumab 52 weeks (per patient) A\$87,819 Trastuzumab 9 weeks (per patient) A\$31,513	No details of total QALYs or incremental QALYs were provided	ICER for 52 week regimen 22,793 ICER for 9 week regimen 1700	Scenario analysis: Univariate analysis on duration of effect showed that the ICER ranges from \$A 18,444 per QALY for 10 years duration of effect to \$A 35,353 per QALY for 2 years duration of effect. When relapse with metastatic disease is treated with trastuzumab (in the 52-week regimen model) the ICER improved Increase in age of patients at start of treatment = increase in ICER.
Dedes et al., 2007 CEA	Adjuvant chemotherapy with or without trastuzumab	Minor limitations	Total cost (15 year model) of trastuzumab group €67,682 observational group €47,791 Incremental cost €19,891	Incremental LYG = 1.01	Cost per LYG of €19,673.	Scenario analysis: Results were given for 5 years and 10 years. The longer the model duration the more favourable the ICERs One way analysis: One way sensitivity analysis showed that the cost effectiveness of the trastuzumab group was sensitive to changes in clinical efficacy of trastuzumab, discounting of the effectiveness and its price. 9 week analysis In each of the analyses (at 5, 10 and 15 years) for the FinHer trials, the trastuzumab group is more effective and cost saving compared to the observational group.
Neyt et al., 2006 CEA	Standard treatment Compared with AC->TH or TCH	Serious limitations in CEA section	Total standard costs for stage III breast cancer patients Std tx - €16,787 AC->TH - €21,523 TCH - €21,827	Not stated	Not stated	The ICER varied considerably with changes in the discount rate, price of trastuzumab and the probability of metastases.
Neyt et al., 2008 CEA	Standard treatment with or without trastuzumab (12 months or 9 weeks).	Minor limitations	Incremental costs - 12 month regimen stage I €32,320 stage II €30,608 stage III €24,202 Incremental costs - 9 week regimen stage I €668 stage II €-1045 stage III €-6869	Incremental LYG - 12 month regimen stage I - 11.99 stage II - 23.88 stage III - 49.74 Incremental LYG - 9 week regimen stage I - 20.35 stage II - 36.09 stage III - 70.33	ICER (€ per life year gained) - 12 month regimen Stage I €34,999 Stage II €16,026 Stage III €5994 ICER (€ per life year gained) - 9 week regimen Dominates std regimen for stages I, II and III.	Scenario analysis: All results were shown by stage and age - the ICERs for trastuzumab treatment are better for younger patients and in patients diagnosed with more advanced disease. Probabilistic analysis: Results are sensitive to the transition probability of progressing to MBC and the hazard ratio of distant recurrence.

Study/ Study design	Interventions	Methodological quality	Cost results	Effectiveness results	ICER (£/QALY)	Uncertainty
Norum et al., 2007 CEA	FEC alone or FEC followed by trastuzumab	Serious limitations	Two survival levels - 10% or 20% improved overall survival level was assumed Only the 20% level figures seem to add up correctly. Incremental costs societal costs €17,844	LYG for 10% survival benefit: 1.095 LYG for 20% survival benefit: 2.19	10% survival benefit LYG – 30290 QALYs – 37862 20% survival benefit LYG – 8148 QALYs – 10185	Univariate sensitivity analyses: Results were most sensitive to variations in the LYG (increases in overall survival), the price of trastuzumab, production gains and the discount rate. Scenario analysis: If trastuzumab is used in the metastatic setting, LYG was the only factor having a significant influence on the cost effectiveness.
Shiroiwa et al., 2008 CEA	Adjuvant trastuzumab compared with observational group	Moderate limitations	Reported in JPY Observational group 7,900,000 Trastuzumab Risk reduction continuing for: 2 years - 11,500,000 5 years - 11,200,000 10 years - 10,900,000	Observational group: 12.46 Trastuzumab Risk reduction continuing for: 2 years - 13.06 5 years - 13.70 10 years - 14.10	Compared with the observational group the cost per LYG in JPY for the groups is: 2 years - 6,000,000 5 years - 2,600,000 10 years - 1,800,000 In Euros: 2 years - €40,000 5 years - €17,000 10 years - €12,000	One way sensitivity analysis: Results were most sensitive to the period of trastuzumab efficacy. Cost per LYG was JPY 4,700,000, JPY 1,900,000 and JPY 1,300,000 for the period of efficacy of two, five and ten years respectively based on the 1 year follow up data. Probabilistic sensitivity analysis: The probability of 1 year of trastuzumab in the standard scenario being below JPY 5,400,000 (€36,000) was above 95%.
KCE CEA	Current breast cancer treatment with either a 12 month or 9 week regimen of trastuzumab given in addition	Moderate limitations	As for Neyt et al. (2008)	As for Neyt et al. (2008)	As for Neyt et al. (2008) 1 yr post-anthracycline trastuzumab is cost effective in 9 out of 15 patient subgroups. Pre anthracycline regimen cost effective in all but one subgroup.	In addition to the results presented by Neyt et al. 2008 tables and cost effectiveness planes are presented for each of the subgroups (based on prognostic factors) for HERA and FinHer and additional results were presented for the B31/N9831 trials (by stage and according to LVEF).
PHARMAC CUA	Trastuzumab compared with standard treatment.	Minor limitations	Not stated	Not stated	NZ\$ 70,000 – 80,000 per QALY for trastuzumab compared with standard therapy	Scenario analysis: Treatment benefit continues after cessation of therapy for the lifetime of the patient (\$24,000 per QALY). Treatment benefits last two years, then adopt comparator rates (\$127,000). Other one-way sensitivity analyses: A discount rate of 3.5% resulted in an ICER of \$46,000 per QALY and a 50% reduction in the risk of relapse in both arms resulted in an ICER of \$113,000 per QALY.
Ward et al and Roche	Trastuzumab therapy added to standard chemotherapy	Minor limitation	Total costs No trastuzumab: £73,323 Trastuzumab:	QALYs No trastuzumab: 8.78 Trastuzumab:	Manufacturer base case Cost per QALY: £5687 ERG base case	The manufacturer undertook several sensitivity analyses. The cost of trastuzumab and the relative risk reduction had the greatest impact on the ICER. A probabilistic analysis was also carried out.

Study/ Study design	Interventions	Methodological quality	Cost results	Effectiveness results	ICER (£/QALY)	Uncertainty
	compared with standard chemotherapy alone		£87,159	11.21	Cost per QALY: £18,449	The ERG carried out sensitivity analysis and revised the manufacturer's base case. They assumed that all patients received trastuzumab in the metastatic setting whether or not they had previously received it in the adjuvant setting and that there was no further benefit in risk of recurrence after five years. These assumptions gave a revised ICER of £18,449 per QALY gained. Further sensitivity analysis by the ERG gave ICERs of £16,000 to £33,000 per QALY gained, the upper estimate was from an analysis assuming that 23% of women receiving trastuzumab would experience a cardiac event.

**Table 4 Summary Table of methods and assumptions presented in the economic evaluations**

This table outlines the methods used by the studies, particularly with regard to the issues raised in TA 107. The table is separated into cost-utility, cost-effectiveness and regulatory body studies.

Study/ Study design	Intervention and dosing schedule (9/52 weeks)	Main sources of efficacy	HER2 testing included?	Risk of recurrence and survival	Trastuzumab considered in metastatic period? (Cost and/or efficacy?)	Cost perspective	Utilities	Cardiac toxicity included?
Garrison et al., 2007 CUA	Trastuzumab plus adjuvant chemotherapy followed by paclitaxel (AC->P+/-T)  12 months	NSABP B-31 and NCCTG N983  EBCTCG report	Yes 20-30% incidence of HER2 assumed 5 tests performed for each patient identified for trastuzumab tx	The first five years of distant free recurrence and survival estimates were based on empirically fitted observed distributions for the first four years of reported trial data (from NSABP B-31 and NCCTG N983) and extrapolation of the trends to the fifth year. From 6 years onwards the transition probabilities for entering recurrence and death states were assumed to be the same in both arms. Patients were assumed to progress to recurrence based on the rates observed in the EBCTCG report. Before progression to recurrence death rates are based on standard tables. After recurrence death rates are based on trastuzumab in MBC literature.	Yes – all patients were assumed to have received trastuzumab treatment after distant recurrence. Efficacy included.	US	Published literature – limited details provided.	Includes rate and cost of cardiac event but it seems no disutility assumed.
Kurian et al., 2007 CUA	Adjuvant chemo followed by paclitaxel plus/minus Trastuzumab (AC->P+/-T) and TCH  12 months	NSABP B-31 and NCCTG N983  HERA  BCIRG 006	Not reported, assume not included.	Relative risk reduction for breast cancer in the no trastuzumab arm was estimated from the NSABP B-31 and NCCTG N983 trials and rates extrapolated beyond four years using published survival data. Relative risk reduction for breast cancer in the trastuzumab arm was assumed to decline. The first two years were taken from clinical trial data then the relative risk reduction was assumed to decrease by one-third with both trastuzumab arms in years 2 to 4, and an additional one-third decrease in years 5 to 10; values were held constant beyond year 10. Non breast cancer deaths were based on standard tables. Deaths from breast cancer were based on trastuzumab in MBC literature.	Yes – all patients received trastuzumab on diagnosis of recurrent systemic HER2neu/positive breast cancer. Patients with metastatic disease are assumed to receive 9 months of trastuzumab therapy. Efficacy included Costs and efficacy varied in SA.	US	Published literature. Life in disease free state adjusted for age – further details were limited.	Costs and utility of cardiac events included.
Lidgren et al. 2007 CUA of testing strategies	Trastuzumab after adjuvant chemotherapy. Adjuvant chemo with no added trastuzumab  12 months	HERA	Yes	A Weibull regression was used to estimate the risks and the mortality of locoregional recurrence, contralateral cancer and distant recurrence for no trastuzumab (based on data on file). The hazard ratio of disease free survival from 1 year of HERA data was used to calculate the probability of locoregional recurrence, contralateral cancer and distant recurrence for trastuzumab. The duration of treatment effect was assumed to last throughout the patient's lifetime. Survival in the no recurrence state was based on standard tables.	No	Sweden	From published literature, based on Swedish population HRQoL data, adjusted by a reduction in HRQoL that the authors derived from	Costs and utility of cardiac events included.

Study/ Study design	Intervention and dosing schedule (9/52 weeks)	Main sources of efficacy	HER2 testing included?	Risk of recurrence and survival	Trastuzumab considered in metastatic period? (Cost and/or efficacy?)	Cost perspective	Utilities	Cardiac toxicity included?
				The hazard ratio used and the duration of treatment effect was varied in sensitivity analysis.			a previous study they carried out.	
Liberato et al., 2006 CUA	Trastuzumab plus adjuvant chemotherapy (AC->P+/-T)  Trastuzumab after adjuvant chemotherapy  12 months	NSABP B-31 and NCCTG N983  EBCTCG report  HERA (sensitivity analysis)	No costs of HER2 testing were included	The rate of relapse for trastuzumab was taken from the NSABP B-31 and NCCTG N983 trials. No additional benefit due to trastuzumab was applied after the first 5 years of follow-up. Relapse rates for patients receiving adjuvant anthracycline based chemo were taken from the EBCTCG report. Local relapse rates taken from published literature. All reported local relapses occurred in the first 5 years of follow up. Deaths from breast cancer were based on trastuzumab in MBC literature (dependent on previous adjuvant treatment). Non breast cancer deaths were based on National mortality rates.	Yes – Patients with metastatic disease received first line therapy including chemotherapy and trastuzumab if they had not received adjuvant trastuzumab, and chemotherapy alone if they had received adjuvant trastuzumab. It is not clear if costs of trastuzumab are included. The efficacy is varied.	US and Italy.	Published literature – further details were limited.	Costs and utility of cardiac events included.
Millar and Millward, 2007 CUA	Trastuzumab compared with no trastuzumab  Both 12 month and 9 week regimen	NSABP B-31  HERA	Cost of testing for HER2 status was not included as it is routine in Australia	The risk of recurrence for no trastuzumab and trastuzumab was taken from the NSABP B-31 and NCCTG N983 trials  When calculating the corresponding transition probabilities for the trastuzumab group, the authors further assumed that the relative risk of trastuzumab preventing relapse (~0.5) remained for five years and then diminished progressively to zero over a further three years (by 25%, 50% and 75% respectively), after which the benefit ceased.  Deaths from causes other than breast cancer were taken from National mortality rates. Deaths from breast cancer were based on trastuzumab in MBC literature.	It was assumed that no patients receive trastuzumab in the metastatic setting in the base case	Australia	From published literature in which utility weights were extracted from 40 papers on economic analysis in cancer	Costs and utility of cardiac events taken into account
Dedes et al., 2007 CEA	Trastuzumab after adjuvant chemotherapy  Both 12 month and 9 week regimen	HERA  FinHer	Yes	A constant yearly risk for local and distant recurrences for the first 5 years after adjuvant treatment was assumed.  The risk for local and distant recurrences was then gradually reduced by 10% from year 6 to year 15 in order to reflect the flattening of recurrence curve in breast cancer patients after 5 years.  The clinical benefit of trastuzumab was assumed to last for the first 5 years in the base case, thereafter the relative risk for recurrent and metastatic disease in the trastuzumab group assumed to be the same as in the observational group.	Yes, base case 50% patients were retreated with trastuzumab. Rate tested in SA.	Sweden	-	The costs and effects of cardiac toxicity was taken into account.

Study/ Study design	Intervention and dosing schedule (9/52 weeks)	Main sources of efficacy	HER2 testing included?	Risk of recurrence and survival	Trastuzumab considered in metastatic period? (Cost and/or efficacy?)	Cost perspectiv e	Utilities	Cardiac toxicity included?
Neyt et al., 2006 CEA	Standard treatment Compared with AC->TH or TCH  12 months	Based on the BCIRG 006 trial and the SEER database	Yes	Unclear – study appeared to take only hypothetical improvements due to trastuzumab into account.	Trastuzumab was considered for use in metastatic cancer although it is not clear if the effectiveness of trastuzumab in this setting has been included.	Belgian	-	Costs and effects of cardiac toxicity were not included.
Neyt et al., 2008 CEA	Standard breast cancer treatment without trastuzumab compared with standard treatment with trastuzumab  Both 12 month and 9 week regimen	HERA and FinHer	Yes	The model was mainly based on the progression (or prevention of progression) of patients to metastases. For patients progressing to metastatic disease, life expectancy data were based on a published study. The incremental percentage of patients not progressing to metastatic disease was estimated by multiplying the hazard ratios of patients surviving free of distant recurrence with the baseline risk of progressing to metastatic disease. LYG were then calculated from the life expectancy of patients progressing and not progressing to MBC.	Yes	Belgian	-	Costs of cardiac toxicity were included. The costs were taken from Dutch data as none were available for Belgium.
Norum et al., 2007 CEA	FEC compared with FEC followed by Trastuzumab  12 months	NSABP B-31 and NCCTG N983	Yes	Distant relapse free survival was used as a surrogate for future overall survival. Using published sources, 10 year survival figures for CMF were adjusted for the regimens examined. A 5% absolute improvement in overall survival was added for the FEC regimen and a 10% and 20% increase due to trastuzumab was estimated. The improved survival level was in addition to a stated level and assumed to be reached at 10 years follow up. The benefit was equally distributed over the 10 year period.	Yes – costs are taken into account.	Norwegian	-	Survival benefit was arbitrarily reduced due to cardiac events and secondary malignancy  Costs of cardiac events were taken into account.
Shiroiwa et al., 2008 CEA	1 year of adjuvant trastuzumab compared with observational group (various chemotherapy)	HERA trial 2-year follow up	Not reported	Three risk reduction strategies were considered: risk reduction continuing for two years (conservative scenario), risk reduction continuing for five years (standard scenario) and for ten years (optimistic scenario). The assumed risk of recurrence during the first five years was higher than that during the next five years.	Yes	Japan	-	Costs of cardiac toxicity included.
KCE	Both 12 month and 9 week	HERA trial	Yes	Short term results were mainly translated to the long term relying on the hazard ratio of patients surviving	No trastuzumab is given to patients developing	Belgium	-	None

Study/ Study design	Intervention and dosing schedule (9/52 weeks)	Main sources of efficacy	HER2 testing included?	Risk of recurrence and survival	Trastuzumab considered in metastatic period? (Cost and/or efficacy?)	Cost perspective	Utilities	Cardiac toxicity included?
	regimen	Fin Her		free of distant recurrence. For patients progressing to metastatic disease, life expectancy was calculated by adding the time to progression by age and stage, and the respective survival of metastatic disease.	metastatic disease in the base case.			
PHARM AC	Trastuzumab after adjuvant chemotherapy  Both 12 month and 9 week regimen	HERA trial for main analysis based on marketing authorisation  Fin Her 9 week regimen	Costs only appeared to be reported for the 9 week analysis	Patients were assumed to have continued benefit from treatment with trastuzumab for four years. Patients who remained in remission had a reduced risk of relapse over time (of both local/regional relapse and metastatic relapse).	Of patients with metastatic disease, 20% were assumed to be HER2 positive and receive trastuzumab.	New Zealand	Taken from EQ-5D NZ weights. Values were estimated using descriptions of breast cancer states derived by oncologists. Full details were provided.	Costs and utility of cardiac events included
Ward et al and Roche	Trastuzumab therapy added to standard chemotherapy compared with standard chemotherapy alone	HERA trial	Yes	Natural disease history modelled using transition probabilities from the HERA trial – extrapolated over 45 years. Rate of recurrence for comparator taken from HERA trial – trend of recurrence taken from the ECGBCG report therefore for the first 5 years recurrence rates are assumed to be the same as in the first year (recurrence reduce by a factor of 0.64 and 0.41 years at 5 and 10 years respectively). The relative risk of recurrence from trastuzumab is taken from the HERA trial and assumed to be maintained for 10 years following the initial administration and that two thirds of the benefit is seen until year 45.	No trastuzumab was given in the metastatic setting if patients had already received trastuzumab previously, efficacy data was taken from a trial of trastuzumab in metastatic setting.	UK	From an external report using standard gamble interviews based on health states established by oncologists, breast cancer specialists and psychometric experts completed by 100 members of the public. Participants also completed the EQ-5D to assess their own current	Costs of cardiac events were taken into account.

Study/ Study design	Intervention and dosing schedule (9/52 weeks)	Main sources of efficacy	HER2 testing included?	Risk of recurrence and survival	Trastuzumab considered in metastatic period? (Cost and/or efficacy?)	Cost perspectiv e	Utilities	Cardiac toxicity included?
							health.	

## Appendix 2: Description of trials

NSABP-B31 and NCCTG N983 trials – carried out separately and a joint analysis was subsequently carried out. This was an open label RCT examining AC->P with AC->PT.

HERA – open label RCT 12 months of trastuzumab following adjuvant chemotherapy, neoadjuvant chemotherapy or both (various regimens were allowed) compared with observation.

FinHer – open label RCT comparing 9 weeks of adjuvant trastuzumab following on from docetaxel or vinorelbine compared with docetaxel or vinorelbine alone.

BCIRG 006 trial – this was a phase III trial comparing 3 treatment regimens. Chemotherapy (AC) followed by docetaxel plus trastuzumab (TH), chemotherapy (docetaxel and carboplatin chemo) plus trastuzumab (TCH), and chemotherapy followed by docetaxel alone (AC->T).

## Economic Evaluations

### Cost-utility analyses

Garrison, L., et al., Cost-effectiveness analysis of trastuzumab in the adjuvant setting for treatment of HER2-positive breast cancer. *Cancer* 2007; 110:489-98.

#### **Design:**

##### Type of economic evaluation:

Cost-utility analysis using modelling (i.e. Markov model – software not specified).

##### Clinical effectiveness:

Based on the joint analysis of randomised controlled trials (RCTs) NSABP B-31 and NCCTG N983, the early breast cancer trialists' collaborative group (EBCTCG) report, published literature, conference abstracts, assumptions, estimates of utilities from published literature.

##### Cost estimation:

Direct costs included cost of therapy and administration, diagnostic tests, cardiotoxicity events, recurrence costs (distant metastases) and costs associated with death. Some indirect costs were included – value of patient time per hour and travel costs per infusion. The payer and (partial) societal perspective was taken. Costs are reported for 2006 and in US dollars. Cost and benefits were discounted at 3%.

**Country:** US, **setting:** Hospital

#### **Inclusion criteria:**

Not reported

#### **Exclusion criteria:**

Not reported

#### **Population:**

Women with early stage HER2-positive Breast Cancer aged 50 years.

#### **Interventions:**

Based on NCCTG N9831 and NSABP B-31.

##### NCCTG N983:

Doxorubicin and cyclophosphamide (AC) given every 3 weeks for 4 cycles. Followed by: weekly paclitaxel for 12 weeks (Arm A - AC->T); 12 weeks of weekly paclitaxel followed by weekly trastuzumab for 52 weeks (Arm B); or weekly paclitaxel plus trastuzumab for 12 weeks, followed by weekly trastuzumab alone for 40 weeks (Arm C) (AC->TH).

##### NSABP B-31:

AC; followed by: 3 weekly or weekly paclitaxel for 12 weeks (Arm 1 - AC->T); or 3 weekly or weekly paclitaxel for 12 weeks plus trastuzumab for 12 weeks, followed by weekly trastuzumab alone for 40 weeks (Arm 2) (AC->TH).

The cost effectiveness analysis was based on a comparison of Arm 1 in NSABP B-31 and Arm A in NCCTG N9831 with Arm 2 in NSABP B-31 and Arm C in NCCTG N9831.

#### **Outcomes:**

Quality adjusted life years (QALYs), Life Years (LYs), costs and incremental cost effectiveness ratios (ICERs)

#### **Follow up:**

Time horizon = lifetime and 20 years

#### **Data used to populate the model:**

##### Assumptions:

- All patients received treatment during the first year while they were still disease-free.
- All patients were assumed to have received trastuzumab treatment after distant recurrence.
- Cardiac dysfunction associated with the addition of trastuzumab was assumed to be reversible and to have no direct mortality effect beyond that reflected in the 4-year trial period.
- The first five years of distant free recurrence and survival estimates were based on empirically fitted observed distributions for the first four years of reported trial data (from the joint analysis of NSABP B-31

- and NCCTG N983) and extrapolation of the trends to the fifth year.
- From 6 years onwards the transition probabilities to recurrence and death were assumed to be the same in both arms.
- Progression to recurrence was based on the rates observed in the EBCTCG report.
- Mortality due to metastatic breast cancer was taken from a conference abstract on the cost effectiveness of trastuzumab in metastatic breast cancer.
- Mortality due to other causes was based on standard US life tables.

Health states: treatment, disease-free, distant recurrence, and death

Data from studies:

<b>Outcome of interest</b>	<b>Estimate</b>
Cumulative probability, year 4	-
Control arm (AC->T)	-
Recurrence free survival	0.719
Overall survival	0.870
Trastuzumab arm	-
Recurrence free survival	0.856
Overall survival	0.911
Annual rate of recurrence after 5 years	-
AC->T (years 6-9)	0.048
AC->TH (years 6 to 9)	0.048
AC->T (years 10+)	0.033
AC->TH (years 10+)	0.033
Annual probability of death following distant metastases	-
Control arm (AC->T)	0.323
Trastuzumab arm	0.323

Utilities: from published literature, further details are limited.

<b>Input parameter</b>	<b>Utility</b>
Year 1 AC->T including treatment	0.770
Year 1 AC->TH treatment	0.710
Year 2+ stable disease utility	0.900
Year 2+ recurrence utility	0.600

Health care resource utilisation and costs: Resource utilisation is taken mainly from published sources and the clinical trial data. Costs were based on Medicare reimbursement rates and published data. Costs of comparator therapies do not seem to have been included.

<b>Unit costs</b>	<b>2006 US\$</b>
Diagnostic tests	-
Immunohistochemical (IHC) tests	89
Fluorescence in situ Hybridisation (FISH)	482
Proportion of HER2 tests by FISH method	30%
Trastuzumab infusion (per vial)	2987
Administration of trastuzumab	172.81
Left ventricular ejection fraction (LVEF) exam	367
Mean cost per cardiotoxicity event	1979
Recurrence cost (distant metastases)	40,000
Costs associated with death	10,000
Indirect costs	-
Value of patient time per hour	25.57
Travel cost per infusion	14.55

## Results

<b>Outcome of interest</b>	<b>AC-&gt;T</b>	<b>AC-&gt;TH</b>
Lifetime health care costs (payer) (US\$)	28,749	73,627

Incremental cost (US\$)	-	44,923
LYS	11.88	13.72
Incremental life years	-	1.84
QALYs	10.08	11.78
Incremental QALYs	-	1.70
Cost per LY (US\$)	-	24,435
Cost per QALY (US\$)	-	<b>26,417</b>

Results were also provided for the alternative scenarios of a 20-year horizon (US\$34,201 per QALY gained) and for the societal perspective (US\$27,637 per QALY gained). It is not clear how long the lifetime horizon is in terms of years.

**Sensitivity analysis:**

One way sensitivity analysis was carried on most parameters in the model. This is presented as a tornado diagram. The cost utility results range from US\$9104 to US\$69,340 per QALY. The ICER varied considerably with changes in the discount rate, price of trastuzumab and the probability of metastases. The model was most robust to changes in the costs of detecting and treating cardiac events and the costs of diagnostic testing.

**Authors' conclusions:**

Overall, the addition of trastuzumab to standard adjuvant therapy appears to reduce the risk of recurrence and improves survival in patients with early stage breast cancer. Over a lifetime horizon it appears that trastuzumab for the treatment of early stage breast cancer is cost effective.

**General comments:**

There are some limitations with regard to the detail in the explanation of the projection of recurrence free survival and overall survival. It seems that a calibration exercise has been conducted. There are some limitations regarding the calculation of cost data in that drug costs other than for trastuzumab do not seem to have been included and there is a lack of reporting the resource use required. The one way sensitivity analysis is extensive, however no probabilistic sensitivity analysis was conducted. There is a detailed section in the discussion comparing the results of this study with the results of other similar studies. Contralateral and local recurrence health states were not included in the model because of limited data available. The authors state that the effect of these states is reflected in the time to distant recurrence estimates. It is not clear how this is the case.

Kurian et al., A cost-effectiveness analysis of adjuvant trastuzumab regimens in early HER2/neu-positive breast cancer; 2007. J Clin Oncol 25:6:634-641.

**Design:**

Type of economic evaluation:

Cost-utility analysis using modelling (i.e. Markov model – TreeAgePro 2005)

Clinical effectiveness:

Taken from the joint analysis of RCTs: NSABP B-31, NCCTG N983 and BCIRG 006 trial, published literature, assumptions, estimates of utilities from published literature.

Cost estimation:

Cost of trastuzumab and other therapies including administration, cardiac monitoring, recurrence costs (including chemotherapy, supportive and end of life care) and cardiac toxicity. A societal perspective was stated, however the only indirect cost included was costs for time lost from work to receive trastuzumab. Costs are reported for 2005 and in US dollars. Both costs and QALYs are discounted at 3% in the base case.

**Country:** US, **setting:** Hospital

**Inclusion criteria:**

Women who have undergone surgical resection of all apparent disease, with and without involved axillary lymph nodes, comparable to the trial populations.

**Exclusion criteria:**

Not stated.

**Population:**

HER2/neu-positive early stage breast cancer with an average age at baseline of 49 years

**Interventions:**

Based on NCCTG N9831, NSABP B-31 and BCIRG 006 trials.

Conventional chemotherapy without trastuzumab; anthracycline based trastuzumab regimens used in NCCTG N9831 and NSABP B-31, and the non-anthracycline trastuzumab regimen used in BCIRG 006 as described below.

Two model schemas were presented, one for no trastuzumab and nonanthracycline trastuzumab and another for anthracycline- based trastuzumab.

NT arm – AC, followed by paclitaxel (based on the control arms of NSABPB-31 and NCCTG9831).

AAT arm (anthracycline-containing) – AC with trastuzumab administered weekly concurrently with paclitaxel; for a total of 1 year of trastuzumab therapy.

NAT arm (non anthracycline-containing) – docetaxel plus carboplatin. Trastuzumab weekly, concurrently with chemotherapy; after completion of chemotherapy, the authors assumed that trastuzumab is administered every 3 weeks to complete a total of 1 year of trastuzumab therapy.

**Outcomes :**

QALYs, LYs, costs and ICERs

**Follow up:**

Time horizon = not stated, although a lifetime horizon may be reasonable to assume. Markov cycle length was 1 month.

**Data used to populate the model:**Assumptions:

- All patients received trastuzumab on diagnosis of recurrent systemic HER2neu/positive breast cancer.
- Beyond the time horizon for the trial the relative risk reduction for breast cancer was assumed to decline.
- The authors assumed a one-third decrease in the relative risk reduction with both AT arms in years 2 to 4, and an additional one-third decrease in years 5 to 10; values were held constant beyond year 10.
- Patients with metastatic disease were assumed to receive 9 months of trastuzumab therapy.
- The rate of cardiac deaths was assumed not to increase in the AAT arm in the base case and the rate of cardiac toxicity was assumed not to be elevated in the NAT arm.
- Mortality due to causes other than breast cancer was based on national mortality rates.

Health states: Well, breast cancer recurrence, cardiac toxicity, simultaneous cardiac toxicity and breast cancer recurrence, and death.

Data from prospective studies: all the monthly probabilities were provided (see table 1 of study). Only the transition probabilities were reported.

<b>Outcome of interest</b>	<b>Estimate</b>
Median survival in metastatic disease (9 months of trastuzumab)	25 months
Percentage increase in cardiac toxicity in the ATT arm	3%
Percentage of patients who improve following cardiac toxicity in the AAT arm (becoming symptomatic with or without ongoing therapy, within 6 months).	80%

Utilities: from published literature, life in the disease free state was adjusted for age. No further details were provided.

<b>Input parameter</b>	<b>Utility</b>
Adjuvant trastuzumab	0.85
Adjuvant chemotherapy without trastuzumab	0.85
Well	1.00
Well, age 45-54 years	0.90
Well, age 55-64 years	0.87
Well, age 65-74 years	0.83
Well, age > 75 years	0.79

CTS	0.64
CTNS	1.00
Weighted average, cardiac toxicity utility	0.91
Metastatic breast cancer	0.55
Death	0.00

Health care resource utilisation and costs: All costs reported are referenced although details of resource use extraction are somewhat unclear.

<b>Unit costs</b>	<b>US\$ 2005</b>
Total trastuzumab costs†	64,185
AAT, total costs	101,192
NAT, total costs	115,208
Cardiac toxicity without symptoms per month	148
Cardiac toxicity with symptoms per month	177
Breast cancer recurrence	3816

## Results

<b>Outcome of interest</b>	<b>NT</b>	<b>AAT</b>	<b>NAT</b>
Total costs (US\$)	133,429	190,092	206,561
QALYs	9.35	10.77	10.61
LYS	12.29	14.01	13.56
Incremental cost per QALY (US\$)	-	39,892	Dominated*
Incremental cost per LY (US\$)	-	32,816	Dominated*

\*the AAT regimen is less costly and more effective than the NAT regimen

### Sensitivity analysis:

Probabilistic sensitivity analysis was undertaken. Scatter plots of the ICERs are presented. The full methods of the probabilistic analysis are unclear; it seems that the authors have only varied the base case recurrence rates in the analysis. Results of this analysis show considerable uncertainty surrounding this variable. The distribution mean shows that the ICER for AAT versus NT was \$56,491 per QALY (at the distribution minimum: NT dominates AAT and at the distribution maximum: \$8,144,473 per QALY) and AAT dominates NAT (minimum: AAT dominates NAT and maximum: \$20,398,133 per QALY).

In a sensitivity analysis that assumed that recurrence rates were minimally improved with either AT arm after year 4 (hazard ratio 0.99), the ICER increased to \$142,516/QALY for AAT and \$157,078/QALY for NAT.

The results of the one-way sensitivity analysis show that results are most sensitive to the discount rate, the cost of AT, median survival after breast cancer recurrence, and the cost of treating metastatic breast cancer. The results are least sensitive to changes in the probability of dying as a result of or recovering from cardiac toxicity, costs of cardiac toxicity, and all utilities.

### **Authors' conclusions:**

The authors state that in their base case analysis and in a probabilistic sensitivity analysis of recurrence rates under different treatment strategies, the anthracycline dominates the NAT arm. If the improvements in overall and disease-free survival seen in the randomised AT trials do not persist over time, then the ICER of an anthracycline-based regimen may be considerably higher than in the base case.

### **General comments:**

There are some limitations regarding the source of clinical effectiveness data. Although the authors have referenced their input data, only the transition probabilities have been presented.

The probabilistic analysis seems to only examine one variable and is therefore not a full probabilistic exploration of the uncertainty surrounding input parameters.

Lidgren et al., Cost-effectiveness of HER2 testing and 1-year adjuvant trastuzumab therapy for early breast cancer. *Annals of oncology* 2007; published December 6, 2007.

### **Design:**

Type of economic evaluation:

Cost-utility analysis using modelling (i.e. Markov model – DATA Pro Suite 2006).

**Clinical effectiveness:**

Based on the HERA trial, published literature, assumptions, data on file and estimates of utilities from published literature.

**Cost estimation:**

Intervention costs: trastuzumab drug costs, trastuzumab infusion costs, cost of cardiac monitoring, cost of cardiac related adverse events, and cost of HER2 testing; Direct breast cancer costs: Inpatient costs, outpatient costs, drug costs, informal care cost, and palliative care cost; Indirect costs: value of productivity loss due to breast cancer. A societal perspective was taken. Costs are reported for 2005 and in Euros. Cost and benefits were discounted at 3%.

**Country:** Sweden, **setting:** Hospital

**Inclusion criteria:**

Not stated

**Exclusion criteria:**

Not stated

**Population:**

Women with early stage breast cancer that had been completely excised and treated with at least four cycles of adjuvant chemotherapy.

**Interventions:**

Five testing strategies were examined

The base case strategy is: no testing followed by adjuvant chemotherapy

The four alternative strategies are: strategies of a first test followed or not followed by a second test then 1 year of adjuvant trastuzumab for subgroups of tested individuals (see study for full details of each strategy).

Estimates of the effectiveness of trastuzumab were based on HERA trial.

**Outcomes:**

QALYs, LYS, costs and ICERs

**Follow up:**

Time horizon = lifetime

**Data used to populate the model:**

**Assumptions:**

- The risk of recurrence and mortality in the model has been based on a sample of 20,624 Swedish breast cancer patients – this data is unpublished.
- A Weibull regression was used to estimate the risks and the mortality of locoregional recurrence, contralateral cancer and distant recurrence.
- The risk of distant recurrence for HER2-positive patients was assumed to be twice as high compared with HER2-negative patients.
- The mortality risk for patients in the no recurrence state was based on Swedish life tables.
- Outcome in terms of survival and QALY was calculated from the effect of 1-year adjuvant trastuzumab on the risk of having a locoregional recurrence, a contralateral recurrence, or a distant recurrence, and the absolute risk in a cohort of patients was multiplied with the hazard ratio of 0.64.
- This risk reduction was only applied for HER2-positive patients in the no recurrence state receiving 1 year of adjuvant trastuzumab. In the base case scenario, the duration of treatment effect was assumed to last throughout the lifetime of the patient.

**Health states:** no recurrence, locoregional recurrence, contralateral recurrence, distant recurrence, and death.

**Data from studies:** data on the probability of IHC test results conditional on FISH test results were provided (see table 2 of study for further details).

Outcome of interest	Estimate
Prevalence of HER2 positive breast cancer	0.25
Cumulative risk of recurrence and mortality (at 20 years – 5 and 10 year figures are also presented in the study)	-
From no recurrence to	-

Locoregional recurrence	18.0%
Contralateral recurrence	9.4%
Distant recurrence	24.9%
Dead	16.5%
From locoregional recurrence	-
Distant recurrence	61.3%
Dead	40.5%
From contralateral recurrence	-
Distant recurrence	37.8%
Dead	40.0%
From distant recurrence	-
Dead	99.7%
Patients in the trastuzumab arm suffering symptomatic congestive heart failure	2.1%

**Utilities:** from published literature, based on Swedish population health related quality of life (HRQoL) data, adjusted by a reduction in HRQoL (general age and sex matched population for each health state) that the authors derived from a previous study they carried out.

Input parameter	Utility
No recurrence	0.935
First year in locoregional recurrence or contralateral recurrence	0.935
Second and consequent years in locoregional recurrence or contralateral recurrence	
Distant recurrence	0.822
Congestive heart failure	Utility reduced by 50% for 6 months

**Health care resource utilisation and costs:** indirect costs were also included based on a previous study by the authors. The indirect costs represented the loss of productivity due to breast cancer (value of productivity loss estimated using the human capital approach). Future costs are also included and were derived from a published study.

Unit costs	2005 Euros €
Outpatient visit	171
Multiple uptake gated acquisition (MUGA) scan	195
IHC test	200
FISH test	548
Trastuzumab (each cycle)	2055
Total drug cost of trastuzumab for 1 year of adjuvant treatment (including loading dose)	36,298
Outpatient costs of administration for trastuzumab (over a year)	2899
Total additional cost of cardiac monitoring and treatment of adverse effects per patient.	1559
Additional cost of palliative care (one-time cost of patients dying from breast cancer in the distant recurrence state).	6813

## Results

Outcome of interest	Strategy 1	Strategy 2	Strategy 3	Strategy 4	Strategy 5
Total cost (€)	115,151	122,450	129,188	124,571	125,503
QALYs gained	11.020	11.211	11.281	11.282	11.304
ICER (€)	-	<b>dominated</b>	<b>dominated</b>	<b>35,975</b>	<b>41,471</b>

Strategy 1 = standard care – no testing and no trastuzumab.

Strategy 2 and 3 dominated (were more effective and less costly).

Strategy 4 and 5 had an ICER of €35,975 and €41,471 respectively compared with Strategy 1.

**Sensitivity analysis:**

Subgroup analysis was carried on age at the start of adjuvant trastuzumab treatment. The results of this analysis found that patients aged 35 had a lower cost per QALY, €26,700 and €30,100 for strategies 4 and 5 respectively. At age 65 the resulting ICERs were €56,200 and €64,700 for strategies 4 and 5 respectively. In one-way sensitivity analysis, the authors found that relative risk reduction (hazard ratio) of an event arising from treatment with trastuzumab, duration of effect and inclusion of future costs were the parameters that affected the ICERs most. An increase of 30% in the hazard ratio of an event after 1 year of trastuzumab resulted in ICERs of €84,400 and €97,000 for strategies 4 and 5 respectively.

Probabilistic analysis was carried out. Distributions were only placed around the following parameters; costs, utilities and effect of 1 year of trastuzumab. Only the cost effectiveness acceptability curve (CEAC) was presented. From the graph it can be estimated that at €40,900, the probability of strategy 4 being cost effective is approximately 65% and of strategy 5 being cost effective is approximately 50%.

**Authors' conclusions:**

The authors state that FISH testing for all patients with 12 months of adjuvant trastuzumab for FISH+ patients is a cost effective treatment option from a societal perspective.

**General comments:**

This study examines cost effectiveness of testing strategies which may be considered outside of the remit of this review. However, this study was included as it was the only study identified that examined treatment with trastuzumab following the testing strategies which makes the paper more relevant for the current review. Risk of recurrence and mortality in the model from unpublished data. This means the figures cannot be fully validated. Not all parameters were included in the probabilistic analysis and only the CEAC was presented.

Liberato et al., Cost effectiveness of adjuvant trastuzumab in human epidermal growth factor receptor 2-positive breast cancer; 2006. J Clin Oncol 25:625-633.

**Design:****Type of economic evaluation:**

Cost-utility analysis using modelling (i.e. Markov model – TreeAgePro).

**Clinical effectiveness:**

Taken from RCTs NSABP B-31 and NCCTG N983 and the subsequent joint analysis, the EBCTCG report, published literature, assumptions, estimates of utilities from published literature.

**Cost estimation:**

Direct costs included cost of therapy, administration and follow up, cardiac dysfunction, local relapse and metastatic disease. No costs of HER2 testing were included. The perspective of the US and Italian health care systems was taken. Costs are reported in Euros and US dollars. No cost year is reported. A discount rate of 3% was applied to both costs and benefits.

**Country:** US and Italy **setting:** Hospital

**Inclusion criteria:**

Not stated.

**Exclusion criteria:**

Not stated.

**Population:**

Women with early stage HER2-positive Breast Cancer with a median age of 50 years.

**Interventions:**

Based on population in NCCTG N9831 and NSABP B-31.

Adjuvant chemotherapy and trastuzumab compared with chemotherapy alone.

In the model patients had already received AC and were then allowed to receive paclitaxel alone or in combination with trastuzumab. After 3 months (one Markov cycle) only patients assigned to the trastuzumab strategy received treatment.

**Outcomes:**

QALYs, LYs, costs and ICERs

**Follow up:**

Time horizon = 15 years, Markov cycle length was 3 months

**Data used to populate the model:**Assumptions:

- No additional benefit was added due to trastuzumab after the first 5 years of follow-up.
- Cardiac mortality assumed zero at baseline analysis.
- Those having cardiac events (and therefore interrupted therapy) were assumed to continue benefiting from trastuzumab and had the same relapse rate as those continuing on therapy.
- All reported local relapses occurred in the first 5 years of follow up.
- Patients with metastatic disease received first line therapy including chemotherapy and trastuzumab if they had not received adjuvant trastuzumab, and chemotherapy alone if they had received adjuvant trastuzumab.
- Mortality due to causes other than breast cancer was based on national mortality rates.

Health states: disease-free, local relapse, disease free after local relapse, metastatic disease, and death

Data from prospective studies:

<b>Outcome of interest</b>	<b>Estimate</b>
Disease free state	
Cardiac dysfunction and permanent trastuzumab discontinuation in patients receiving ongoing adjuvant trastuzumab	-
0-3 months	2%
4-6 months	7%
7-9 months	6%
10-12 months	2%
Cardiac dysfunction in patients who have never received adjuvant trastuzumab	-
0-6 months	4%
Percentage of symptomatic patients with cardiac dysfunction	-
0-12 months	23%
Any relapse in patients who have never received adjuvant trastuzumab	-
0-12 months	2%/yr
13-60 months	11%/yr
5-10 years	3.4%/yr
11-15 years	2.7%/yr
Relative risk of any relapse in patients receiving ongoing or previous adjuvant trastuzumab	-
0-5 years	0.48
5-15 years (assumption)	1.00
Percentage of local relapses	-
0-5 years	32%
6-15 years (assumption)	0%
Local relapse state	
Disease free after local relapse	-
0-12 months	90%
Disease free after local relapse	
Systemic relapse in patients with a local relapse occurring in the first year of follow-up	-
0-3 years	40%/yr
>3 years	7%/yr
Systemic relapse in patients with a local relapse occurring after the first year of follow-up	-
0-3 years	20%/yr
>3 years	7%/yr
Metastatic disease state	
Death in patients not receiving trastuzumab	59%/yr
Death in patients receiving trastuzumab	48%/yr

Utilities: from published literature, further details are not given.

Input parameter	Utility
Disease free - without symptomatic cardiac dysfunction	0.97
Disease free - with symptomatic cardiac dysfunction	0.51
Disease free after local relapse	0.92
Local relapse	0.82
Metastatic disease	0.58

Health care resource utilisation and costs: Much of the resource utilisation was extracted from clinical trials (NCCTG N9831 and NSABP B-31). All costs were derived from published sources including economic evaluations. Full descriptions of costs and references are given.

Unit costs	Italy (€)	US (\$)
Adjuvant trastuzumab treatment (overall cost)	40,100	44,881
Paclitaxel treatment (overall cost)	2716	7592
Adjuvant hormone therapy	2117 per year	2701 per year
Echo Echocardiography	62	420
Symptomatic cardiac dysfunction	375 per 3 months	1750 per 3 months
Asymptomatic cardiac dysfunction	188 per 3 months	1000 per 3 months
Early follow-up (< 5 years)	96 per year	700 per year
Late follow-up (>= 5 years)	56 per year	700 per year
Local relapse (overall cost)	3780	16,200
Metastatic disease	15,600 per year	20,280 per year

## Results

Outcome of interest	Adjuvant trastuzumab	No adjuvant trastuzumab
15 year survival	0.43	0.56
Life years (discounted)	9.82	8.80
Incremental LY	-	1.02
QALYs (discounted)	9.22	8.03
Incremental QALYs	-	1.18
Italian costs	€54,058	€36,522
Incremental costs	-	€17,536
Cost per LYS	-	€17,192
Cost per QALY	-	<b>€14,861</b>
US costs	\$77,947	\$55,562
Incremental costs	-	\$22,385
Cost per LYS	-	\$21,946
Cost per QALY	-	<b>\$18,970</b>

## Sensitivity analysis:

The time frame of the analysis substantially affects the result. The author's probabilistic analysis showed that the ICER ranged from €11,286 to €128,780 per QALY (US\$15,165 to US\$143,064 per QALY) when the time horizon is varied from 20 to 5 years respectively. Varying the baseline age of women in the cohort, and therefore the annual risk of death due to causes other than breast cancer, also affected the result. Adjuvant trastuzumab was less cost effective in older women.

The impact of the patients' risk of relapse was tested. Adjuvant trastuzumab cost more than €50,000/QALY (\$60,000/QALY) in very low risk patients (i.e. those with a forecasted risk of relapse lower than 15% at 10 years), whereas it cost less than €20,000/QALY (\$30,000/QALY) if the risk was higher than 40%.

The results were not sensitive to the proportion of women receiving trastuzumab either in the adjuvant or in the metastatic phase, changes in the quality of life assigned to the health states or the mortality rate of patients developing symptomatic cardiac toxicity.

Probabilistic analysis on the base case demonstrated that adjuvant trastuzumab was less than €20,000 per QALY (\$27,000 per QALY) with a probability of 91%.

A multiway analysis using the main characteristics of the HERA trial was performed. Patients received

trastuzumab after adjuvant chemotherapy, incurred a 1.27 higher risk of relapse in the first 5 years and the hazard ratio of relapse in patients receiving adjuvant trastuzumab was calculated according to the hazard ratio reported by HERA (0.54). Cardiac toxicity was decreased from 17% to 8.8% and the proportion of symptomatic patients was reduced from 23% to 20%. The results were that adjuvant trastuzumab cost €11,228 per QALY (95% confidence limits (CI): €5,895 to €28,936) for the Italian setting and \$16,199 per QALY (95% CI: \$3,059 to \$52,538) for the US setting.

**Authors' conclusions:**

Overall, the cost effectiveness of adjuvant trastuzumab in the Italian health care setting was €14,861 per QALY. The time frame of the analysis affects the results the most. The drug was only cost effective after 7 to 10 years because the clinical benefits of trastuzumab were gained over time. Patient age, along with the ability of trastuzumab to prevent relapses also substantially affected the result. Therefore, adjuvant treatment with trastuzumab might not be cost effective in older HER2-positive patients who have a low risk of relapse. From the US perspective adjuvant trastuzumab had an ICER of \$18,970 per QALY.

**General comments:**

The authors performed a probabilistic sensitivity analysis. The results of varying main parameters were presented individually as well as presenting a CEAC. There is some confusion over the combined effects of some of the parameters on the overall result. However, the CEAC seems to show that adjuvant treatment may be cost effective. The multiway analysis using the HERA trial protocol could have been presented more clearly. More detail on the generalisability of the EBCTCG report would also have been useful.

Millar and Millward, Cost effectiveness of trastuzumab in the adjuvant treatment of early breast cancer. A lifetime model, 2007. *Pharmacoeconomics*, 25(5): 429-442.

**Design:**

Type of economic evaluation:

Cost-utility analysis using modelling (i.e. Markov model in Microsoft Excel).

Clinical effectiveness:

RCTs including NSABP-B31 and HERA, assumptions, published literature, estimates of utilities from a published source.

Cost estimation:

Cost of trastuzumab (for both a 52-week course and a 9-week course), treatment of illnesses other than cancer, metastatic cancer after relapse, local or regional recurrence and heart failure screening. Cost of testing for HER2 status was not included as it is routine in Australia. Direct medical costs only, taken from the Australian health system perspective. All costs were reported in 2005 values and in Australian dollars (\$A). Cost and benefits were discounted at 3%.

**Country:** Australia, **setting:** Hospital

**Inclusion criteria:**

Not stated.

**Exclusion criteria:**

Not stated.

**Population:**

Women with HER2-positive breast cancer with an age at diagnosis of 50 years.

**Interventions:**

52-week course of trastuzumab, 9-week course of trastuzumab or no treatment. Further details were not provided.

**Outcomes:**

QALYs, LYS costs and ICERs

**Follow up:**

Time horizon = Life time (51 years). Cycle length was 1 year.

**Data used to populate the model:**

Health states:

Remission; relapse with local or regional recurrence; relapse with distant disease (metastases); and death

from metastatic breast cancer, or from non-cancer causes while in any of the first three disease states.

**Assumptions:**

- Development of new or contralateral breast cancer was not included.
- Death from breast cancer could only occur in the metastatic disease state.
- Risk of cardiac toxicity was assumed maximal at the end of trastuzumab therapy and it resolved over the next three years. No increase in cardiac mortality with trastuzumab was assumed.
- All patients survived the 52-week course of trastuzumab without relapse (or the 9-week course with the non-relapse assumption carried forward to 52 weeks).
- 70% of patients experiencing relapse with metastatic disease received trastuzumab in sensitivity analyses. It was assumed that no patients receive trastuzumab in the base case.
- Transition probabilities for the 52-week course were also applied to the 9-week course model except for the probability of remission to metastatic disease.
- Transition probabilities for remission to local recurrence and metastases over time were adjusted to correspond with the risk of relapse in breast cancer decreased progressively over time. Transition probabilities for this adjustment were taken from the published literature.
- When calculating the corresponding transition probabilities for the trastuzumab group, the authors further assumed that the relative risk of trastuzumab preventing relapse (~0.5) remained for five years and then diminished progressively to zero over a further three years (by 25%, 50% and 75% respectively), after which the benefit ceased. This three year tailing off effect was held constant throughout sensitivity analysis.
- Mortality due to causes other than breast cancer was based on standard life tables.

**Data from RCTs:**

<b>Outcome of interest</b>	<b>Estimate</b>
Initial annual transition probabilities	-
Remission to metastatic disease (no trastuzumab)	0.087
Relative risk of reported survivals for developing distant metastases following a year of trastuzumab	0.48
Relative risk of survival free of first distant recurrence for HER2 positive patients given or not given 9 weeks of trastuzumab.	0.29
Remission to local recurrence	One third of the probabilities for development of metastases
Local recurrence to metastases	Corresponding rate from remission, adjusted by a factor of 3 – same for both groups
Metastases to death from breast cancer	0.325 – same for both groups
Metastases to death from breast cancer – when including trastuzumab as palliative care	0.280
Remission to distant metastases	Adjusted empirically to produce disease free survival in each group at 3 years equal to the reported value in the joint analysis

**Utilities:** From published literature in which utility weights were extracted from 40 papers on economic analysis in cancer. These were the only details provided.

<b>Health States</b>	<b>Utility</b>
Remission	0.98
Locoregional relapse	0.80
Metastatic disease	0.55
Heart failure	Factor of 0.85 applied to each of the above weights
Remission	0.83
Locoregional relapse	0.68
Metastatic disease	0.47

**Health care resource utilisation and costs:** All health care resource utilisation and costs were presented in

detail. Resource use was estimated by a clinical expert.

<b>Unit costs</b>	<b>2005 \$A</b>
Trastuzumab 52-week course per patient	59,752
Trastuzumab 9-week course per patient	11,332
Trastuzumab in metastatic disease – 9 months	41,208
Treatment of illnesses other than cancer	1560
Metastatic disease	47,674
Recurrence	29,834
Heart failure screening	641
Heart failure treatment	2251

## Results

Outcomes for trastuzumab for 52-week regimen

<b>Outcome of interest</b>	<b>Trastuzumab</b>	<b>No trastuzumab</b>
Total costs with drug acquisition costs added and discounted at 3% (\$A)	87,818,858	31,513,284
Breast cancer deaths	346	482

<b>Outcome of interest</b>	<b>Trastuzumab 52-weeks</b>	<b>Trastuzumab 9-weeks</b>
Cost per cancer death avoided (\$A)	414,012	30,608
Cost per LYS (\$A)	13,730	1016
Cost per QALY (\$A)	<b>22,793</b>	<b>1700</b>

### Sensitivity analysis:

- When relapse with metastatic disease is treated with trastuzumab (in the 52-week regimen model) the ICER improved (\$A 20,967 per QALY).
- Results of the one way and multivariate sensitivity analysis showed that the model was most sensitive to drug acquisition costs (indicated by the 9-week model), assumption on the duration of benefit and the discount rate.
- Univariate analysis on duration of effect showed that the ICER ranges from \$A 18,444 per QALY for 10 years duration of effect to \$A 35,353 per QALY for 2 years duration of effect.
- Sensitivity analysis for the 9-week course showed that when the risk reduction for distant recurrence is varied (using 95% CI) the range of cost effectiveness is from \$A 1018 to \$A 5569 per QALY.

### Authors' conclusions:

The author state that adjuvant therapy with trastuzumab may be cost effective. The overall budget impact with a 52-week course is significant while the 9-week course costs much less and is therefore economically attractive.

### General comments:

This study is a useful addition to the review despite some limitations around the reporting of results. This is due to the comparison of the 9 week and 12 month treatment regimens. The difference in cost effectiveness between these regimens is an important consideration in this review. The authors do not explicitly state the comparator in the model, only that they were comparing trastuzumab versus no trastuzumab and did not seem to cost current therapy.

No details of QALYs or incremental QALY results were provided.

## Cost-effectiveness analyses

Dedes K. J. et al., Cost-effectiveness analysis of trastuzumab in the adjuvant treatment of early breast cancer: a model-based analysis of the HERA and FinHer trial, 2007. *Annals of Oncology* 25: 1493-1499.

### Design:

#### Type of economic evaluation:

Cost-effectiveness analysis using modelling (i.e. Markov model – software not specified).

#### Clinical effectiveness:

Taken from the clinical data from HERA and FinHer RCTs, published literature, assumptions.

#### Cost estimation:

Cost of trastuzumab and other therapies, cost of hospitalisation, treatment for recurrent and metastatic disease, radiotherapy, diagnostics and palliative chemotherapy, treatment of symptomatic CHF and echocardiography were estimated. Direct medical costs were calculated from the perspective of a Swiss health care provider in Euros and from the year 2006. Only costs were discounted at 3% in the base case. Effectiveness was discounted by 3% in sensitivity and scenario analysis.

**Country:** Switzerland, **setting:** Hospital

### Inclusion criteria:

As for HERA and FinHer trial.

### Exclusion criteria:

Not stated.

### Population:

Women with early stage HER2-positive breast cancer with an average age of 50 years.

### Interventions:

Two strategies were examined based on HERA and FinHer: adjuvant treatment after surgical therapy of early breast cancer with or without trastuzumab.

### Outcomes:

LYs, costs and ICERs

### Follow up:

Time horizon = 15 years (5 and 10 year scenarios were also presented). Markov cycle length was 1 year.

### Data used to populate the model:

#### Assumptions:

- A constant yearly risk for local and distant recurrences for the first 5 years after adjuvant treatment was assumed.
- The risk for local and distant recurrences was then gradually reduced by 10% from year 6 to year 15 in order to reflect the flattening of recurrence curve in breast cancer patients after 5 years.
- The clinical benefit of trastuzumab was assumed to last for the first 5 years in the base case, thereafter the relative risk for recurrent and metastatic disease in the trastuzumab group assumed to be the same as in the observational group.
- The authors assumed that medical treatment for congestive heart failure (CHF) was carried out for 1 year (assuming trastuzumab's cardiotoxicity is reversible).
- Mortality due to side-effects was assumed to be zero.
- Mortality due to causes other than breast cancer was based on national mortality rates.

**Health states:** disease-free survival, local recurrence, regional recurrence, metastatic disease and death.

**Data from prospective studies:** Annual probabilities were provided for survival, recurrence and mortality. Only the transition probabilities were reported.

Outcome of interest	Estimate for trastuzumab – HERA data
After adjuvant treatment	-
Local recurrence	0.01
Regional recurrence	0.006
Metastatic disease	0.05
Death rate for the first year	0.017

Yearly mortality for 2nd–15th year rate	0.0018 (50 years) to 0.0067 (65 years)
Outcome after treatment of metastatic disease – treatment with trastuzumab	-
Metastatic disease	0.78
Death	0.22
Outcome after treatment of metastatic disease – treatment with trastuzumab	-
Metastatic disease	0.67
Death	0.33

Outcome of interest	Estimate for trastuzumab – FinHer data
After adjuvant treatment:	-
Local recurrence	0.003
Regional recurrence	0.003
Metastatic disease	0.023
Death rate for the first year	0.017

Utilities: no utilities were included in this study

Health care resource utilisation and costs: resource utilisation was extracted from published sources.

Unit costs	2006 €
Disease free survival	1345 / year
Local recurrence	7280 for first year
Regional recurrence	13,640 for first year
Metastatic disease	-
- first year in the control group (trastuzumab treatment rate of 80%)	41,412
- first year in the trastuzumab group (trastuzumab treatment rate of 50%)	27,219
- further years in both groups	13,025
Cost of trastuzumab administration in the HERA trial	39,245
Cost of trastuzumab administration in the FinHer trial	9248

## Results

Outcome of interest	Trastuzumab	Observational group
Recurrence rates at 10 years [risk ratio (RR) = 0.70]	10.44%	15.0%
Recurrence rates at 15 years [RR = 0.71]	11.3%	15.8%
Overall survival rate at 10 years [RR = 0.87]	71.8%	62.8%
Overall survival rate at 15 years [RR = 0.84]	62.9%	52.7%

At 5 years the total cost of the trastuzumab group was €53,403 and of the observational group was €27,304. The incremental cost and LYG between the groups were €26,304 and 0.12 respectively giving a cost per LYG of €212,360. At 15 years the total cost of trastuzumab group was 67,682 and of the observational group was €47,791. The incremental cost and LYG were €19,891 and 1.01 respectively giving a cost per LYG of €19,673. Results were also given for 10 years.

### Sensitivity analysis:

Scenario analyses were explored including the clinical benefit of trastuzumab limited to 3 years, varying re-treatment with trastuzumab percentages for patients with adjuvant trastuzumab, and discounting life years gained at 3% (only costs were discounted in the base case).

One way sensitivity analysis showed that the cost effectiveness of the trastuzumab group was sensitive to changes in clinical efficacy of trastuzumab, discounting of the effectiveness and its price.

For the FinHer regimen:

Outcome of interest	Trastuzumab	Observational group

Recurrence rates at 10 years [risk ratio (RR) = 0.55]	4.91%	8.77%
Recurrence rates at 15 years [RR = 0.60]	5.48%	9.19%
Overall survival rate at 10 years [RR = 0.81]	81.8%	66.1%
Overall survival rate at 15 years [RR = 0.77]	73.6%	57.0%

In each of the analyses (at 5, 10 and 15 years) for the FinHer trials the trastuzumab group is more effective and cost saving compared to the observational group. Even in sensitivity analysis all the results show that the trastuzumab group dominates (is more effective and less costly than) the observational group.

**Authors' conclusions:**

Based on the HERA regimen, the ICER is above €50,000 per LYG, after 10 and 15 years the ICERs improve and become lower than €50,000 per LYG. Data supplied by the FinHer trial show that the 9-week regimen may save costs compared with no adjuvant trastuzumab treatment.

**General comments:**

It is not clear from the study what the LYG are for each of the strategies. Some of the calculations in the results tables suggest more accurate figures could have been presented to improve clarity. A comparison of figures from other studies in this area was presented in the discussion. Further data on the clinical inputs would have been helpful. All the inputs were presented as annual probabilities. Some costs were derived from standard treatment guidelines and from a retrospective chart review for metastatic disease. The authors recognised this is a limitation of the model.

Neyt, M., et al., An economic evaluation of herceptin in adjuvant setting: the breast cancer International research group 006 trial. Annals of oncology 2006; 17:381-390.

**Design:**

Type of economic evaluation:

Cost-effectiveness analysis using modelling (i.e. Treatment model – software not specified).

Clinical effectiveness:

Based on the BCIRG 006 trial, the SEER database, mortality rates from the US census bureau and progression from metastatic disease from the Canadian provincial cancer registry data, published literature, expert opinion and assumptions.

Cost estimation:

Direct costs included cost of therapy and administration, diagnostic tests, surgery and metastatic disease. The payer perspective was taken. Costs are reported in Euros, the cost year does not seem to have been reported. Cost and benefits were discounted at 5%.

**Country:** Belgium, **setting:** Hospital

**Inclusion criteria:**

As for the trials

**Exclusion criteria:**

As for the trials

**Population:**

Women > 50 years with stage III (node positive) diagnosed breast cancer that is HER2-positive

**Interventions:**

Based on the BCIRG 006 trial:

AC followed by docetaxel (standard treatment)

AC for four cycles followed by docetaxel for four courses and trastuzumab for 1 year (AC->TH).

Docetaxel and carboplatin for six courses with concurrent trastuzumab given for 1 year (TCH).

**Outcomes:**

Life Years (LYs), costs and ICERs

**Follow up:**

Time horizon = until the metastatic phase

**Data used to populate the model:**

Assumptions:

- The authors stated that the BCIRG 006 trial was ongoing and that there was no effectiveness data

regarding the use of trastuzumab in the adjuvant setting. Instead a threshold analysis was carried out on the number of breast cancers that become metastatic and time to disease progression.

- Cost and effectiveness data were not included in the cost model as there is a lack of treatment standard during this period.
- Life expectancy data were extracted from a study on the lifetime costs in patients with metastatic disease.
- Survival data were taken from the SEER database.
- Mortality and estimates of progression to metastatic disease were taken from US and Canadian databases respectively.

Health states: phases in the model were: diagnosis, surgery, breast reconstruction, radiotherapy, pre- and post-operative chemotherapy, hormonal treatment, and metastatic treatment.

Data from studies: It is unclear what data were used in the model in terms of the effectiveness of trastuzumab.

Outcome of interest	Estimate
Average life expectancy at diagnosis for those who progressed to the metastatic phase	6.7 years
Average life expectancy at diagnosis for those who did not progress to the metastatic phase	7.8 years

Utilities: no utilities were included in this study

Health care resource utilisation and costs: Resource utilisation was based mainly on databases of the University hospital where the study took place. Experts were used when data were unavailable. Treatments for adverse events (cardiac events) did not seem to have been costed, although cardiac monitoring was included.

Unit costs	Euros €
Hematoxylin and eosin staining and IHC	146
FISH	167
Trastuzumab	10,032
AC->TH	45,034
TCH	47,765
LVEF test	55

## Results

Outcome of interest	Standard tx	AC->TH	TCH
Total costs for stage III breast cancer patient over 50 years	€16,787	€21,523	€21,827

### Sensitivity analysis:

One way sensitivity analysis was carried out on most parameters in the model. Results were only shown for AC->TH (as the results were similar for AC-> TH and TCH). Parameters that had the greatest impact on costs were discount rate, number of patients with HER-2 overexpression, transition probabilities, cost of resource inputs and cost of treatment phases. The ICER varied considerably with changes in the discount rate, price of trastuzumab and the probability of metastases. The model was most robust to changes in the costs of detecting and treating cardiac events and the costs of diagnostic testing.

Only a small section of this paper deals with cost effectiveness. This was based on the number of patients who may not progress to metastatic cancer. The percentage of cancers not becoming metastatic and the improvement in time to disease progression to metastatic cancers were plotted against an ICER. It is not clear whether this ICER is by LYG and this figure is not provided. A threshold analysis was conducted showing the price discounts (of drugs) needed to meet an ICER of €50,000 per life year. Again, it has not been clearly explained how the life years are calculated and this as not been provided else where in the study.

### **Authors' conclusions:**

According to the authors' threshold analysis, an acceptable incremental cost-effectiveness ratio can be reached if health improvements are large enough and/or price discounts are given. Authors state that cost

implications of using trastuzumab in the adjuvant setting must be calculated before use of the product becomes wide-spread.

**General comments:**

This study was a costing study. The study states that an ICER and threshold analysis was carried out, however details on the calculation have not been given and no reliable single estimates of cost effectiveness were stated.

Neyt, M., et al., Trastuzumab in early stage breast cancer: A cost effectiveness analysis for Belgium. Health Policy 2008. E-publication ahead of print.

**Design:**

Type of economic evaluation:

Cost-effectiveness analysis using modelling (model type for main analysis is a treatment model presented previously in Neyt et al. (2006) – software reported for probabilistic modelling - @risk software.

Clinical effectiveness:

Based on RCTs; HERA, NSABP B-31 and NCCTG N983 and FinHer, published literature, expert opinion, a national survey, a small patient sample from a university hospital and assumptions. Survival data and charges for CHF were based on data collected in the Netherlands.

Cost estimation:

Direct costs included cost of therapy and administration, diagnostic tests, heart failure, metastatic breast cancer, local breast cancer and follow-up costs. The perspective was that of the health care payer. Costs are reported for various years (no single cost year is reported) and in Euros. Costs and benefits were discounted at 3% and 1.5% respectively.

**Country:** Belgium **setting:** Hospital

**Inclusion criteria:**

Not reported

**Exclusion criteria:**

Not reported

**Population:**

As for the clinical trials – women with HER2-overexpressing breast cancer.

**Interventions:**

Comparator is standard breast cancer treatment without trastuzumab for early stage breast cancer.

The use of trastuzumab is based on two clinical trials – HERA and FinHer to demonstrate the cost effectiveness of a long regimen (1 year) and short regimen (9 weeks).

**Outcomes:**

LYs, costs and ICERs

**Follow up:**

Time horizon = lifetime

**Data used to populate the model:**

Assumptions:

- The model was mainly based on the progression (or prevention of progression) of patients to metastases.
- For patients progressing to metastatic disease, life expectancy data were based on a published study. These data were clearly outlined in the study
- The incremental percentage of patients not progressing to metastatic disease is estimated by multiplying the hazard ratios of patients surviving free of distant recurrence with the baseline risk of progressing to metastatic disease.
- The difference in life expectancy between patients progressing and not progressing to metastatic breast cancer (MBC) allows for the calculation of the number of life-years gained.
- The decrease in life expectancy that may be caused by CHF was based on Dutch data.
- Mortality for causes other than breast cancer was taken from Belgian life tables (adjusted due to the increased risk of secondary cancer in breast cancer patients).

Health states: health states were not explicitly stated in the study. No schematic of the model was included.

Data from studies: the risk of progressing to MBC, the mean time of progressing to MBC, mean survival of MBC (according to age and stage) and mean life expectancy with heart failure were also provided. Some Dutch data were used where no data for Belgium existed.

Outcome of interest	Estimate
Hazard ratio of surviving free of distant recurrence HERA	0.49
Hazard ratio of surviving free of distant recurrence FinHer	0.29
Probability of local recurrence – Stage I	8%
Probability of local recurrence – Stage II	10%
Probability of local recurrence – Stage III	12%
Hazard ratio of surviving free of disease – HERA	0.54
Hazard ratio of surviving free of disease – FinHer	0.42
Reduced remaining life expectancy due to risk of second cancer (mean)	97.5%
Incremental risk of heart failure – HERA	1.67%
Incremental risk of heart failure – FinHer	-0.86%
Mean time to brain relapse	11.89 months
Probability of brain metastases	26%

Utilities: Utilities were not included. Authors state no quality of life data were available.

Health care resource utilisation and costs: Resource utilisation is taken mainly from published sources and the clinical trial data. Costs were based on the Belgian National Health Insurance. Follow up costs were also included. Resource use and costs were very clearly outlined in detail in the study.

Unit costs	Euros
FISH test	299
Trastuzumab infusion (per 150mg vial)	671
Administration of trastuzumab (per administration)	246
Mean cost of heart failure	7171
Mean metastatic treatment cost (without trastuzumab)	14,050
Mean metastatic treatment cost (with trastuzumab)	31,878
Mean cost of local recurrence	5065
MUGA scan	188

## Results

Outcome of interest	HERA	FinHer
Stage I	-	-
Incremental LYG	11.99	20.35
Incremental cost €	32,320	668
ICER (€ per LYG)	<b>34,999</b>	<b>Dominates std regimen</b>
Stage II	-	-
Incremental LYG	23.88	36.09
Incremental cost €	30,608	-1045
ICER (€ per LYG)	<b>16,026</b>	<b>Dominates std regimen</b>
Stage III	-	-
Incremental LYG	49.74	70.33
Incremental cost €	24,202	-6869
ICER (€ per LYG)	<b>5994</b>	<b>Dominates std regimen</b>

Base case scenario – includes possible lack of efficacy of trastuzumab to block the development of brain metastases, no re-treatment with trastuzumab in case of disease progression to MBC is assumed and costs of wasted trastuzumab are included. The above results were also provided by age. Overall the initial treatment costs for trastuzumab were €40,657 and €8667 for HERA and FinHer respectively.

Sensitivity analysis:

- As well as treatment stage and regimen, results were provided by age and showed that there were better outcomes for younger patients.
- A probabilistic sensitivity analysis was carried out and a cost effectiveness plane was presented.
- HERA – applying a threshold of €30,000 per LYG, early stage breast cancer treatment with trastuzumab is not cost effective in 6 out of the 15 analysed groups.
- FinHer – applying a threshold of €30,000 per LYG, trastuzumab is not cost effective in only 1 group.
- Multi parameter sensitivity analysis was carried out (prices and discount rates were fixed in the first scenario) and showed that the transition probability of progressing to MBC and the hazard ratio of distant recurrence are the most important variables. The percentage of brain metastases and heart failure are also important.

**Authors' conclusions:**

An additional trial must be carried out examining the length of treatment regimens for trastuzumab. The authors state they found no rationale in the literature consulted for administering trastuzumab for 1 year. For each of the treatment regimens tested, the ICERs for trastuzumab treatment were better for younger patients and in patients diagnosed with more advanced disease. The results of the shorter 9-week FinHer regimen were more cost-effective compared with the 1-year HERA regimen. The FinHer treatment regimen mostly results in cost savings.

**General comments:**

This is the published study of the Belgian KCE report.

There are some limitations with regard to the detail in the explanation of the structure in the model and no schematic was presented. Important discussion on the hazard ratios is included and good explanation of results is provided. This study also examines various subgroups. This study provides a budget impact of the introduction of treatment with trastuzumab for patients with non-metastatic breast cancer for HERA and FinHer regimens. No utilities were included in the analysis. Although all the cost calculations are presented in detail, costs were not adjusted to reflect the same year. This would have been a useful addition to the study. A clearer explanation of the probabilistic analysis would also have been useful.

Norum et al., Trastuzumab in adjuvant breast cancer therapy. A model base cost-effectiveness analysis, 2007. Acta Oncologica, 46: 153-164.

**Design:**

Type of economic evaluation:

Cost-effectiveness analysis using modelling (i.e. decision analytic model, software not specified).

Clinical effectiveness:

Taken from RCTs NSABP B-31 and NCCTG N983 and the subsequent joint analysis, assumptions, published literature, estimate of utility from a published source.

Cost estimation:

Drug costs, administration costs, cost of HER-2 analysis, cost of hospitalisation, cost of out-patient therapy. Taken from the societal perspective including indirect costs: patient/family costs (travel) and costs in other sectors (production losses). All costs were reported in 2006 values and in Euros (€). Cost and benefits were discounted at 3%.

**Country:** Norway, **setting:** Hospital

**Inclusion criteria:**

Not stated.

**Exclusion criteria:**

Not stated.

**Population:**

Women aged between 20 and 70 years with HER2-positive breast cancer.

**Interventions:**

Fluorouracil, epirubicin, cyclophosphamide (FEC) regimen administered for six cycles on a 3-weekly basis compared with FEC followed by trastuzumab 3-weekly administration for 17 cycles.

**Outcomes:**

## QALYs, LYG costs and ICERs

### Follow up:

Time horizon = The time horizon of the model is stated as time to death (lifetime horizon is assumed).

### Data used to populate the model:

#### Health states:

Decision tree – schematic (see figure 1 in Norum et al.). The model has the following phases, diagnosis of breast cancer, surgical treatment, adjuvant chemotherapy, radiotherapy, hormonal therapy and treatments in the metastatic phase.

#### Assumptions:

- Distant relapse free survival was used as a surrogate for future overall survival.
- Using published sources, 10 year survival figures for a different chemotherapy regimen cyclophosphamide, methotrexate and fluorouracil (CMF) were adjusted for the regimens examined. A 5% absolute improvement in overall survival was added for the FEC regimen and a 10% and 20% increase due to trastuzumab was estimated.
- The improved survival level was in addition to a stated level and assumed to be reached at 10 years follow up. The benefit was equally distributed over the 10 year period.
- Life expectancy following adjuvant trastuzumab therapy was based on national mortality rates.

#### Data from RCTs:

Outcome of interest*	Estimate
Overall survival (hazard ratio)	0.67
Life expectancy following adjuvant trastuzumab therapy was found to be 26.53 years. This was reduced to 20 years to take death rates from long term side effects into account (heart disease and secondary malignancy)	20
Rate of congestive heart failure without trastuzumab	4%
Rate of congestive heart failure with trastuzumab	1%

Utilities: the study reported QALYs. The use of utilities is not explained in any detail. The authors state that the quality of life (Q=0.8) was based on a previous publication, a review and the Harvard database.

Health care resource utilisation and costs: All health care resource utilisation and costs were presented in detail. Resource use derived mainly from published sources. Cost of testing for HER2 status was not included as they were assumed to be equal in both groups.

Unit costs	2006 €
Mean drug cost per patient treated with trastuzumab	42,354
Cardiac check ups (5 check ups – MUGA scan)	330
Pharmacy costs for IV drugs	326
Outpatient clinic costs – trastuzumab	2192
Outpatient clinic costs – patients not receiving trastuzumab	98
Treatment of congestive heart failure – reflects numbers of patients who experience CHF	23
Traveling costs – trastuzumab	1249
Traveling costs – patients not receiving trastuzumab	157
Costs in other sectors – production losses with trastuzumab treatment	2272

### Results

The results were calculated for each level of costs included (health care costs, net health care resources, travelling and production gains). They were also calculated for different levels of discounting and on whether a 10% or 20% improved overall survival level was assumed. This resulted in a lowest cost per LYG of €8148 (all resource use included, 20% improved survival level) and a highest cost per LYG of €44,284 (total costs not inclusive of any savings made, 10% improved survival level). The cost per QALY was also calculated, however, only one QALY figure was calculated. The authors state that specific quality of life figures for various treatment periods among HER-2 positive breast cancer patients undergoing adjuvant trastuzumab therapy were not available.

### Outcomes for trastuzumab plus FEC compared with FEC

<b>Outcome of interest</b>	<b>Result</b>
All resource use cost	€17,844
Incremental LYG (10%)	1.095
Incremental LYG (20%)	2.19
QALYs (10 and 20%)	0.8
Cost per LYG (10%)	€30,290
Cost per LYG (20%)	€37,862
Cost per QALY (10%)	<b>€8148</b>
Cost per QALY (20%)	<b>€10,185</b>

#### Sensitivity analysis:

- Univariate sensitivity analyses showed that results were most sensitive to variations in the LYG (increases in overall survival), the price of trastuzumab, production gains and the discount rate.
- If trastuzumab is used in the metastatic setting, LYG was the only factor having a significant influence on the cost effectiveness.

#### **Authors' conclusions:**

Overall, the authors state that if there is a minimum of an 8% improvement in absolute 10 year overall survival then trastuzumab appears to be a cost effective option in adjuvant HER-2 positive breast cancer.

#### **General comments:**

The method used to derive the utility weight was not discussed in the paper. There were also limitations around the reporting of clinical data in the methods section. The results of the sensitivity analysis were presented in limited detail. There were major limitations and inconsistencies in the presentation of results. The authors compared their results with the findings of other studies in the discussion. The authors state that they are aware that other studies do not generally take production gains and that the net costs are likely to be considered by readers rather than the full societal costs. The authors acknowledge that further sensitivity analyses on time horizons (for clinical benefit) would be useful.

Shiroiwa et al, The model based cost-effectiveness analysis of 1-year adjuvant trastuzumab treatment: based on 2-year follow-up HERA trial data 2008. Breast Cancer Research and Treatment, 109:559-566.

#### **Design:**

##### Type of economic evaluation:

Cost-effectiveness analysis using modelling (i.e. Markov model in TreeAge Pro 2006).

##### Clinical effectiveness:

RCTs (HERA), assumptions and published literature.

##### Cost estimation:

Cost of trastuzumab (1 year course) and other chemotherapy therapies, follow up, local and metastatic recurrence, heart monitoring and adverse events (cardiotoxicity). Direct medical costs were taken into account from the health care system perspective. Costs were reported in Japanese Yen (JPY) with costs in Euros provided using an exchange of €1 = JPY 150. The cost year does not appear to have been reported. Cost and outcomes were discounted at 3%.

**Country:** Japan, **setting:** Hospital

#### **Inclusion criteria:**

Not stated.

#### **Exclusion criteria:**

Not stated.

#### **Population:**

Based on the HERA trial - women with HER2-positive breast cancer who met the HERA trial entry criteria (median age of 49). Japanese and node-negative patients were also included.

#### **Interventions:**

1 year course of trastuzumab was compared with an observation group (adjuvant or neoadjuvant chemotherapy only).

**Outcomes:**

LYG, costs and ICERs

**Follow up:**

Time horizon = essentially life time (50 years). Cycle length was 1 month.

**Data used to populate the model:**

Health states:

The Markov model consisted mainly of four parts: without recurrence, local recurrence, metastatic recurrence and death.

Assumptions:

- Three risk reduction strategies were considered: risk reduction continuing for two years (conservative scenario), risk reduction continuing for five years (standard scenario) and for ten years (optimistic scenario).
- The assumed risk of recurrence during the first five years was higher than that during the next five years.
- Cardiac events were assumed to be reversible and therefore no increase in cardiac mortality with trastuzumab was assumed.
- Patients experiencing relapse with metastatic disease received trastuzumab even if they received it as adjuvant therapy.
- Mortality due to causes other than breast cancer was based on natural death rates in Japan.

Data from RCTs:

<b>Outcome of interest</b>	<b>Estimate</b>
Hazard ratio for the risk of recurrence in the 1 year trastuzumab group	0.64
Cardiotoxicity (severe)	0.6%
Cardiotoxicity (symptomatic)	2%
Cardiotoxicity (asymptomatic)	3%
Transition rates – Trastuzumab	-
Without recurrence to metastatic recurrence	0.004483
Without recurrence to local recurrence	0.001296
Transition rates – observation group	-
Without recurrence to metastatic recurrence	0.006916
Without recurrence to local recurrence	0.001737

Utilities: Utilities were not included.

Health care resource utilisation and costs: All health care resource utilisation and costs were presented in detail. No total costs were presented for example, overall treatment with trastuzumab. This was split into different weight categories and cost for the first cycle versus costs for the consequent cycles. Therefore not all costs have been extracted into the table below. Only relevant costs with cost per event details have been included. See table 1 of the study for further details

<b>Unit costs</b>	<b>JPY</b>
Palliative care in metastatic disease	1,100,000
Severe CHF	810,000
Symptomatic CHF	170,000
Asymptomatic CHF	40,000

**Results**

Results were also available for varying weight categories of patients

<b>Outcome of interest</b>	<b>Costs</b>	<b>Effectiveness</b>	<b>ICER (JPY)</b>	<b>ICER (€)</b>
Observation	7,900,000	12.46	-	-

Conservative	11,500,000	13.06	6,000,000	40,000
Standard	11,200,000	13.70	2,600,000	17,000
Optimistic	10,900,000	14.10	1,800,000	12,000

**Sensitivity analysis:**

- All the results of sensitivity analyses in the standard scenario produced ICERs of less than JPY 5,000,000 (€33,000).
- The model was most sensitive to the period of trastuzumab efficacy. Cost per LYG was JPY 4,700,000, JPY 1,900,000 and JPY 1,300,000 for the period of efficacy of two, five and ten years respectively based on the 1 year follow up data.
- The model was not sensitive to other one way analyses for discount rate, recurrence rate, cardiotoxicity costs and terminal costs showed little change. Of these, the discount rate changed the results the most.
- Probabilistic sensitivity analysis was carried out. The results showed that the probability of 1 year of trastuzumab in the standard scenario being below JPY 5,400,000 (€36,000) per LYG was above 95%.

**Authors' conclusions:**

The authors stated that their results showed that 1 year of adjuvant trastuzumab treatment is cost effective. Both the clinical and economic benefits were superior for the 1 year adjuvant trastuzumab group compared with the observation group.

**General comments:**

This study is a useful addition to the review showing an evaluation that examines the 2-year follow up data from the HERA trial. The study may not be directly applicable to the UK because the study was carried out in Japan however the authors mention in their discussion that they felt it appropriate to use NICE cost effectiveness thresholds due to the similar and medical environments in UK and Japan. The authors discussed the limitation of not including health related quality of life stating that in Japan there are no data for breast cancer patients to apply to the analyses.

## Regulatory submissions

PHARMAC – Technology assessment number 75 and supplementary analysis 75b. Trastuzumab (herceptin) in HER-2 positive early stage primary breast cancer. **Part 1: 12-month sequential trastuzumab treatment, August 2006.** Part 2: 9 week concurrent trastuzumab treatment in HER-2 positive early breast cancer, April 2007.

### Design:

#### Type of economic evaluation:

Cost-utility analysis using modelling (i.e. Markov model – software not specified).

#### Clinical effectiveness:

Main analysis based on the HERA trial (according to the manufacturer's application for funding for trastuzumab after completion of adjuvant chemotherapy using a one-year course), published literature, assumptions, estimates of utilities derived from published literature.

#### Cost estimation:

Direct costs included: cost of therapy and administration; diagnostic tests; cardiotoxicity tests, monitoring and events; costs of outpatient visits for disease free patients; cost of local relapse; cost of contralateral breast cancer; cost of distant relapse; cost of terminal care; and cost of severe infection and other serious adverse events. The perspective of the DHB (funder of hospital pharmaceuticals) was taken. The cost year does not seem to have been reported. Costs are reported in New Zealand dollars. Cost and benefits were discounted at 8%.

**Country:** New Zealand, **setting:** Hospital

### Inclusion criteria:

Not reported.

### Exclusion criteria:

The analysis is restricted to those up to and including 79 years.

### Population:

Women with early breast cancer who have completed locoregional therapy (surgery and/or radiotherapy) and at least four cycles of adjuvant chemotherapy, have tested IHC (3+) or FISH-positive for HER2 overexpression.

### Interventions:

Intervention is trastuzumab compared with standard treatment.

Standard treatment for women with early breast cancer following surgery and chemotherapy comprising of hormone receptor positive patients who usually receive tamoxifen or hormone receptor negative patients who do not usually receive treatment after chemotherapy.

### Outcomes:

QALYs, costs and ICERs

### Follow up:

Time horizon = lifetime. Markov cycle length = 6 months

### Data used to populate the model:

#### Assumptions:

- HER2 testing, was carried out in the model. Patients randomised to trastuzumab arm were tested for HER2 status and cardiac risk.
- Those with high cardiac risk were excluded from the analysis.
- Baseline risk of cardiac events was based on the age distribution of the patients.
- Patients who developed a severe adverse event or a relapse could discontinue treatment.
- Patients were assumed to have continued benefit from treatment with trastuzumab for four years.
- All patients who developed symptomatic CHF were assumed to discontinue treatment.
- All severe adverse events are assumed to result in discontinuation of treatment.
- It was assumed that cardiac events were reversible.
- The analysis assumed that patients who remain in remission had a reduced risk of relapse over time.
- Patients having a local relapse were assumed not to have an increased risk of mortality.
- Of patients with metastatic disease, 20% were assumed to be HER2 positive and receive

trastuzumab.

- Mortality due to other causes was based on standard NZ age specific mortality rates for women.

Health states: treatment, local relapse, contralateral, distant relapse, palliative care, remission and death

Data from studies:

<b>Outcome of interest</b>	<b>Estimate</b>
Overall percentage of severe adverse events in the trastuzumab arm	7%
Percentage of severe adverse events that were due to infection (trastuzumab)	24.8%
Percentage of severe adverse events that were due to cardiac event (trastuzumab)	14.5%
Fatal adverse events (trastuzumab)	0.4%
Risk of relapse (of the baseline risk) years zero to four.	100%
Risk of relapse (of the baseline risk) years five to nine	64%
Risk of relapse (of the baseline risk) for the remainder of life	41%
Probability of local relapse in the first 6 months (trastuzumab)	1.0%
Probability of a regional relapse in the first 6 months (trastuzumab)	0.6%
Probability of a contralateral relapse (both treatment arms)	0.4%
Probability of a distant relapse (trastuzumab)	5%
Risk of death in metastatic breast cancer (weighted average mortality after 6 months)	12.1%

Utilities: taken from EQ-5D NZ weights, informed in part by further published data. Values were estimated using descriptions of breast cancer states derived by oncologists with modifications to map to EQ-5D generic health states. All details were provided.

<b>Input parameter</b>	<b>Utility</b>
Disease free/remission, >5 years	1.00
Disease free/remission, <5 years	0.85
Local/regional relapse	0.46
Contralateral primary	0.46
Metastatic cancer	0.13
Terminal phase (one month prior to death)	-0.01
Serious infection	0.78
Cardiac toxicity including severe heart failure	0.63
Other serious adverse events averaged over 6 months	0.83

Health care resource utilisation and costs: Resource utilisation was taken mainly from published sources, clinical trial data and in-house analyses. Cost of HER2 diagnostic tests was not reported.

<b>Unit costs</b>	<b>NZ\$</b>
Trastuzumab (cost per mg)	8.81
Administration of trastuzumab (per infusion)	100
LVEF exam (echocardiography)	250
Total cost of local relapse	8033
Total cost of contralateral breast cancer	12,269
Total cost of trastuzumab for distant relapse	32,213
Total cost of distant relapse	35,878
Total average cost per 6 months of terminal care	27,930
Average cost of hospitalisation for serious infection	4359
Total cost of cardiac toxicity	4181
Average one off cost attributed to other serious adverse events	4000

## Results

<b>Outcome of interest</b>	<b>Trastuzumab ICER</b>
Cost per QALY (NZ\$)	70,000 – 80,000

### Sensitivity analysis:

Scenario analyses were carried out:

- Treatment benefit continued after cessation of therapy for the lifetime of the patient (\$24,000 per QALY).
- Treatment benefits lasted two years, then adopted comparator rates (\$127,000).
- Patients required two years of treatment to obtain four years increased benefit (144,000).

Other one way sensitivity analyses were carried out including using a discount rate of 3.5% resulting in an ICER of \$46,000 per QALY and a 50% reduction in the risk of relapse in both arms, resulting in an ICER of \$113,000 per QALY. The price of trastuzumab also influenced the results. A 30% reduction in the price resulted in an ICER of \$46,000 per QALY.

Further analysis carried out following consultation produced the following results:

### Results of additional analysis

<b>Outcome of interest</b>	<b>Trastuzumab ICER (NZ\$)</b>
Base case	73,000
Lifetime duration of breast cancer risk reduction	26,500
FinHer dose, 4 year duration of breast cancer risk reduction	12,318
FinHer dose, 2 year duration of breast cancer risk reduction	29,240
4yr duration of breast cancer risk reduction +4yr half benefit	54,302
2yr benefit and lifetime half benefit	52,649
2yr benefit and 6yr half benefit	67,507

### **Authors' conclusions:**

Based on the available information it is not possible to determine with sufficient certainty whether or not trastuzumab is a cost effective investment without a significant reduction in cost through shorter treatment duration or trastuzumab price reduction or that the clinical benefit continues to increase beyond treatment cessation.

### **General comments:**

There are some limitations with regard to the detail in the explanation of the projection of disease free survival. The one way sensitivity analysis is extensive however no further probabilistic sensitivity analysis was conducted. There is a detailed section in the discussion comparing the results of this study with the results of other similar studies.

A supplementary analysis was carried out and is reviewed in the next table.

PHARMAC – Technology assessment number 75 and supplementary analysis 75b. Trastuzumab (herceptin) in HER-2 positive early stage primary breast cancer. Part 1: 12-month sequential trastuzumab treatment, August 2006. **Part 2: 9 week concurrent trastuzumab treatment in HER-2 positive early breast cancer, April 2007.**

The analysis was carried out as for the 12 month regimen outlined above except for the following changes:

- The original analysis used age-adjusted cardiac risk to determine the number of HER2 positive patients who would meet the criteria for trastuzumab. The updated analysis used LVEF function for women in this age group. More patients were therefore expected to receive trastuzumab in the updated analysis; however, this did not affect the cost utility, only the budget impact.
- Prevalence of HER2 positive disease was reduced from 24% to 17% - this change transfers to a conservative assumption
- Baseline risk was lowered by 10% in order to closer align the modelled mortality with observed data for HER2 positive disease progression.
- Incidence of adverse events was reduced by half as the rates were unchanged but only one Markov cycle will have cardiac toxicity rates assigned. This may underestimate the benefits and overestimate the costs of this regimen as there is some evidence to show that a shorter duration of therapy combined with pre-anthracycline treatment could result in a reduction of adverse events in clinical practice compared to the HERA regimen.
- Costs were adjusted for the 9 week regimen and costs of testing for HER2 overexpression were added.
- Concomitant administration of docetaxel was considered (not currently funded in NZ – paclitaxel is). Under the 9 week model patients are assumed to receive concurrent treatment with docetaxel.

### Results

Base case (where assumptions generally favoured standard treatment) = NZ\$ 14,500 to NZ\$ 16,500. The main assumption in this analysis was that the 9 week regimen is equally effective compared to the 52 week regimen.

#### Sensitivity analysis

Sensitivity analyses were carried out to determine the effect of reduced efficacy in the 9 week regimen. When the effectiveness of trastuzumab was reduced to the level of the upper confidence limit (HR 0.83 – 17% reduction in risk of recurrence of disease) and consequent worse case scenario, the ICER was increased from NZ\$ 15,900 in the base case to NZ\$ 57,000 per QALY. Probabilistic analysis was not carried due to the timeframe available. In all other scenarios results were less than NZ\$ 30,000 per QALY.

#### **Authors' conclusions**

The 9 week regimen was given high priority recommendation for funding by PTAC and CaTSOP in 2006. Compared with the current standard care (FAC chemo), the 9 week trastuzumab concurrent regimen is cost effective when compared with other investment options for pharmaceuticals.

#### **General comments**

This was a supplementary analysis and so could be considered to be less thorough than the original analysis. The supplementary analysis was based closely on the original analysis and is therefore likely to be a valid attempt to include the 9 week regimen and the necessary alterations were made. An appeal was made against PHARMAC's decision and the result has recently been made available – the Court specifically upheld PHARMAC's decision to fund the 9 week treatment regimen.

KCE Belgian Health Care Knowledge Centre 2006. Trastuzumab in early stage breast cancer. KCE reports, Vol 34C. Reviewed alongside – Neyt, M., et al., Trastuzumab in early stage breast cancer: A cost effectiveness analysis for Belgium. Health Policy 2008. E-publication ahead of print. Only additional data presented in this report has been outlined here – refer to Neyt et al. 2008 for full review of publication.

#### **Design:**

##### Type of economic evaluation:

Cost-effectiveness analysis using modelling (model type not specified – software: @risk).

##### Clinical effectiveness:

Based on the following RCTs; HERA, NSABP B-31 and NCCTG N983 and FinHer, published literature and assumptions. Survival data and charges for congestive heart failure (CHF) were based on data collected in the Netherlands.

##### Cost estimation:

Direct costs included cost of therapy and administration, diagnostic tests, heart failure, metastatic breast cancer, local recurrence and follow-up costs. The perspective was that of the health care payer. Costs are reported for various years (no single cost year is reported) and in Euros. Costs and benefits were discounted at 3% and 1.5% respectively in the base case.

**Country:** Belgium **setting:** Hospital

##### **Inclusion criteria:**

Not reported

##### **Exclusion criteria:**

Not reported

##### **Population:**

As for the clinical trials – women with HER2-overexpressing breast Cancer.

##### **Interventions:**

Based on the clinical trials – comparators are current breast cancer treatment with either a one year regimen or 9 weeks of trastuzumab given in addition respectively from the HERA and B31/N9831 trial, and the FinHer trial.

The use of trastuzumab is based on four clinical trials – HERA and FinHer to demonstrate the cost effectiveness of a long regimen (1 year) and short regimen (9 weeks) and the joint analysis of NSABP B-31 and NCCTG N983 (plus FinHer) to explore the effect of LVEF.

##### **Outcomes:**

LYs, costs and ICERs

**Follow up:**

Time horizon = lifetime

**Data used to populate the model:**

Assumptions: Assumptions presented here are in addition to those stated in Neyt, M., et al 2008.

- Short-term results were mainly translated to the long term relying on the hazard ratio of patients surviving free of distant recurrence.
- For patients not progressing to metastatic disease the life expectancy according to Belgian 2001 life tables was used.
- In the metastatic disease state, life expectancy was calculated by adding the time to progression by age and stage, and the survival of metastatic disease from published sources.
- Cost effectiveness was calculated for several subgroups defined by 5 age groups (all >50 years) and stage (I, II and III) for the HERA and FinHer trial regimens.
- For concurrent 1 year trastuzumab (NSABP B-31 and NCCTG N983 trials) cost effectiveness was calculated for subgroups defined by 3 age groups (all, <50, <=50) and by LVEF at the start of trastuzumab treatment (50-54% or >=55%) because these variables were reported as determinants of heart failure after trastuzumab.
- Two scenarios were also modelled assuming efficacy of trastuzumab as for other sites of metastasis and a second scenario (default), where trastuzumab delayed by about a year (but did not stop) the development of metastatic disease in some patients expected to develop brain metastasis without trastuzumab.
- Survival of patients with brain metastasis was assumed to be similar to survival of metastatic disease.
- The base case assumed no re-treatment with trastuzumab if the patient progresses to metastatic disease.
- The base case assumed that trastuzumab drug wastage was included.

Health states: as for Neyt et al. 2008

Data from studies: as for Neyt et al. 2008

Utilities: as for Neyt et al. 2008

Health care resource utilisation and costs: as for Neyt et al. 2008

**Results**

Several scenarios were modelled: whether or not trastuzumab would be re-administered in metastatic disease when it has already been given for adjuvant treatment, two scenarios of costs for metastatic treatment, wasted trastuzumab due to part use of vials and the possibility of trastuzumab not being able to prevent brain metastases.

The results of these scenarios were presented for the HERA and FinHer trials for stage II breast cancer patients (all ages). Six discount rate scenarios were also presented for the HERA trial for stage II breast cancer patients (all ages). The incremental cost effectiveness of trastuzumab compared with standard treatment is presented below. All the ICER results for the FinHer trial showed that trastuzumab dominated standard treatment.

<b>Outcome of interest</b>	<b>HERA</b>
Scenario 1 – Default Trastuzumab not re-administered in MBC if patients already received the drug in adjuvant setting MBC treatment costs were not increased, Percentage of unused trastuzumab was taken into account, The effect of trastuzumab on the development of brain metastases included.	€16,026
Scenario 2 – Cost of re-administering trastuzumab in MBC included	€19,226
Scenario 3 – Cost of MBC increased	€15,672
Scenario 4 – Didn't take into account the percentage of waste (affecting costs)	€13,516
Scenario 5 – Didn't take into account that trastuzumab may have no effect on brain metastases	€11,620

In addition to the results presented by Neyt et al. 2008 tables and cost effectiveness planes are presented for each

of the subgroups (based on prognostic factors) for HERA and FinHer and additional results were presented for the B31/N9831 trials (by stage and according to LVEF).

Sensitivity analysis:

Probabilistic sensitivity analysis was presented – this does not seem to be probabilistic in the conventional sense. Uncertainty in variables was tested. This is carried out using a rank correlation calculation in which correlation coefficients are calculated between the output variables and the sampled input values. This helped to determine the importance of the different parameters behind the model on the results.

The results of this analysis are outlined under multi parameter sensitivity analysis in the table for Neyt et al. 2008

**Authors' conclusions:**

Trastuzumab administered post anthracycline proved on average effective in most patient subgroups defined by age and stage while the pre-anthracycline regimen was on average effective in all subgroups studied. Within each modelled regimen trastuzumab was more effective in younger women and in women with a more advanced disease stage.

When the post-anthracycline regimen was modelled on patients with a borderline cardiac function (LVEF 50-54%) trastuzumab treatment reduced life expectancy in stage I-II patients older than 50.

According to the author's model, pre-anthracycline trastuzumab is more cost-effective than the post-anthracycline options, can even lead to cost-savings, and reaches 20% more women in need of treatment for their cancer. Treatment with trastuzumab as in the HERA scenario was not cost-effective in 6 of the 15 analysed subgroups whereas this is only the case in 1 of the 15 subgroups for FinHer.

**General comments:**

General comments are as for Neyt et al. 2008 with the following additions. As well as stating that they found no rationale in the literature consulted for administering trastuzumab for 1 year, the authors question why shorter pre-anthracycline regimens were not included in any of the phase three trials.

There are some limitations in the reporting of the probabilistic analysis. Most of the scenarios presented simply altered the costs rather than the effectiveness, this would have been a useful addition to the study.

Ward, Pilgrim and Hind, 2006. Trastuzumab for the treatment of Primary Breast Cancer in HER2 Positive Women – A single technology appraisal. University of Sheffield. School of Health and Related Research (SchARR). Report reviews submission of clinical and cost effectiveness of trastuzumab for early breast cancer by manufacture (Roche) therefore the cost effectiveness analysis described was carried out by Roche and the criticism provided is that of SchARR. Some data were marked as commercial in confidence (CiC) and has therefore been excluded from this table.

**Design:**

Type of economic evaluation:

Cost-utility analysis using modelling (i.e. state transition cohort model – software not specified).

Clinical effectiveness:

Effectiveness estimates (transition probabilities) taken from the HERA trial and a previous study by the manufacturer for death due to metastatic disease, estimates of utilities provided by an external report.

Cost estimation:

Direct costs included cost of therapy and administration, diagnostic tests, cardiotoxicity events, recurrence costs (distant metastases), follow up treatment and end of life care. The analysis was undertaken from the perspective of the NHS and PSS. Costs are reported for 2004/5 and in UK pounds. Cost and benefits were discounted at 3.5%.

**Country:** UK, **setting:** Hospital

**Inclusion criteria:**

Not reported

**Exclusion criteria:**

Not reported

**Population:**

Women with primary invasive breast cancer that overexpress HER2 (determined by IHC 3+ or FISH positive) who have completed (neo-) adjuvant systemic chemotherapy and radiotherapy, if applicable.

**Interventions:**

Addition of 1 year of adjuvant trastuzumab therapy to standard chemotherapy compared with standard chemotherapy alone based on the HERA trial.

**Outcomes:**

QALYs, LYs, costs and ICERs

**Follow up:**

Time horizon = lifetime horizon of 45 years using a 1 year cycle length

**Data used to populate the model:**Assumptions:

- The effect of time on the rate of recurrence was relative to that collected by the EBCTCG based on all women with breast cancer
- The same trastuzumab relative risk of recurrence collected from the HERA trial was applied until year 10 when it was increased by a third until year 45 (only two thirds of the benefit is seen until year 45).
- All-cause mortality was applied to patients in the Disease Free and Recurrence Health State as well as in the Cardiac Adverse Event State.
- Only 1 loco-regional/contralateral breast cancer recurrence was experienced per patient.
- After a single year in the locoregional/contralateral recurrence state, the patients returned to a health state with a similar utility and cost as the DFS state. Patients remained there until they died or experienced metastases.
- IHC and FISH testing was used to determine HER2 status. FISH testing was carried out on around 10% of patients who receive borderline (2+) IHC results.
- Cardiac monitoring was carried out at baseline, 3, 6 and 9 months.
- Occurrence of a cardiac event did not increase mortality.

Health states: Disease-free survival, metastatic recurrence, local/contralateral recurrence, cardiac events and death

Data from studies: The majority of data taken from the studies was marked commercial in confidence. Data were taken from the HERA trial database.

Utilities: Taken from an external report using standard gamble interviews based on health states established by oncologists, breast cancer specialists and psychometric experts and completed by 100 members of the public. The participants also completed the EQ-5D to assess their own current health. The health utility scores used were marked CiC however, the SchARR state that the values compare favourably with other values used in other recent breast cancer models. Two values taken from public sources were provided.

<b>Input parameter</b>	<b>Utility</b>
Disutility of local recurrence	0.24
Contralateral breast cancer event	0.24

Health care resource utilisation and costs: Most costs were marked CiC in the manufacturer's submission. Costs available are presented below. Costs associated with the administration of trastuzumab were omitted from the manufacturer's model.

<b>Unit costs</b>	<b>2004/5 £</b>
Cost of trastuzumab (one year as adjuvant treatment)	21,185
Cost per trastuzumab vial	407
Cost per HER-2 Test	47
Cost of heart monitoring per year	475
Cost of other cardiac event NYHA Grade II	1395
Cost chronic cardiac event long- term treatment	316
Cost of severe cardiac events grade NYHA 3 and 4	6727

**Results**

<b>Outcome of interest</b>	<b>No trastuzumab</b>	<b>Trastuzumab</b>
Costs (£)	73,323	87,159
Incremental cost (£)	-	13,835
LYS	11.69	14.11
Incremental life years	-	2.43
QALYs	8.78	11.21
Incremental QALYs	-	2.43
Cost per LY (£)	-	5702
Cost per QALY (£)		<b>5687</b>

**Sensitivity analysis:**

The manufacturer undertook several sensitivity analyses. Following one way sensitivity analysis the manufacturer stated that the cost of trastuzumab and the relative risk reduction have the greatest impact on the ICER. A probabilistic sensitivity analysis was also carried out.

SchHARR carried out some sensitivity analysis and revised the manufacturer's base case. They assumed that all patients received trastuzumab in the metastatic setting whether or not they had previously received it in the adjuvant setting and that there was no further benefit in risk of recurrence after five years. Combining these assumptions gave a base case ICER of £18,449 per QALY gained.

SchHARR combined the above assumption with further sensitivity analyses and this resulted in ICERs of £16,000 to £33,000 per QALY gained, the upper estimate coming from an analysis that assumed that 23% of women receiving trastuzumab would experience a cardiac event (as is known to occur with anthracycline-including chemotherapy regimens).

**Authors' conclusions:**

The manufacturer stated that robust and extensive economic modelling confirms that trastuzumab can be regarded as a highly cost effective treatment from the perspective of the UK NHS.

Commenting on their revised base case estimate of £18,449, SchHARR stated that variations in the comparator arm to allow for different chemotherapy regimens including taxanes, did not affect the ICER by more than £3,000 per QALY gained. SchHARR stated that the cost effectiveness of trastuzumab could be improved if it were provided for 9 weekly transfusions instead of 12 month 3-weekly infusions. However, further research is required to ensure that the two regimens are equally effective.

**General comments:**

This was a well conducted economic evaluation with a very thorough critique of the issues including some additional sensitivity analyses to evaluate the impact of various assumptions made in the manufacturer model. It appears that when the assumptions are made more conservative by SchHARR, trastuzumab remains to represent a cost effective adjuvant treatment option for women with early breast cancer.

## ***5.6 What are the indication for the measurement of bone mineral density in patients with invasive breast cancer who are on adjuvant hormonal therapy?***

### **Short Summary**

The following evidence based guideline was used to inform the recommendation for management of bone loss after breast cancer treatment; Guidance for the management of breast cancer treatment induced bone loss: A consensus position statement from a UK Expert Group. Cancer Treatment Reviews (2008). This guideline was appraised using the AGREE Instrument (2001) and was rated as high quality. The evidence based approach was clearly conducted.

### **Evidence Summary**

**AGREE Instrument Appraisal (2001)- Summary of findings:** Overall, this guideline was of high quality;

#### **The following areas had strong agreement with appraisal check points:**

**Scope & purpose:** 3. *The patients to whom the guideline is meant to apply were specifically described.*

**Stakeholder involvement:** 6. *The target users of the guideline were clearly defined.*

**Editorial Independence:** 23. *Conflicts of interest of guideline development members were recorded. (Fully stated)*

#### **The following areas had agreement with appraisal check points:**

##### **Scope & purpose**

1. *The overall objective(s) of the guideline was specifically described.*

2. *The clinical question(s) covered by the guideline was specifically described.*

##### **Stakeholder involvement**

4. *The guideline development group did include individuals from all the relevant professional groups.*

11. *The health benefits, side effects and risks were considered in formulating the recommendations.*

##### **Rigour of development**

8. *Systematic methods were used to search for evidence. (Details of the strategy used to search for evidence were not provided, however, some information about databases used was included.)*

12. *There was an explicit link between the recommendations and the supporting evidence.*

13. *The guideline was externally reviewed by experts prior to publication. (The guideline was reviewed externally before it was published. Reviewers included some experts in the clinical area and possibly some methodological experts. Patients' representatives were not included. A description of the methodology used to conduct the external review was not presented.)*

##### **Clarity and presentation**

15. *The recommendations were specific and unambiguous.*

16. *The different options for diagnosis and/or treatment of the condition were clearly presented.*

17. *Key recommendations were easily identifiable.*

18. *The guideline was supported with tools for application.* (While there are clearly produced algorithms and a quick reference guide associated with this guideline, there is no information about dissemination and implementation provided with the guideline.)

### **Applicability**

19. *The potential organizational barriers in applying the recommendations were discussed.* (This was addressed in a very brief manner in the guideline.)

20. *The potential cost implications of applying the recommendations were considered briefly.* (Addressed in this guideline)

21. *The guideline did present key review criteria for monitoring and audit purposes* (Addressed in this guideline)

### **Editorial Independence**

22. *The guideline was editorially independent from the funding body.* (The role of the funding body was acknowledged and no influence on content was included by guideline producers .

### **The following areas had no agreement with appraisal check points:**

#### **Stakeholder involvement**

5. *The patients' views and preferences were not sought.* (Information about patients' experiences and expectations of health care were not described in the guideline document and so therefore it is expected that this did not inform the development of clinical guidelines.)

### **The following areas had strong disagreement with appraisal check points:**

#### **Stakeholder involvement**

7. *The guideline was not piloted among end users.* (There was no indication that the guideline was pre-tested for further validation amongst its intended end users prior to publication.)

9. *The criteria for selecting the evidence was not clearly described.* (Criteria for including /excluding evidence identified by the search were not provided.)

10. *The methods used for formulating the recommendations should be clearly described.* (There was no description of the methods used to formulate the recommendations and how final decisions were arrived at.)

14. *A procedure for updating the guideline was not provided.* (There was no clear statement about the procedure for updating the guideline)

### Further Details about AGREE Instrument Appraisal

#### Scope & purpose

1. *The overall objective(s) of the guideline should be specifically described.*

Agree -3

2. *The clinical question(s) covered by the guideline should be specifically described.*

Agree -3

3. *The patients to whom the guideline is meant to apply should be specifically described.*

Strongly agree - 4

#### Stakeholder involvement

4. *The guideline development group should include individuals from all the relevant professional groups.*

Agree -3

5. *The patients' views and preferences should be sought.*

Do not agree – 2

Information about patients' experiences and expectations of health care were not described in the guideline document and so therefore it is expected that this did not inform the development of clinical guidelines.

6. *The target users of the guideline should be clearly defined.*

Strongly agree - 4

7. *The guideline should be piloted among end users.*

Strongly disagree – 1

There was no indication that the guideline was pre-tested for further validation amongst its intended end users prior to publication.

#### Rigour of development

8. *Systematic methods should be used to search for evidence.*

Do not agree – 2

Details of the strategy used to search for evidence were not provided, however, some information about databases used was included.

9. *The criteria for selecting the evidence should be clearly described.*

Strongly disagree – 1

Criteria for including /excluding evidence identified by the search were not provided.

10. *The methods used for formulating the recommendations should be clearly described.*

Strongly disagree – 1

There was no description of the methods used to formulate the recommendations and how

final decisions were arrived at.

*11. The health benefits, side effects and risks should be considered in formulating the recommendations.*

Agree -3

*12. There should be an explicit link between the recommendations and the supporting evidence.*

Agree – 3

While there is mention of the evidence that has been used to inform the recommendation, the link is not explicit and could be clearly described.

*13. The guideline should be externally reviewed by experts prior to publication.*

Agree -3

A guideline was reviewed externally before it is published. Reviewers included some experts in the clinical area and possibly some methodological experts. Patients' representatives were not included. A description of the methodology used to conduct the external review was not presented.

*14. A procedure for updating the guideline should be provided.*

Strongly disagree – 1

There was no clear statement about the procedure for updating the guideline

### **Clarity and presentation**

*15. The recommendations should be specific and unambiguous.*

Agree -3

*16. The different options for diagnosis and/or treatment of the condition should be clearly presented.*

Agree -3

*17. Key recommendations should be easily identifiable.*

Agree -3

*18. The guideline should be supported with tools for application.*

Agree -3

While there are clearly produced algorithms and a quick reference guide associated with this guideline, there is no information about dissemination and implementation provided with the guideline.

Agree - 3

Addressed in this guideline briefly.

*21. The guideline should presents key review criteria for monitoring and audit purposes*  
Strongly agree – 3  
Addressed in this guideline

## **5.7 What are the indications for the use of bisphosphonates in patients with early breast cancer?**

### **Short Summary**

There is considerable, high quality evidence from systematic reviews and meta-analyses of RCTs that have indicated the effectiveness of bisphosphonates for specific groups of breast cancer patients:

Evidence from RCTs (Brufsky 2006 and Bundred *et al.* 2008) have indicated that in women who were receiving adjuvant letrozole; immediate treatment with zoledronate compared to delayed may prevent loss of bone mineral density at both lumbar spine and total hip. There is evidence that immediate treatment with zoledronic acid maintains the baseline osteopenia status of patients compared with delayed treatment at 12 months. Furthermore, Bundred *et al.* (2008) showed no evidence to suggest a difference in the occurrence of fractures in immediate versus delayed treatment with zoledronate and that there was no difference in breast cancer recurrence when comparing immediate and delayed treatment with zoledronate. There are no significant acute adverse effects with zoledronate.

A systematic review of RCTs of bisphosphonates showed no statistically significant reduction in the risk of developing skeletal metastases (Wu *et al.* 2007). Fuleihan *et al.* (2005) has shown that pamidronate prevents chemotherapy induced bone loss compared with placebo. An RCT by Greenspan *et al.* (2007) compared risedronate with placebo and showed that in postmenopausal women with breast cancer with or without aromatase inhibitors therapy, once-weekly oral risedronate was beneficial for spine and hip BMD and reduced bone turnover. There were no significant acute adverse effects with risedronate.

Saarto *et al.* 2004 showed that there was no difference in bone metastases or overall survival in women with lymph node-positive disease who were treated with chemotherapy or endocrine therapy and received clodronate or a control. Disease free survival was poorer in the clodronate group which may be attributed to visceral metastases. When IV clodronate was compared to a control during adjuvant chemotherapy there was no statistically significant difference in chemotherapy induced bone loss at 6 months or 12 months. (Vehmanen 2004)

A meta-analysis of RCTs (Ha *et al.* 2007) compared clodronate with placebo and found no statistically significant difference in overall survival skeletal metastasis or non-skeletal metastases. A Cochrane systematic review by Pavlakis *et al.* (2006) compared adjuvant oral clodronate with placebo and found no significant difference with skeletal metastases but overall survival was significantly improved with clodronate.

Gnant *et al.* (2007) conducted a four-arm trial comparing tamoxifen and goserelin +/- zoledronate versus anastrozole and goserelin +/- zoledronate for 3 years in premenopausal women with hormone-responsive breast cancer. Overall bone loss was significantly more severe in patients receiving anastrozole/goserelin compared with patients receiving tamoxifen and goserelin. Conversely, BMD remained stable in zoledronate treated patients compared with endocrine therapy alone. Brufsky *et al.* (2006) compared letrozole with early versus delayed zoledronate and found at 12 months BMD was higher in 'early' group versus 'delayed', both in the spine and hip. Mystakidou *et al.* (2005) conducted an RCT comparing

zoledronate with a control and found that the median bone metastases-free interval for zoledronate was significantly higher than with the control. Furthermore, there was a significant difference in favour of zoledronate in the bone-metastases-free interval at the 18 month follow up.

The following evidence based guideline was also used to inform the recommendation for the role of bisphosphonates 'Guidance for the management of breast cancer treatment induced bone loss: A consensus position statement from a UK Expert Group' Cancer Treatment Reviews *et al.* (2008). This guideline was appraised using the AGREE Instrument and rated as high quality. The evidence based approach was clearly conducted.

**PICO**

Population	Intervention	Comparison	Outcome
Patients with invasive breast cancer	Bisphosphonate treatment: Pamidronate, clodronate, ibandronate, zoledronate, risodronate, aledronate	No Bisphosphonate treatment	Bone Health Bone Mineral Density Recurrence Disease free survival Overall survival Patient Acceptability Quality of Life Cost Effectiveness

The search strategy developed from this PICO table and used to search the literature for this question can be found in Appendix A

**Evidence Summary**

There is strong evidence that bisphosphonates (pamidronate, zoledronate, risedronate ) prevent chemotherapy induced bone loss in early breast cancer patients although this evidence is inconclusive for clodronate. Some evidence from retrospective analysis of case series that alendronate favours improvement in BMD. Bone metastases were detected at the same frequency in intervention and control groups (clodronate) and some weak evidence suggest that patients administered zoledronic acid group fare better in short term. There is no evidence of improved disease free survival (pamidronate) or overall survival (with the exception of 1 trial that shows strong evidence of improved 5 year bone relapse free survival by using adjuvant clodronate for node positive patients). There is insufficient evidence supporting the efficacy of one bisphosphonate over the other. The studies included in the review have a relatively high degree of heterogeneity, due to the inclusion criteria and the patient population), the type and administration route of bisphosphonate.

**At risk of osteoporosis due to AI**

There is fairly strong evidence from a randomized, double blind, placebo controlled trial comparing Pamidronate 60mg iv every 3 months with placebo that IV pamidronate prevented chemotherapy-induced bone loss in young pre-menopausal women, was well tolerated, and is an attractive alternative in preserving skeletal health in such patients. The mean difference in percentage change in BMD at 12 months between the two treatment groups was 5.1% at the lumbar spine (p=0.002) in the overall study group and 5 % at lumbar spine and 5.2% at the total hip in the amenorrhoeic sub- group (p<0.03). [Fuleihan, G, *et al*, 2005]

Similarly, RCT of adjuvant clodronate treatment in node-positive breast cancer patients receiving adjuvant chemo- or endocrine therapy ± oral clodronate 1600mg daily for 3 years showed that within 10 years bone metastases were detected at the same frequency in the

clodronate and control groups: 44(32%) vs. 42(29%), respectively, ( $p=0.35$ ). 10 year DFS remained significantly lower in the clodronate group (45% vs. 58%,  $p=0.01$ , respectively). This was especially seen in oestrogen receptor negative patients (25% vs. 58%,  $p = 0.004$ , respectively). No significant overall survival difference was found between the groups. As previously reported 3-year adjuvant clodronate treatment did not prevent the development of bone metastases in node-positive breast cancer patients. A negative effect of clodronate on DFS by increasing the development of visceral metastases was still seen at 10 years, but this did not significantly compromise overall survival. [Saarto, T. *et al.* 2004]

There is some evidence from an RCT that zoledronic acid as adjuvant treatment might be useful for prevention of bone metastases; the percentage of patients being bone metastases free at 12 mo was 60% in the zoledronic acid and 10% in the control group ( $p < 0.0005$ ), while the percentages at 18 mo were 20% and 5% respectively ( $p = 0.0002$ ). [Mystakidou *et al.*, 2005]

There is strong evidence from an RCT patients starting letrozole (2.5 mg per day for 5 years) receiving upfront zoledronic acid versus delayed zoledronic acid (4 mg, IV, 6 months) that combining the anticancer efficacy of letrozole with the bone-protective effect of zoledronic acid is an effective way to prevent cancer treatment induced bone loss. Lumbar spine BMD in women receiving upfront zoledronic acid showed a mean increase of 1.55%, compared with a mean decrease of 1.78% in women receiving delayed zoledronic acid (an overall difference of 3.33% between groups). Total hip BMD in the upfront group showed a mean increase of 1.02%, whereas the delayed group showed a mean decrease of 1.40% (an overall difference of 2.42% between groups). [Brufsky, A 2006]

There is inconclusive evidence from a small RCT investigating the effect of seven cycles IV intermittent 1500mg clodronate during adjuvant chemotherapy in prevention chemotherapy induced bone loss that clodronate treatment did not seem to prevent clinically significantly the bone loss related to chemotherapy-induced ovarian failure in pre-menopausal women with early stage breast cancer. The reported mean bone loss in the lumbar spine at 6 months was -0.5% in the clodronate group and 1.4% in the control group ( $p = 0.22$ ) and at 12 months, -3.9% and 3.6%, respectively ( $p=0.62$ ). [Vehmanen, L. *et al.*, 2004]

There is some evidence from a retrospective case series of 48 patients treated with cyclic etidronate disodium (400mg/day for 14 days); alendronate 10mg/day) concomitant with chemotherapy that oral daily alendronate treatment was associated with significantly greater improvements in lumbar spine bone density than use of cyclic etidronate or calcium and vitamin D alone. BMD increases were significantly greater in patients with prevalent vertebral fractures (VF) compared to those without VF ( $P = 0.025$ ). In contrast, time since diagnosis of breast cancer was significantly associated with a decrease in BMD ( $P = 0.002$ ). [Sawka, A. M. *et al.*, 2005]

There is fair evidence from an unsystematic review of trials of clodronate and zoledronic acid in the prevention of bone loss of localized breast cancer patients with chemotherapy-induced ovarian failure that clodronate was compatible with adjuvant chemotherapy. The main toxicity with this bisphosphonate was diarrhoea, experienced by 27% of patients in the clodronate group and 8% in the placebo group ( $P \leq 0.001$ ). Zoledronic acid, a third-generation bisphosphonate, is a more potent inhibitor of osteoclasts than first- and second-generation agents, and does not have a strong impact of bone mineralization. This agent has been shown to be effective in the treatment of tumour-induced hypercalcemia at doses of 0.5-3.0 mg. [Anon, 2005]

A further unsystematic review shows that oral clodronate (1,600 mg/d) is effective for treatment of patients with chemotherapy-induced bone loss. When used as adjuvant therapy,

given to patients with operable breast cancer for 2 years, clodronate has been reported to reduce the risk of bone metastases during the 2-year study period [19 clodronate patients versus 35 placebo patients; hazard ratio (HR), 0.546; P = 0.03] and 5-year study period (51 clodronate patients versus 73 placebo patients; HR. 0.692; P = 0.04) with a significant reduction in mortality (HR. 0.768; P = 0.048). This benefit, together with the low toxicity and safety of clodronate, supports its use as additional adjuvant therapy for patients with primary breast cancer. [Powles, T. et al., 2006 (2)]

### **Made menopausal by treatment for BC**

There is strong evidence from a systematic review that bisphosphonates are useful for preventing bone loss resulting from cancer or its therapy. The efficacy of bisphosphonates for early-stage breast cancers remains controversial. Significant risks of bisphosphonate therapy include nephrotoxicity, electrolyte abnormalities, and osteonecrosis of the jaw. Bisphosphonate therapy has a clear role in the management of skeletal metastases. However, significant side effects require ongoing monitoring and treatment.[Wu, S. et al, 2007]

This is confirmed by further evidence from a fairly large RCT set up to determine whether risedronate, 35 mg/wk is efficacious and safe in preventing bone loss associated with chemotherapy-induced menopause. Risedronate 35 mg/wk prevented bone loss and reduced bone turnover in women with breast cancer treated with chemotherapy. Early measures to prevent bone loss should be considered in this cohort of breast cancer survivors [Greenspan SL, et al, 2007]

There is fair evidence from the ASCO 2003 guidelines on the role of bisphosphonates in bone health issues in women with breast cancer that bisphosphonates provide a supportive, albeit expensive and non-life-prolonging, benefit to many patients with bone metastases. For patients with plain radiographic evidence of bone destruction, intravenous pamidronate 90 mg delivered over 2 hours or zoledronic acid 4 mg over 15 minutes every 3 to 4 weeks is recommended. There is insufficient evidence supporting the efficacy of one bisphosphonate over the other. Starting bisphosphonates in women who demonstrate bone destruction through imaging but who have normal plain radiographs is considered reasonable treatment. Starting bisphosphonates in women with only an abnormal bone scan but without evidence of bone destruction is not recommended. The presence or absence of bone pain should not be a factor in initiating bisphosphonates. [Hillner, B. E., et al. 2003]

### **Treatment in itself for BC**

A meta-analysis of randomised clinical trials that investigating overall, bone metastasis-free or non-skeletal metastasis free survival among breast cancer patients receiving oral clodronate 1600mg/day given for either 2 or 3 years compared with an identical placebo or no treatment, found no evidence of any statistically significant difference in overall survival or non-skeletal metastasis-free survival in early breast cancer patients receiving adjuvant clodronate treatment compared with those who did not receive any active treatment. Potential limitations exist because of the availability, quality and heterogeneity of the published data.[Ha, T. & Li, H., 2007]

There is some evidence from a systematic review of the use of bisphosphonates in treatment for breast cancer that clodronate does not significantly reduce the risk of developing skeletal metastases and there is inconclusive evidence that bisphosphonates affect survival rates. [Pavlakis, N., et al., 2006]

There is strong evidence from an RCT study of bone loss associated with adjuvant endocrine therapy in pre-menopausal women, comparing goserelin (3.6 mg every 28 days, SC) plus tamoxifen (20mg/d, orally) ± zoledronic acid (4mg every 6 months, IV) versus goserelin (3.6 mg every 28 days, SC) plus anastrozole (1mg/d, orally) ± zoledronic acid (4mg every 6 months, IV) in 401 breast cancer patients (grade 1-3) that regular BMD measurements and initiation of concomitant bisphosphonate therapy on evidence of bone loss should be considered for patients undergoing endocrine therapy. Endocrine therapy caused significant bone loss that increased with treatment duration in pre-menopausal women with breast cancer. Zoledronic acid (4mg/6months) effectively inhibited bone loss. [Gnant, M.F, *et al*, 2007]

There is strong evidence from an RCT in which patients received letrozole 2.5mg orally daily for 5 years or until disease progression and were randomly assigned to upfront or delayed zoledronic acid 4 mg IV over 15 minutes every 6 months for 5 years that upfront zoledronic acid therapy prevents bone loss in the LS in postmenopausal women receiving adjuvant letrozole for early-stage breast cancer. At month 12, LS BMD was 4.4% higher in the upfront group than in the delayed group (95% CI, 3.7% to 5.0%; P<.0001), and TH BMD was 3.3% higher (95%CL, 2.8% to 3.8%; P<.0001). [Brufsky, A., *et.al* 2007]

There is strong evidence form an RCT designed to determine if the addition of oral clodronate 1,600 mg/day for 2 years to standard treatment for primary operable breast cancer could reduce the subsequent occurrence of bone metastases and thereby reprove overall survival, that oral clodronate will significantly improve the 5 year bone relapse free survival. Survival data also favoured the clodronate arm. Oral clodronate was well tolerated, with mild-to-moderate diarrhoea being the most frequently reported adverse event.[Powles, T. *et al*, 2006]

## Evidence Tables

<b>Study Identification:</b>	Anonymous report, Phase 3 Trial of Intravenous Zoledronic Acid in the Prevention of Bone Loss in Localized Breast Cancer Patients With Chemotherapy-Induced Ovarian Failure, Clinical Advanced in Haematology & Oncology, vol. 3:2, Feb. 2005
<b>Design:</b>	Unsystematic review of RCTs, evidence level 4
<b>Country /Setting:</b>	International
<b>Population:</b>	Breast Cancer Patients with Chemotherapy-Induced Ovarian Failure
<b>Intervention:</b>	RCT's randomizing to: adjuvant systemic therapy (chemotherapy and/or tamoxifen) receiving 1,600mg/day of clodronate or placebo; zoledronic acid
<b>Outcomes:</b>	Bone Mineral Density
<b>Follow-up:</b>	2 years
<b>Results:</b>	<p>Clodronate was compatible with adjuvant chemotherapy. The main toxicity with this bisphosphonate was diarrhoea, experienced by 27% of patients in the clodronate group and 8% in the placebo group (P≤.0001).</p> <p>Zoledronic acid, a third-generation bisphosphonate, is a more potent inhibitor of osteoclasts than first- and second-generation agents, and does not have a strong impact of bone mineralization. This agent has been shown to be effective in the treatment of tumour-induced hypercalcemia at doses of 0.5-3.0 mg.</p> <p><b>Bone mineral density-</b> The mean percentage difference in bone mineral density (BMD) of the total spine and total hip for the clodronate group versus the placebo group at 1 year was +2.38% (95% confidence interval [CI] 1.36-34.1, P&lt;.001) and +1.72% at 2 years (95% CI 0.51-3.34, P=.04). The mean percentage BMD difference in the total hip for the clodronate group versus the placebo group at 1 year was +0.74% (95% CI 0.13-1.60, P=.09) and +1.85% at 2 years (95% CI 0.51-3.20, P=.008).</p>
<b>General comments:</b>	-

<b>Study Identification</b>	Atula, S., Powles, T., Paterson, A., McCloskey, E - Extended safety profile of oral clodronate after long-term use in primary breast cancer patients, Drug Safety, 2003, 26:9, pp. 661-671
<b>Design:</b>	RCT; evidence level 1+
<b>Country Setting:</b> /	USA, hospital setting
<b>Population:</b>	1079 patients with histologically or cytologically confirmed operable primary breast cancer with no evidence of metastases, significant renal or hepatic impairment, or non-malignant bone disease
<b>Intervention:</b>	randomised, double-blind, placebo- controlled, multicentre study, patients randomised to receive oral clodronate 1600 mg/day or placebo for 2 years, (4X 400mg capsules in the morning without food or 2X 400mg capsules twice daily without food depending on the tolerability)in addition to normal therapy regimen for the primary breast cancer including local (surgery, either resection or mastectomy, and radiotherapy) and systemic (chemotherapy, endocrine therapy) treatments.
<b>Outcomes:</b>	AEs, SAEs.
<b>Follow-up:</b>	total median treatment period plus follow-up was 5.5 years.
<b>Results:</b>	<p>In women with early breast cancer receiving adjuvant systemic therapy, oral clodronate for 2 years is generally well tolerated with no serious long-term sequelae, providing a safe, long-term therapy in the adjuvant setting.</p> <p>Overall incidence of AE (96.5% of the patients) was the same in both treatment groups, although gastrointestinal disorders were significantly more frequent in the clodronate group during the total study period (66% vs 56.2%; 95% CI 4.0—15.6; <math>p &lt; 0.05</math>). SAE were reported for 39.4% of the patients receiving clodronate and 44.5% of those receiving placebo; no drug-related (clodronate or placebo) SAE were identified.</p> <p>Clodronate significantly lowered mortality (98 deaths vs. 129 deaths; hazard ratio (1.77; 95% CI 0.59—1.00: <math>p = 0.047</math>) reducing the risk of death over the total study period by 23%. AEs caused 58 early discontinuations (five drug-related events) in the clodronate group and 43 discontinuations (three drug-related events) in the placebo group.</p> <p><b>Overall survival</b>— A total of 227 patients died (during the study (medication period 10 vs. follow-up period 217): 98 (18.5%) in the clodronate group and 129(23.9%) in the placebo group, including 188 deaths due to the underlying malignancy (clodronate group 83 vs. placebo group 105). As regards non-breast cancer deaths (clodronate group 15 vs placebo group 24). Pneumonia, secondary neoplasms and vascular events were the most common causes, five of them occurring during the medication period (clodronate group 3 vs. placebo group 2). The mortality rate was significantly lower in the clodronate group (<math>p = 0.047</math>), with a hazard ratio of 0.77 (95% CI 0.59-1.00) indicating a 23% reduction in the overall risk of death during the total study time.</p> <p><b>Patient acceptability</b> – A total of 1041 patients (96.5%) experienced AEs with a similar overall incidence in both treatment groups: AEs were reported for 519 patients (96.5%) in the clodronate group and 522 patients (96.5%) in the placebo group. Of those patients with reported AEs, severe AEs were reported for 248 patients (47.8%) in the clodronate group and 262 patients (50.2%) in the placebo group. Moderate AEs were reported for 225 patients (43.4%) in the clodronate group and for 215 patients (41.2%) in the placebo group. For the rest of the patients, AEs were either mild or their nature was not recorded (five patients).</p>

When the occurrence of AEs by System Organ Class was assessed, GI system disorders were significantly more common in the clodronate group, particularly during the medication period. In contrast, skin and appendage disorders and red blood cell disorders were significantly more frequent in the placebo group, the difference was seen both on and off medication. There were no significant differences between the treatment groups as regards any other SOCs. Interestingly, no renal toxicity was observed for clodronate based on the equal distribution of urinary tract disorders for the treatment groups during both the medication period and the off medication period.

A total of 747 SAEs (clodronate group 355 vs placebo group 392) were reported for 453 patients during the study (clodronate group 212 [39.4%] vs placebo group 241 [44.5%]). The number of patients with SAE was equally distributed between the treatment groups when evaluated by SOCs (table 111), nor was an imbalance evident when SAEs affecting the 01 system were compared. Moreover, there were statistically significant differences between the treatment groups as shown by the 95% CIs for the most frequent preferred terms.

<b>Study Identification</b>	Brufsky, A., Management of Cancer-Treatment-Induced Bone Loss in Postmenopausal Women Undergoing Adjuvant Breast Cancer Therapy, Seminars in Oncology 33(suppl 7):S13-S17 2006
<b>Design:</b>	RCT; evidence level 1+
<b>Country Setting:</b> /	USA, hospital setting
<b>Population:</b>	Post-menopausal women (n = 602) with stage 1-3a estrogen-receptor-positive and/or progesterone-receptor-positive breast cancer
<b>Intervention:</b>	RCT; patients starting letrozole (2.5 mg per day for 5 years) receiving upfront zoledronic acid versus delayed zoledronic acid (4 mg intravenous infusion every 6 months).
<b>Outcomes:</b>	BMD
<b>Follow-up:</b>	12 months
<b>Results:</b>	<p>Combining the anticancer efficacy of letrozole with the bone-protective effect of zoledronic acid is an effective way to prevent cancer treatment induced bone loss.</p> <p><b>Bone mineral density-</b> BMD values were available for 415 women. Lumbar spine BMD in women receiving upfront zoledronic acid showed a mean increase of 1.55%, compared with a mean decrease of 1.78% in women receiving delayed zoledronic acid (act overall difference of 3.33% between groups). Total hip BMD in the upfront group showed a mean increase of 1.02%, whereas the delayed group showed a mean decrease of 1.40% (an overall difference of 2.42% between groups).</p>

<b>Study Identification</b>	Brufsky, A, Harker, W.G., Beck, J.T. - Zoledronic acid inhibits adjuvant letrozole-induced bone loss in postmenopausal women with early breast cancer, Journal of Clinical Oncology, 2007, 25, 7, pp. 829-836.																																																						
<b>Design:</b>	RCT; evidence level 1+																																																						
<b>Country/ Setting:</b>	USA, hospital setting																																																						
	<p>The study included postmenopausal women from 94 Us and Canadian community-based centres who had a history of surgically respectable stage 1, 2, or 3A, estrogen receptor-positive and/or progesterone receptor-positive breast cancer; a baseline Eastern Cooperative Oncology Group performance status of <math>\leq 2</math>; and baseline lumbar spine (LS) and total hip (TH) T scores <math>\geq -2.0</math>. All patients underwent tumour resection, completed chemotherapy and/or radiation therapy within 12 weeks of study entry, and had no evidence of residual disease. Patients were excluded if they had clinical or radiologic evidence of distant metastases, an existing LS or TH fracture, or a history of low-intensity fractures. Patients were also excluded if they had received: letrozole or other adjuvant hormone therapy; endocrine therapy; intravenous (IV) bisphosphonates or prolonged systemic corticosteroids within the previous 12 months; growth hormone, anabolic steroids, or tibolone within the previous 6 months; or teriparatide or systemic sodium fluoride. The use of any other drug known to affect the skeleton was prohibited 2 weeks before and throughout the study. Patients who reported receiving oral bisphosphonates or hormone replacement therapy discontinued use before study entry. Patients with renal dysfunction, other malignancies, and diseases known to influence bone metabolism were excluded.</p>

<b>Intervention:</b>	Randomised study; patients received letrozole 2.5mg orally daily for 5 years or until disease progression and were randomly assigned to upfront or delayed zoledronic acid 4 mg IV over 15 minutes every 6 months for 5 years. The upfront group received zoledronic acid after random assignment, whereas the delayed group received zoledronic acid when either post baseline LS or TH T score decreased to less than -2.0 or a nontraumatic clinical fracture occurred. Patients were instructed to take an oral calcium supplement (1,000 to 1,200mg) and a multivitamin tablet containing vitamin D (400 to 800 U) once daily during the study. Patients were stratified according to adjuvant chemotherapy (yes v no) and baseline T score (normal [T score > -1.0 and -2.0] v mild to moderate osteopenia [T score between -1.0 and -2.0]). The definitions for normal BMD, osteopenia, and osteoporosis were modelled after the WHO osteoporosis guidelines.				
<b>Outcomes:</b>	BMD, Fractures, Markers of bone turnover, Safety				
<b>Follow-up:</b>	1 year				

**Results:**

Upfront zoledronic acid therapy prevents bone loss in the LS in postmenopausal women receiving adjuvant letrozole for early-stage breast cancer. At month 12, LS BMD was 4.4% higher in the upfront group than in the delayed group (95% CI, 3.7% to 5.0%;  $P < .0001$ ), and TH BMD was 3.3% higher (95%CL, 2.8% to 3.8%;  $P < .0001$ ). In the upfront group, mean serum N-telopeptide and bone-specific alkaline phosphatase concentrations decreased by 15.1% ( $P < .0001$ ) and 8.8% ( $P = .0006$ ), respectively, at month 12, whereas concentration increased significantly in the delayed group by 19.9% ( $P = .013$ ) and 24.3% ( $P < .0001$ ), respectively.

**Bone health (subsequent fractures, etc)** – At month 12, no- or low-trauma fractures occurred in 1% of patients in the upfront group and 0.7% of patients in the delayed group. Traumatic fractures occurred in 2.3% and 2% of patients in the upfront and delayed groups, respectively.

**Bone mineral density:** At month 12, the mean percent difference in BMD between the groups was 4.4% for LS (95% CI, 3.7% to 5.0%;  $P < .0001$ ) and 3.3% for TH (95% CI, 2.8% to 3.8%;  $P < .0001$ ). The risk of developing severe osteopenia within the first year of A1 therapy may be significant in a small percentage of postmenopausal women. In the delayed group, 12.6% of patients with normal baseline BMD developed mild to moderate osteopenia by month 12, and 14.8% of patients with baseline mild to moderate osteopenia progressed to severe osteopenia. However, in the upfront group, only 3.4% of patients with normal baseline BMD developed osteopenia by month 12, and 1.4% of patients with baseline mild to moderate osteopenia progressed to severe osteopenia.

Baseline and Month 12 BMD	Upfront Group		Delayed group	
	n	%	n	%
<b>Normal Baseline BMD</b>	203		198	
Month 12 BMD				
Normal	175	86.2	152	76.8
Mild to moderate osteopenia, T score $\leq -1$ to $\geq 2$	7	3.4	25	12.6
Severe osteopenia, T score $< -2$	0	0	0	0
Invalid data	21	10.3	21	10.6
<b>Osteopenia at baseline</b>	70		81	
Month 12 BMD				
Normal	18	25.7	8	9.9
Mild to moderate osteopenia, T score $\leq -1$ to $\geq 2$	44	62.9	54	66.7
Severe osteopenia, T score $< -2$	1	1.4	12	14.8
Invalid data	7	10	7	8.6

**Patient acceptability**– The safety analysis consisted of 300 patients in both groups. The occurrence of AEs was similar between the groups with the exception of bone pain, which was higher in the upfront zoledronic acid group compared with the delayed group (11.3% v 4%, respectively), as expected. Neither group experienced grade 3 or 4 renal dysfunction; one patient in the upfront group experienced a grade 1 increase in serum creatinine level. Osteonecrosis of the jaw (ONJ) was not reported in either group. Serious AEs occurred in 16.7% and 18.7% of patients in the upfront and delayed groups, respectively. Seven percent of patients in the upfront group and 9.7% of patients in the delayed group withdrew from the study as a result of AEs; 1.3% and 1% of patients in the upfront and delayed groups, respectively, discontinued therapy because of serious AEs.

**General comments:**

small sample size (n=40)

<b>Population:</b>	patients with tumour induced bone disease
<b>Intervention:</b>	Trials of bisphosphonates
<b>Outcomes:</b>	Vertebral fractures, non-vertebral fractures
<b>Follow-up:</b>	Not applicable
<b>Results:</b>	<p>Taken together, oral bisphosphonates are highly efficacious in patients with established osteoporosis, particularly in those with existing fractures or at high risk of fracture. By contrast, patients with a low risk of fracture or those determined by the risk of falling do not seem to benefit from anti-resorptive drugs in the same way as do high risk patients.</p> <p><b>Bone health (subsequent fractures, etc):</b> When alendronate and risedronate are given over a period of 3 years to women with prevalent osteoporotic fractures, a significant risk reduction of new vertebral fractures (47% and 49%, respectively) was seen compared with the placebo group. The effect on vertebral fracture risk can occur as early as 6 months into treatment and is commonly explained by the rapid action of bisphosphonates on bone remodelling and on micro-architecture.</p> <p>Newer studies indicate similar effects of oral ibandronate on vertebral fracture risk, with the advantage of wider (i.e. monthly rather than weekly) dosing intervals.</p> <p>The effect of oral bisphosphonates on non- vertebral fractures is less consistent, particularly with regard to 'hip' fractures, some studies have shown no effect, while others have revealed a significant effect on non-vertebral fractures.</p>
<b>General comments:</b>	

<b>Study Identification</b>	Fuleihan, G., Salamound, M., Mourad, Y.A. – Pamidronate in the prevention of chemotherapy-induced bone loss in pre-menopausal women with breast cancer: a randomized controlled trial, The Journal of clinical endocrinology and metabolism, 2005, 90,6, pp. 3209-3214

<b>Intervention:</b>	Randomized, double blind, placebo controlled trial comparing Pamidronate 60mg iv every 3 months with placebo. Most patients (>80%) were prescribed a 5-FU, adriamycin, cyclophosphamide (FAC) regimen, 10% a cytophophamide, methotrexate, 5-FU (CMF) regimen, and 10-15% an anthracyclin (adriamycin or epirubicin) and cyclophosphamide (FAC0like) regimen. Over two thirds were also started on tamoxifen at completion of the chemotherapy at a dose of 20mg/d for a duration of 5 yr. This treatment was equally balanced between the two arms at study entry and by development of amenorrhea.				
<b>Outcomes:</b>	Bone mineral density of the spine (L1-L4) and the hip and total body BMD, content, and body composition were performed at 0, 6, and 12 months using dual-energy x-ray absorptiometry.; remodelling markers				
<b>Follow-up:</b>	2 ± 0.8 years in the placebo arm, 1.9 ± 0.8 years in the Pamidronate arm (p=0.8)				
<b>Results:</b>	<p>IV Pamidronate given at the dose of 60mg every 3 months prevented chemotherapy-induced bone loss in young pre-menopausal women, was well tolerated, and is an attractive alternative in preserving skeletal health in such patients. The mean difference in percentage change in BMD at 12 months between the two treatment groups was 5.1% at the lumbar spine (p=0.002) in the overall study group and 5 % at lumbar spine and 5.2% at the total hip in the amenorrheic sub- group (p&lt;0.03).</p> <p><b>Bone mineral density:</b></p> <p>BMD stabilized at the lumbar spine in the Pamidronate group and decreased in the placebo group, with a significant treatment effect at both the 6- and 12-month time points. Although the trend was similar at the total hip, a significant treatment effect was not achieved. Over half of the patients became amenorrheic during the study, with no differences between the two treatment arms.</p> <p>Amenorrheic group.</p> <p>BMD stabilized at the lumbar spine in the Pamidronate group and decreased in the placebo group, with a significant treatment effect at both the 6- and 12-month time points. Similarly, at the total hip, BMD stabilized in the Pamidronate group and decreased in the placebo group, with a treatment effect noted at 12 months and an almost significant effect at 6 months.</p> <p>Non amenorrheic group.</p> <p>There were no differences in percent change in BMD at either the lumbar spine or the total hip by treatment group at either time point in the nonamenorrheic subgroup (P= 0.15 at the lumbar spine; P= 0.81 at the hip at 12 months).</p>

	L1-L4	1.058		1.028		1.038		1.002	
	Trochanter	0.712		0.707		0.728		0.704	

**Intervention:** Study of bone loss associated with adjuvant endocrine therapy in pre-menopausal women: goserelin (3.6 mg every 28 days, SC) plus tamoxifen (20mg/d, orally) ± zoledronic acid (4mg every 6 months, IV) versus goserelin (3.6 mg every 28 days, SC) plus anastrozole (1mg/d, orally) ± zoledronic acid (4mg every 6 months, IV) for 3 years

**Outcomes:** Bone mineral density (does zoledronic acid prevent bone loss in the intervention group); assessed by bone densitometry of lumbar spine and trochanter by dual energy x-ray absorptiometry at baseline, 6 months, 12 months and 36 months.

**Follow-up:** 36 months

**Results:**  
Endocrine therapy caused significant bone loss that increased with treatment duration in pre-menopausal women with breast cancer. Zoledronic acid (4mg/6months) effectively inhibited bone loss. Regular BMD measurements and initiation of concomitant bisphosphonate therapy on evidence of bone loss should be considered for patients undergoing endocrine therapy.

**Bone mineral density:**

Endocrine treatment without zoledronic acid led to significant (p<0.001) overall bone loss after 3 years of treatment (BMD – 14.4% after 36 months; mean T score reduction, - 1.4). Overall bone loss was significant more severe in patients receiving anastrozole/goserelin (BMD – 17.3%; mean T score reduction, - 2.6) compared with patients receiving tamoxifen/goserelin (BMD – 11.6%; mean T score reduction, - 1.1). In contrast BMD remained stable in zoledronic acid treated patients (p<0.0001 compared with endocrine therapy alone). No interaction with age or other risk factors were noted.

Characteristic	Tamoxifen alone (n=103)	Tamoxifen+ Zoledronic acid (=100)	Anastrozole alone (n=94)	Anastrozole + Zoledronic acid (=104)
BMD measurements	n	n	n	n
Baseline n=343	82	87	79	95
6 months n=331	80	89	75	87
12 months n=318	78	83	73	84
36 months n=114	26	26	25	37

**Patient acceptability** – the combination of zoledronic acid with endocrine therapy was well tolerated.

The most common AE reported were consistent with the known toxicity profiles of each drug. Specifically patients treated with tamoxifen reported a greater frequent cy of hot flashes and vaginal bleeding whereas patients treated with anastrozole reported a greater frequency of musculoskeletal

disorders. Administration of zoledronic acid was associated with the infusion-related flu-like symptoms common to all IV bisphosphonates (nausea, vomiting, fever and myalgia).

These events were mild to moderate in intensity and were primarily limited to the first infusion of the drug. Importantly, there was no evidence of additive toxicity between zoledronic acid and either goserelin/anastrozole or goserelin/tamoxifen.

No fractures or other skeletal-related events were recorded in this trial. Finally, administration of zoledronic acid was not associated with changes in renal function in this patient population. Across a total of 2,904 serum creatinine measurements over 3 years, mean serum creatinine level was  $0.78 \pm 0.17$  mg/dL, and no patient had a serum creatinine value greater than 1.5x the upper limit of normal. No cases of jaw osteonecrosis were reported in this trial.

**General comments: -**

<b>Study Identification</b>	Greenspan, SL., Bhattacharya, R.K., Sereika, SM, et al - Prevention of Bone Loss in Survivors of Breast Cancer: A Randomized, Double-Blind, Placebo-Controlled Clinical Trial, The Journal of Clinical Endocrinology & Metabolism 52(1):151—126, 2007
<b>Design:</b>	RCT; evidence level 1+
<b>Country/ Setting:</b>	USA, hospital setting
<b>Population:</b>	87 breast cancer women newly postmenopausal (up to 8 yr) after being treated with chemotherapy with or without tamoxifen or aromatase inhibitors. Exclusion criteria: stage 4 breast cancer (presence of distant metastases), a history of any illness known to affect bone and mineral metabolism (renal failure or hepatic failure), malignancy (excluding breast cancer), hyperparathyroidism, and mal absorption. Women were allowed to begin or continue with tamoxifen or an aromatase inhibitor if prescribed by their physician. Participants who had been treated with other medications known to affect bone and mineral metabolism were excluded. Women with an adult fragility fracture or with an initial BMD T-score of -2.5 or below at the hip or spine were counselled about therapy but given the option to participate in the study.
<b>Intervention:</b>	RCT of risedronate received 35mg/wk or placebo to establish effect on bone loss in newly post menopausal women with breast cancer treated with chemotherapy with or without concomitant use of tamoxifen or AI.
<b>Outcomes:</b>	BMD was measured at the spine (PA and lateral projections), hip (femoral neck, total hip, trochanter, and inter trochanter), one-third distal radius, and total body by dual-energy x-ray absorptiometry.
<b>Follow-up:</b>	12 months
<b>Results:</b>	<p>Risedronate, 35 mg/wk is efficacious and safe in preventing bone loss associated with chemotherapy-induced menopause. Risedronate 35 mg/wk prevented bone loss and reduced bone turnover in women with breast cancer treated with chemotherapy. Early measures to prevent bone loss should be considered in this cohort of breast cancer survivors.</p> <p>After 12 months, bone mineral density increased by 1.2% at the spine and 1.3% at the hip in women on risedronate vs. significant decreases for women in the placebo group of 0.9% at the spine and 0.8% at the hip (<math>P &lt; 0.01</math>, difference between groups). N-telopeptide cross-linked collagen type I, a marker of bone resorption, decreased by 19.3%, and N-terminal propeptide of type I procollagen, a marker of bone formation, decreased by 26.6% in participants on active therapy compared with increases in the control group. Risedronate was well tolerated, and the retention rate was 95% at 1 yr.</p> <p><b>Bone health (subsequent fractures, etc)</b> - Two fractures; no difference between the groups</p> <p><b>Bone mineral density-</b> After 1 yr BMD in the spine increased by <math>1.2 \pm 0.5\%</math> in participants treated with risedronate and decreased by <math>0.9 \pm 0.5\%</math> in the placebo group (<math>P &lt; 0.01</math>, difference between groups at 12 months)</p> <p>Total hip BMD increased <math>1.3 \pm 0.3\%</math> in women on risedronate therapy and decreased <math>0.8 \pm 0.3\%</math> in those who received placebo (<math>P &lt; 0.001</math>, difference between groups at 6 and 12 months)</p> <p>Similar trends were observed in the lateral spine and trochanter.</p> <p>At the distal radius and total body, BMD remained stable in the treatment group but decreased in the placebo group (<math>0.8 \pm 0.4</math> and <math>0.8 \pm 0.3\%</math>, respectively, both differences between groups, <math>P &lt; 0.05</math>).</p>

When the rates of change in BMD were adjusted for baseline bone turnover markers (individually as well as simultaneously), similar results were found.

BMD changes at the spine, hip, and all other skeletal sites for women on tamoxifen and risedronate were similar to changes for women on risedronate alone. (approximately 70% in each group were on tamoxifen at baseline and 31% at 12 months) However, in the placebo group, the rate of change for total hip BMD was  $1.2 \pm 0.05\%$  greater ( $P < 0.05$ ) in women on tamoxifen compared with those who were not .

There were no significant differences in the PA spine between those on or off tamoxifen in the placebo group.

At baseline, 18.6% of participants were on an AI in the treated group, and 13.6% of participants were on an AI in the placebo group. During the first year this increased to 39.5% of women on an aromatase inhibitor in the risedronate group and 34.1% in the placebo group. There was a marginally significant treatment effect (less improvement) at the PA spine for women on an aromatase inhibitor ( $P < 0.10$ ); no significant effect was observed at other skeletal sites.

**Recurrence** – Two patients; no difference between the groups

**Patient acceptability** – The tolerability profile of risedronate was similar to that of placebo. There were no differences between the groups in the number of women who reported heartburn, epigastric distress, arthralgias, myalgias, or other adverse events.

**General comments:** -

<b>Study Identification:</b>	Ha, T. C. & Li, H., Meta-analysis of clodronate and breast cancer survival, British Journal of Cancer, 2007, 96:12, p.1796-1801
<b>Design:</b>	Meta-analysis evidence level 1+
<b>Country/ Setting:</b>	International
<b>Population:</b>	Participants were patients with histologic- or cytologic-proven breast cancer but no prior history of other malignant diseases (besides recurrent breast cancer) or bisphosphonate usage. Early breast cancer was defined as patients who were diagnosed with primary operable breast cancer.
<b>Intervention:</b>	Trials included randomised clinical trials that investigated overall, bone metastasis-free or non-skeletal metastasis free survival among breast cancer patients receiving oral clodronate 1600mg/day given for either 2 or 3 years compared with an identical placebo or no treatment.
<b>Outcomes:</b>	Outcome measures included for 5-year overall, bone metastasis-free and non-skeletal metastasis free survival.
<b>Follow-up:</b>	Not applicable
<p><b>Results:</b>  The meta-analysis found no evidence of any statistically significant difference in overall survival or non-skeletal metastasis-free survival in early breast cancer patients receiving adjuvant clodronate treatment compared with those who did not receive any active treatment.</p> <p><b>Disease-free survival</b> – There was no evidence to suggest that clodronate therapy improves overall, non-skeletal metastasis free survival or bone metastasis-free survival significantly in either group of patients.  Pooled analysis did not find any statistically significant difference in the time to appearance of bone metastasis in patients who received adjuvant clodronate treatment compared with those who did not (HR=0.60, 95% CI=0.30, 1.23).  No statistically significant delay in the occurrence of non-skeletal metastases between patients receiving adjuvant clodronate therapy and those receiving no treatment (HR=0.99, 95% CI=0.40, 1.99).</p> <p><b>Overall survival</b>–The pooled results demonstrated no statistically significant difference in the overall survival between patients treated with adjuvant clodronate therapy and those receiving no treatment (HR=0.75, 95% CI=0.31, 1.02).</p>	
<p><b>General comments:</b> Potential limitations exist because of the availability, quality and heterogeneity of the published data.</p>	

<b>Study Identification:</b>	Hillner, B. E., Ingle, J. N., Chlebowski, R. T., Gralow, J., Gary C. Yee, G. C., Janjan, N. A., Cauley, J. A., Blumenstein, B. A., Albain, K. S., Lipton, A. and Brown, S. American Society of Clinical Oncology 2003 Update on the Role of Bisphosphonates and Bone Health Issues in Women With Breast Cancer, Journal of Clinical Oncology, 2003, 21:21, p. 4042-4057
<b>Design:</b>	guideline evidence level 4
<b>Country / Setting:</b>	USA
<b>Population:</b>	-
<b>Intervention:</b>	Update to 2000 ASCO guidelines on role of bisphosphonates in women with breast cancer and address the subject of bone health in these women.
<b>Outcomes:</b>	BMD
<b>Follow-up:</b>	n/a
<p><b>Results:</b>  Bisphosphonates provide a supportive, albeit expensive and non-life-prolonging, benefit to many patients with bone metastases.  For patients with plain radiographic evidence of bone destruction, intravenous pamidronate 90 mg delivered over 2 hours or zoledronic acid 4 mg over 15 minutes every 3 to 4 weeks is recommended. There is insufficient evidence supporting the efficacy of one bisphosphonate over the other. Starting bisphosphonates in women who demonstrate bone destruction through imaging but who have normal plain radiographs is considered reasonable treatment. Starting bisphosphonates in women with only an abnormal bone scan but without evidence of bone destruction is not recommended. The presence or absence of bone pain should not be a factor in initiating bisphosphonates.</p> <p><b>Bone mineral density-</b> Oral bisphosphonates are one of several potential options that can be used for preservation of bone density in pre-menopausal women with treatment-induced (usually secondary to chemotherapy) menopause.</p> <p><b>General comments:</b> the evidence level of the guideline is also compromised by the review of outdated trials which provide inconclusive evidence.</p>	

<b>Study Identification:</b>	Pavlakakis, N., Schmidt, R. L., & Stockler, M., Bisphosphonates for breast cancer, The Cochrane Library, 2006, (1): CD003474, 1, p. CD003474
<b>Design:</b>	systematic review of RCTs evidence level 1++
<b>Country / Setting:</b>	international
<b>Population:</b>	Randomised studies comparing bisphosphonates and placebo, or different bisphosphonates in women with metastatic breast cancer.
<b>Intervention:</b>	Three RCTs examining the effect of oral bisphosphonate, clodronate, on the development of bone metastases or skeletal events in 1670 women with early breast cancer.
<b>Outcomes:</b>	Risk of developing skeletal metastases; survival
<b>Follow-up:</b>	Not applicable
<b>Results:</b>	
Clodronate does not significantly reduce the risk of developing skeletal metastases and there is inconclusive evidence that bisphosphonates affect survival rates.	
<b>Bone health (subsequent fractures, etc)</b> - Updated fixed effects meta-analysis of three studies that included 162 events among 1653 women indicates that adjuvant oral clodronate does not significantly reduce the risk of developing skeletal metastases (RR 0.82; 95% CI 0.66 to 1.01; P = 0.07). However, there is significant heterogeneity among these three studies.	
<b>Overall survival</b> – Treatment with bisphosphonates does not appear to significantly affect survival in women with early breast cancer.	
<b>General comments:</b> This review is focusing on trials of bisphosphonates in advanced breast cancer and only three trials of early breast cancer have been included. Also, the three trials have a high degree of heterogeneity and therefore the findings are inconclusive.	

<b>Study Identification</b>	Powles, T., Paterson, A., McCloskey, E., Schein, P. - Reduction in bone relapse and improved survival with oral clodronate for adjuvant treatment of operable breast cancer, Breast Cancer Research, 2006, vol 8:2, p.R13
<b>Design:</b>	RCT; evidence level 1+
<b>Country/Setting:</b>	UK, hospital setting
<b>Population:</b>	(N=1069) with histologically or cytologically confirmed primary operable breast cancer with no evidence of metastasis; Primary treatment consisted of surgery and/or radiotherapy with or without systemic endocrine therapy and/or chemotherapy. Exclusion criteria: significant renal, hepatic, or non-malignant bone disease; a history of malignant disease or prior bisphosphonate use.
<b>Intervention:</b>	randomized, double-blind, placebo-controlled, multi-centre trial designed to determine if the addition of oral clodronate 1,600 mg/day for 2 years to standard treatment for primary operable breast cancer could reduce the subsequent occurrence of bone metastases and thereby improve overall survival.
<b>Outcomes:</b>	Development of bone metastases; survival
<b>Follow-up:</b>	mean 5.6 years; range 5-10.5 years
<b>Results:</b>	<p>Oral clodronate will significantly improve the 5 year bone relapse free survival when used as a supplementary adjuvant treatment for patients receiving standard treatment for primary operable breast cancer</p> <p>Oral clodronate significantly reduced the risk of bone metastases in all patients over the 5 year study period (51 patients versus 73 patients with placebo; HR = 0.692, p=0.043); the difference was also statistically significant over the 2 year medication period (19 patients versus 35 patients with placebo; HR 0.546, P= 0.031). These differences were most pronounced in patients with stage II/III disease (39 patients versus 64 patients with placebo, HR = 0.592, P 0.009 over 5 years; 16 patients versus 32 patients with placebo, HR=0.496, P=0.020 over 2 years).</p> <p>Survival data also favoured the clodronate arm (HR for all patients = 0.768, P=0.048; HR for stage II/III disease = 0.743, P=0.041) although this was not significant due to multiple analyses. Oral clodronate was well tolerated, with mild-to-moderate diarrhoea being the most frequently reported adverse event.</p> <p><b>Bone health (subsequent fractures, etc)</b> - The addition of oral clodronate to adjuvant therapy for breast cancer significantly reduced the risk of bone metastases by 31% over the 5 year study period (51 patients versus 73 patients receiving placebo, HR=0.692: P=0.043). During the 2-year treatment period patients in the clodronate arm had a 45% reduction in the risk of bone metastases (P = 0.03). Over the 5 year study period only 6% of patients with stage I disease developed bone metastases compared with 15% of patients with stage II disease and 34% of patients with stage III disease. Hazard ratios for bone metastases confirmed a similar risk reduction for bone metastases for all patient subgroups that received oral clodronate, apart from patients with relatively low risk stage I disease where the numbers of events were too small to provide any meaningful comparison. For stage II/III disease, over the 5 year study period, the clodronate treated patients had a 41% decrease in the risk of developing bone metastases (P = 0.009) during the 2 year medication period, the risk was decreased by 50% (P = 0.020).</p> <p>For the 51 of 530 clodronate patients and the 73 of 539 placebo patients who developed bone</p>

metastases, there was evidence of a reduction in the number of bone metastases related hosts events in clodronate patients (29/530; 5.5%) compared with placebo patients (53/532; 9.8%) ( $p < .001$ ). This shows that, although there were only 51 of the clodronate patients who relapsed in bone compared to 73 of the placebo patients, they did not do worse because of previous adjacent clodronate. In fact, only 57% of these patients developed skeletal events compared to 73% of the bone relapsed placebo patients. This indicates that previous clodronate therapy does not appear to have compromised the subsequent treatment of relapsed metastatic bone disease.

**Overall survival**– Patients who received oral clodronate had an overall survival advantage, although this is no longer statistically significant due to multiple analyses. This was observed for all patients and for patients with stage II/III disease. There was a 23% reduction in the risk of death in all patients (HR= 0.768, 95% CI 0.591-0.999;  $p=0.048$ ) and a 26% reduction in risk of death in the subset of patients with stage II/III disease (HR = 0.743, 95% CI 0.558-0.989;  $p=0.041$ ), although neither of these reached statistical significance because of multiple analyses.

**Patient acceptability** – Overall, there were no reports of drug-related serious adverse events. Study medication was stopped early due to adverse events in 13% of patients receiving oral clodronate compared with 1% of patients receiving placebo.

Although the most frequently reported adverse events were gastrointestinal, diarrhoea was the only adverse event to demonstrate a statistically significant increase in incidence in the clodronate treatment group. Diarrhoea occurred in 19.9% of the clodronate treated patients versus 10% of the placebo-treated patients ( $P < 0.05$ ) and was generally mild. There were no cases of oesophageal perforation or ulceration or osteonecrosis of the mandible and/or maxilla, which have been associated with the use of other bisphosphonates.

**General comments:** -

<b>Study Identification:</b>	Powles, T., McCloskey, E., Paterson, A, Oral Bisphosphonates as Adjuvant Therapy for Operable Breast Cancer, Clinical Cancer Research 2006, 12:20:2, p.6301s-6304s.
<b>Design:</b>	Unsystematic review of RCTs, prospective cohort studies and retrospective case series; evidence level 4
<b>Country/ Setting:</b>	UK, hospital setting
<b>Population:</b>	RCTs of patients with primary operable breast cancer
<b>Intervention:</b>	clodronate 1,600mg/day or placebo
<b>Outcomes:</b>	Metastatic bone events; spine and hip BMD; patient acceptability
<b>Follow-up:</b>	Up to 5 years

**Results:**

The oral bisphosphonate clodronate (1,600 mg/d) is effective for treatment of patients with chemotherapy-induced bone loss. When used as adjuvant therapy, given to patients with operable breast cancer for 2 years, clodronate has been reported to significantly reduce the risk of bone metastases during the 2-year study period [19 clodronate patients versus 35 placebo patients; hazard ratio (HR), 0.546; P = 0.03] and 5-year study period (51 clodronate patients versus 73 placebo patients; HR. 0.692; P = 0.04) with a significant reduction in mortality (HR. 0.768; P = 0.048). This benefit, together with the low toxicity and safety of clodronate, supports its use as additional adjuvant therapy for patients with primary breast cancer.

**Bone health (subsequent fractures, etc)** - Oral clodronate significantly reduced the risk of bone metastases during the 2-year study period f 19 clodronate patients versus 35 placebo patients; hazard ratio (HR), 0.546; P = 0.03] and 5-year study period (51 clodronate patients versus 73 placebo patients; HR, 0.692; P 0.04). This reduction was predominantly seen in patients with stage 11 and III disease. An analysis of the incidence of skeletal-related events in the 51 clodronate patients and 73 placebo patients who developed bone metastases was also done to estimate the clinical benefit of early treatment. Clodronate patients were less likely to have metastatic bone events (fractures, hypercalcemia, and bone irradiation) even when corrected for the fewer numbers, indicating a probable spill over benefit for these patients even if they had relapsed in bone.

A further small, randomized, open-label study with oral clodronate involving 302 women with newly diagnosed primary breast cancer has also been reported. These patients had operable breast cancer but also had micro-metastases detected in their bone marrow at the time of primary diagnosis. The patients were randomly assigned to receive oral clodronate (1,600 mg/d) or no clodronate during a 2-year treatment period. All patients received standard adjuvant therapies, including surgery, radiotherapy, endocrine therapy, and/or chemotherapy. The two arms were well balanced with respect to prognostic factors during the 3-year follow-up period; patients who received oral clodronate had an ~50% reduction in the incidence of bone metastases (8% versus 17% with placebo; P= 0.003) and a significantly longer bone metastasis-free survival (P < 0.001) compared with those receiving standard treatment. A later analysis still confirmed a significant reduction in overall survival for clodronate patients, although the significant reduction in disease-free survival no longer persisted.

**Bone mineral density-** Oral clodronate (1,600 mg/d) protected against cancer treatment-induced loss of spine and hip bone mineral density. After the discontinuation of use of clodronate, rates of

bone loss returned after 1 year to the rate of bone loss in placebo-treated women. The women randomized to clodronate still had a significantly greater bone mineral density at 5 years than those treated with placebo.

**Overall survival**– There was also a significant reduction in mortality (HR. 0.768; P = 0.048; ref. 19). Furthermore, there was an overall significant reduction in mortality (98 clodronate patients versus placebo 129 patients; P = 0.048).

**Patient acceptability** – In this trial, oral clodronate (1,600 mg/d) was well tolerated, with no significant toxicity apart from mild to moderate diarrhoea.

**General comments:** -

<b>Study Identification:</b>	Saarto, T., Vehmanen, L., Virkkunen, P. and Blomqvist, C, Ten-year Follow-up of a Randomized Controlled Trial of Adjuvant Clodronate Treatment in Node-positive Breast Cancer Patients Acta Oncologica Vol. 43, No. 7, pp. 650 656, 2004
<b>Design:</b>	RCT; evidence level 1+
<b>Country Setting:</b> /	Finland, hospital setting
<b>Population:</b>	299 pre- and postmenopausal women with primary node positive breast cancer.
<b>Intervention:</b>	All patients received adjuvant chemo- or endocrine therapy ± oral clodronate 1600mg daily for 3 years. Pre-menopausal patients had chemotherapy, 6 cycles of cyclophosphamide (600 mg/rn2), methotrexate (40 mg/rn2), and 5-fluorostracil (600 mg/rn2) intravenously on day 1, and at successive 3-week intervals (CMF). Postmenopausal women were randomly allocated to receive either adjuvant tamoxifen 20mg or toremifene 60 mg per day for three years.
<b>Outcomes:</b>	Bone metastases and morbidity, Survival analysis and non-skeletal recurrence, DFS according to oestrogen receptor and menopause status
<b>Follow-up:</b>	10 years
<p><b>Results:</b>  Within 10 years bone metastases were detected 25 the same frequency in the clodronate and control groups: 44(32%) vs. 42(29%), respectively, (p=0.35). The frequency of non-skeletal recurrences (visceral and local) was significantly higher in the clodronate group 69 (50%) as compared with the controls 51(36%) (p=0.005). 10 year DFS remained significantly lower in the clodronate group (45% vs. 58%, p=0.01, respectively). This was especially seen in oestrogen receptor negative patients (25% vs. 58%, p =0.004, respectively). No significant overall survival difference was found between the groups. As previously reported 3-year adjuvant clodronate treatment did not prevent the development of bone metastases in node-positive breast cancer patients. A negative effect of clodronate on DFS by increasing the development of visceral metastases was still seen at 10 years, but this did not significantly compromise overall survival.</p> <p><b>Bone health (subsequent fractures, etc) -</b>  Bone metastases were detected as often in the clodronate group as in the controls: 44 (32%) vs. 42 (29%). There were no significant differences in 10-year skeletal disease-free survival between the study groups: 68% in the clodronate group and 71% in the controls (p =0.35). Bone was the first site of relapse in 29 patients (11 in the clodronate group and 18 in the controls, p=0.03), non- skeletal metastases in 78 patients (46 and 32, respectively, p=0.40) and simultaneous skeleton and non-skeleton in 26 patients (17 and 9, respectively, p=0.28). Bone as the first site of relapse was mainly seen in ER receptor positive patients: in 22 ER positive, 4 ER negative, and 3 ER unknown patients.</p> <p><b>Recurrence</b>  Seventy-six patients (55%) in the clodronate group and 60 (42%) control patients developed metastatic disease. Extra-skeletal (visceral and local) metastases were detected in 69 (50%) clodronate treated patients and in 51(36%) control patients with extra-skeletal DFS of 50% vs. 64%, respectively (p=0.004).</p> <p><b>Disease-free survival</b>  Ten-year disease-free survival (DFS) was significantly lower in the clodronate group: 45% vs. 58%, respectively (p=0.01).</p>	

In ER-positive patients 10-year DFS was 55% in the clodronate group, and 59% in the controls with no difference between the groups ( $p = 0.47$ ); while in ER- negative patients the DFS difference was highly significant in favour of the controls: 25% vs. 58%, respectively ( $p = 0.004$ ).

When pre- and postmenopausal patients were analysed separately according to receptor status, the only subgroup where no negative effect of clodronate was seen was ER- positive postmenopausal women treated with 3 years' antioestrogen therapy (10 year DFS 56% in both groups). In all the other subgroups the clodronate group did worse than the controls.

#### **Overall survival**

Sixty-four (46%) clodronate treated patients and 55 (38%) control patients died. Ten-year overall survival was 54% and 62% respectively ( $p = 0.13$ ). The number of non-breast-cancer-related deaths was 12 (4 in the clodronate and 8 in the control group).

**General comments:** -

<b>Study Identification:</b>	Sawka, A. M., Ioannidis, G., Papaioannou, A. - Are oral bisphosphonates effective in improving lumbar bone mineral density in breast cancer survivors with osteopenia or osteoporosis? Journal of Obstetrics and Gynaecology, Canada, JOGC, 2005, 27:8 pp 759-764
<b>Design:</b>	retrospective case series; evidence level 3
<b>Country/ Setting:</b>	Canada, hospital setting
<b>Population:</b>	70 breast cancer survivors, age >50, with at least one year of clinical follow-up identified from the prospective observational Canadian Database of Osteoporosis and Osteopenia (CAN000).
<b>Intervention:</b>	Patients treated with cyclic etidronate disodium (400mg/day for 14 days); alendronate 10mg/day) concomitant with chemotherapy
<b>Outcomes:</b>	BMD performed using dual-energy X-ray absorptiometry (DXA).
<b>Follow-up:</b>	1 year
<b>Results:</b>	<p>Oral daily alendronate treatment was associated with significantly greater improvements in lumbar spine bone density than use of cyclic etidronate or calcium and vitamin D alone. BMD increases were significantly greater in patients with prevalent vertebral fractures (VF) compared to these without VF (P = 0.025). In contrast, time since diagnosis of breast cancer was significantly associated with a decrease in BMD (P = 0.002).</p> <p><b>Bone mineral density-</b> Lumbar spine bone density measurements at baseline and at one year were available for 55 patients (79%). In control patients, lumbar BMD decreased at one year by 1.4% (SD 3.8), whereas BMD increased by 2.3% (SD 4.7) in etidronate-treated patients and increased by 4.3% (SD 4.1) in alendronate-treated patients. Minimal changes in femoral neck bone mineral densities were seen over the course of one year in each treatment group; in the control group, there was a decrease of 1 .7% (SD 3.7), to the etidronate group an increase of 0.1% (SD 4.5), and in the alendronate group an increase of 0.6% (SD 5.0).</p>

<b>Study Identification</b>	Vehmanen, L., Saarto, T., Risteli, J, Short-term intermittent intravenous clodronate in the prevention of bone loss related to chemotherapy-induced ovarian failure, Breast cancer research and treatment, 2004, 87:2, p.181-188
<b>Design:</b>	RCT; evidence level 1+
<b>Country/ Setting:</b>	Finland, hospital setting
<b>Population:</b>	48 pre-menopausal newly diagnosed breast cancer patients with operable T1-3 NO-2 MO breast cancer. Exclusion criteria: Karnofsky performance index < 70; S-Krea > 150 µmol/l.; peptic ulcer; hysterectomy or ovariectomy; osteoporosis; untreated hypothyreosis; bisphosphonate, calcitonin or peroral steroid therapy; pregnancy or lactation; other malignancies; and age >55 years. Pre-menopausal status was defined as ongoing menstruation during the last 6 months.
<b>Intervention:</b>	RCT investigating the effect of seven cycles IV intermittent 1500mg clodronate during adjuvant chemotherapy in prevention chemotherapy induced bone loss.
<b>Outcomes:</b>	Lumbar spine BMD
<b>Follow-up:</b>	12 months
<b>Results:</b>	<p>Short-term intermittent intravenous clodronate treatment did not seem to prevent clinically significantly the bone loss related to chemotherapy- induced ovarian failure in pre-menopausal women with early stage breast cancer. The mean bone loss in the lumbar spine at 6 months was -0.5% in the clodronate group and 1.4% in the control group (p = 0.22) and at 12months, -3.9% and 3.6%, respectively (p=0.62).</p> <p><b>Bone mineral density-</b> Four month intermittent intravenous clodronate treatment did not prevent the bone loss associated with chemotherapy-induced ovarian failure and amenorrhea. The change in lumbar spine BMD at six months was -0.5%. (CI -1.6% to + 0.7%) in the clodronate group and -1.4% (CI -2.7% to -0.2%) in the control group (p = 0.22). and in the femoral neck -0.4% (CI -2.2% to +1.4%) and 1.9% (CI-3.9% to 0%), respectively (p = 0.37). The bone loss in the lumbar spine at 12 months was -3.9% (CI -5.1% to -2.8%) in the clodronate group and 3.6% (CI 4.8% to 2.4%) in the control group (p = 0.62); in the femoral neck -1.4% (CI -3.6% to +0.8%) and -2.9% (CI -4.7% to -1.1%) (p =0.43), respectively. The effect of clodronate treatment on BMI) change at 12 months was not significant (p = 0.83 for lumbar spine and p=0.54 for femoral neck) while a highly significant effect of menopausal status (amenorrhea vs. irregular or regular menstruation) was found in the lumbar spine (p = 0.003). In the femoral neck, the effect of menopausal status on BMD was not statistically significant (p = 0.31).</p>

<b>Study Identification:</b>	Wu, S., Dahut, W. L., & Gulley, J. L., The use of bisphosphonates in cancer patients, Acta Oncologica, 2007, 46:5, p.581-591
<b>Design:</b>	systematic review of RCTs evidence level 1++
<b>Country / Setting:</b>	international
<b>Population:</b>	RCTs of bisphosphonates in cancer patients
<b>Intervention:</b>	Clodronate and zoledronic acid
<b>Outcomes:</b>	Bone health, metastases, overall survival
<b>Follow-up:</b>	Majority of studies included in the review had long-term follow-up
<b>Results:</b>	<p>Emerging data indicate that bisphosphonates are useful for preventing bone loss resulting from cancer or its therapy. The efficacy of bisphosphonates for early-stage breast cancers remains controversial. Significant risks of bisphosphonate therapy include nephrotoxicity, electrolyte abnormalities, and osteonecrosis of the jaw. Bisphosphonate therapy has a clear role in the management of skeletal metastases. However, significant side effects require ongoing monitoring and treatment.</p> <p><b>Bone health (subsequent fractures, etc)</b> - The utility of bisphosphonates as an adjuvant treatment for breast cancer remains controversial. In 3 studies of oral clodronate that included 1,653 women with early-stage breast cancer but high risk for metastatic disease, there was no significant reduction in the risk of developing skeletal metastases (RR 0.82, p = 0.07). Early results from several large randomized trials indicate that zoledronic acid may reduce bone loss associated with aromatase inhibitors. Short-term intermittent use of clodronate has not been shown to prevent bone loss in women with chemotherapy-induced premature menopause.</p>
<b>General comments:</b>	

## UPDATE EVIDENCE

Bundred, Campbell, Davidson, DeBoer, Eidtmann, Monnier, Neven, Minckwitz, Miller, Schenk, Coleman. Effective Inhibition of Aromatase Inhibitor-associated Bone Loss by Zoledronic Acid in Postmenopausal Women with Early Breast Cancer Receiving Adjuvant Letrozole (2008) *Cancer* 112;5:1001-1010

**Design:** Randomised Controlled Trial, Evidence level: 1-

**Country:** 28 countries

**Aim:** To evaluate the effect of either immediate or delayed use of 4mg zoledronic acid on the prevention of bone loss in both recently postmenopausal (due to chemotherapy or LHRH suppression) and established postmenopausal women with early stage breast cancer who had received adjuvant letrozole for 5 years.

### **Inclusion criteria**

Postmenopausal women

ER positive early breast cancer

Baseline lumbar spine (LS) and total hip (TH) T-scores above -2.0

Eligibility criteria for this trial were similar to the previously published Z-Fast study which was included in the original evidence base (Brufsky 2007).

### **Exclusion criteria**

None given

Similar to Brufsky et al. 2007

### **Population**

N=1065

### **Interventions**

Immediate or delayed zoledronic acid for 15 minutes every 6 months for 5 years.

Immediate group received zoledronic acid after randomisation; Delayed group received zoledronic acid when 1) post-baseline spine or hip T-score decreased to below -2.0, when a non-traumatic clinical fracture occurred or when asymptomatic fracture was discovered at the month 36 scheduled visit.

### **Outcomes**

Primary: percentage change in spine bone mineral density (BMD) at 12 months in patients receiving immediate start compared with delayed zoledronic acid.

Secondary: percentage change in TH BMD, changes in serum N-telopeptide (NTX) and bone-specific alkaline phosphate (BSAP) concentrations at 12 months.

Note: BMD is a surrogate measure for fracture risk

Analyses of BMD and bone markers were based on the intent to treat (ITT) population (N=1065); analyses relating to cancer recurrence used a modified ITT (mITT), defined as all randomized patients that underwent at least 1 post-baseline assessment (N=1064) and;

analyses of adverse effects and clinical fractures used a safety population, defined as all patients who received at least 1 dose of zoledronic acid or letrozole (N=1050).

The procedure for measuring NTX concentrations was changed during the trial and the methods were not standardized against each other thus limiting the ability to interpret the magnitude of change from baseline.

## Results

### **BMD:**

In the ITT population the unadjusted mean percentage change for lumbar spine from baseline in the immediate arm was 2.1% and in the delayed arm was -3.5% (p<0.0001). In the safety population the results were similar with adjusted mean percentage change from baseline of 1.9% (p<0.0001; 95% CI: 1.6-2.2) in the immediate arm and -3.1% (p<0.0001; 95% CI: -3.5 to -2.8) in the delayed arm.

The adjusted mean percentage difference between the two groups at month 12 for the ITT and safety populations was 5.7% (p<0.0001; 95% CI: 5.2-6.1) at spine and 3.6% (p<0.0001; 95% CI: 3.3-4.0) at hip.

In the safety population, immediate zoledronic acid prevented BMD loss at both L<sub>2</sub>-L<sub>4</sub> LS and TH compared with the delayed treatment population in recently post-menopausal women. Adjusted mean percentage change from baseline at 12 months was -0.2% (95% CI: -1.1 to 0.7) at LS and 0.07% (95% CI: -0.6 to 0.7) at TH. In the delayed group the change in BMD was -5.5% (95% CI: -6.3 to -4.7%) at LS and -3.4% (95% CI: -4.0 to -2.8) at TH.

In the delayed treatment arm, losses in BMD were -5.49% in the recently post-menopausal group versus -2.61% in the established post-menopausal group, suggesting more rapid bone loss in the recently post-menopausal women.

Changes to osteopenia status from baseline:

	Immediate		Delayed	
	Baseline	12 Month	Baseline	12 Month
Normal LS	69.5%		68.9%	
Mild to Moderate Osteopenia		0.9%		19.1%
Mild to Moderate Osteopenia	30.5%		31.1%	
Severe Osteopenia		0.6%		18%

The difference in distributions was statistically significant (p<0.0001).

### **Fractures**

The incidence of fractures was similar in both groups for the first 12 months; 1.5% in the

immediate group and 1.7% in the delayed group.

### **Breast Cancer Recurrence**

Breast cancer recurrence was similar for both groups; 2.3% recurrence and 4 deaths in the immediate group and 2.1% recurrence and 5 deaths in the delayed group.

### **Markers of Bone Turnover**

Unadjusted mean percentage change from baseline serum BSAP concentrations decreased significantly in the immediate group (-15.5%,  $p < 0.0001$ ) and increased significantly in the delayed group (30.1%,  $p < 0.0001$ ).

NTX concentration was, on average, 33% higher in the delayed group compared to the immediate group ( $p < 0.0001$ ).

### **Safety**

The occurrence of adverse events was similar in both groups apart from bone pain which was higher in the immediate group (12.3% vs. 6.9%).

Serious adverse events occurred in 8.2% of patients in the immediate arm and in 6.7% of patients in the delayed arm.

Withdrawal as a result of adverse effects was 5.3% in the immediate group and 4.7% in the delayed group. 1.5% of patients in the immediate group and 1% in the delayed group discontinued therapy as a result of adverse events.

### **General comments**

Greenspan, Brufsky, Lembersky, Bhattacharya, Vujevich, Perera, Sereika & Vogel. Risedronate Prevents Bone Loss in Breast Cancer Survivors: A 2-Year, Randomised, Double Blind, Placebo Controlled Clinical Trial (2008) *Journal of Clinical Oncology* 26;16:2644-2652

**Design:** Randomised Controlled Trial, Evidence level: 1-

**Country:** USA

**Aim:** To examine the prevention of breast cancer related bone loss.

#### **Inclusion criteria**

Newly post-menopausal ( $\leq 8$  years, verified by gonadotrophin levels)  
Stage I-III breast cancer, treated with chemotherapy  
With or without tamoxifen, an antiestrogen or an AI concomitant therapy

#### **Exclusion criteria**

Women with any illness known to affect bone mineral metabolism  
Women on any medications known to affect bone mineral metabolism

#### **Population**

N=87

#### **Interventions**

35mg risedronate orally once a week.

## Outcomes

Changes in spine and hip bone mineral density  
Biochemical markers of bone turnover  
Safety

## Results

Compliance for the study was 70.5% in the placebo group and 65.1% in the risedronate group ( $p=0.88$ ).

### Comparison of Treatment Groups

Bone Mineral Density (BMD) and bone turnover marker % change at 24 months:

Outcome	Placebo		Risedronate		P for difference between groups
	Mean $\pm$ SD	P	Mean $\pm$ SD	P	
<b>BMD</b>					
Spine	-1.2 $\pm$ 0.7	0.088	0.4 $\pm$ 0.8	0.63	0.082
Total Hip	-1.6 $\pm$ 0.4	0.001	0.9 $\pm$ 0.6	0.176	<0.001
<b>Bone Turnover</b>					
Urinary NTX	39.4 $\pm$ 14.4	0.0097	-6.5 $\pm$ 10.4	0.534	0.020
P1NP	37.2 $\pm$ 13.5	0.009	2.8 $\pm$ 16.7	0.870	0.195
Osteocalcin	13.7 $\pm$ 9.3	0.151	-2.5 $\pm$ 7.4	0.736	0.1850

### Comparison of Treatment and Cancer Therapy Groups

Significant differences across the groups with respect to bone mineral density were observed at 2 years.

BMD of spine included a decrease of 4.8%  $\pm$  0.8% ( $p<0.01$ ) for placebo + AI and a decrease of 2.4%  $\pm$  1.1% ( $p<0.05$ ) for risedronate + AI.

There was no significant change for placebo with no AI or risedronate with no AI, although there was an increase of 2.4%  $\pm$  0.8% ( $p=0.011$ ) at 18 months for risedronate with no AI.

For total hip, patients on placebo + AI had the greatest loss of bone mass with a decrease of 2.8%  $\pm$  0.5% ( $p<0.001$ ) compared with the risedronate + AI group which maintained bone mass. Placebo with no AI showed a decrease of 1.2%  $\pm$  0.5 ( $p=0.04$ ) and risedronate with no AI showed an increase in BMD of 2.2%  $\pm$  0.99% ( $p<0.05$ ).

Comparing patients on AIs showed a difference of 2.4  $\pm$  1.0 percentage points in spine bone density in women on placebo and risedronate ( $p=0.025$ ). For total hip there was a difference of 3.0  $\pm$  0.7 percentage points in women on placebo and risedronate.

Bone turnover was greatest in the placebo + AI group with an increase in urinary NTX of approximately 99%  $\pm$  24% ( $p<0.001$ ) compared with risedronate + AI and placebo with no AI, which showed no significant change. Risedronate with no AI showed a significant decrease at 12 and 18 months, but was no longer significant at 18 months.

### Safety

Risedronate was well tolerated and there was no significant difference in adverse effects in women receiving risedronate compared to women receiving placebo.

**General comments**

If a patient had an initial bone mineral density T-score in the osteoporotic range at the hip or spine, or an adult fragility fracture, they were counseled about options for therapy versus participation in the trial.

The study was a double blind, placebo controlled, randomised clinical trial conducted over 12 months with a 12 month extension.

Compliance was defined as taking at least 80% of the medication and was assessed through pill counts.

Subgroup analyses examined the effect of treatment  $\pm$  AI and placebo  $\pm$  AI.

**Author's conclusion:** once weekly oral risedronate was successful at maintaining or improving bone mass in post-menopausal women with cancer related bone loss. The medication was well tolerated and proved to be effective with or without the use of an AI.

Kristensen, B., Ejlersen, B, Mouridsen, H., Jensen, M., Anderson, J., Bjerregaard, B., Cold, S., Edlund, P., Ewertz, M., Kamby, C., Lindman, H., Nordenskjold, B., Bergh, J. (2008) Bisphosphonate treatment in primary breast cancer: Results from a randomised comparison of oral pamidronate versus no pamidronate in patients with primary breast cancer. *Acta Oncologica* 47:740-746

**Design:** Randomised Controlled Trial

**Evidence Level:** 1-

**Country:** Denmark, Sweden & Iceland

**Aim:** To investigate whether oral pamidronate can prevent the occurrence of bone metastasis and fractures in patients with lymph node positive primary breast cancer.

**Inclusion criteria**

Women with resectable adenocarcinoma of the breast and without signs of distant metastases according to an initial physical examination, x-ray examination of the chest and axial x-ray examination of the skeleton or a whole body scintigraphy confirmed by x-ray examination if suspect for bone metastases.

**Exclusion criteria**

None given

**Population**

N = 953

Patients were recruited from three groups:

premenopausal women without lymph node metastases but with grade 2 or 3 malignancy

and a primary tumour  $\leq 5$ cm in diameter independent of hormone status premenopausal women with negative or unknown hormone receptor status and with either axillary lymph node metastases or with primary tumour  $> 5$ cm in diameter. Postmenopausal women with hormone receptor negative tumours and with either axillary lymph node metastases or a primary tumour  $>5$ cm in diameter.

**Interventions**

150mg oral pamidronate twice daily for 4 years vs. no pamidronate

**Outcomes**

Overall Survival  
Skeletal Events  
Bone Mineral Density

**Results**

No significant difference in overall survival was observed between the treatment groups.

Hazard ratio for recurrence in bone in the pamidronate group compared to the control group was 1.03 (95% CI 0.75-1.40;  $p=0.86$ ).

No significant difference observed in the rate of fracture between the two groups ( $p=0.17$ ) although there were more fractures in the pamidronate group.

There was a significant decrease in lumbar bone mineral density in the control group ( $p=0.0001$ ).

**General comments**

Analysis was carried out according to both intention to treat and a per protocol analysis.

**Authors Comments:**

The results of the intention to treat and the adjusted per protocol analysis were identical and it is unlikely that closer adherence to the pamidronate regimen would have changed the outcomes.

Data from the trial do not support a beneficial effect of oral pamidronate on occurrence of bone metastases and fractures in patients with primary breast cancer receiving adjuvant chemotherapy.

## Health Economics Summary

### Overview

A systematic review was conducted to assess the cost-effectiveness of undertaking measurements of bone mineral density (BMD) in patients with invasive breast cancer who are on adjuvant hormonal therapy to assess bone health. The initial search identified 207 hits, from which 205 papers were excluded on the bases of the title and the abstract. Two papers were obtained for appraisal: 1 of them (Boyc *et al* 2004) was excluded because it was not relevant for the study question: it assessed health care resources used and costs of treatment patterns for cancer therapy induced bone loss. The other paper (Yeh *et al* 1995) was considered for further appraisal, and it was finally excluded on the grounds that it did not assess the patient population considered in the PICO question (it was not clear that patients in this study were on hormonal treatment; in addition, some patients with stage IV breast cancer were also included). Therefore, no economic evaluations were found that were relevant for this topic; uncertainty remains about the cost-effectiveness of using measurements of BMD in patients with invasive breast cancer that are on adjuvant hormonal therapy.

## Chapter 6 – Adjuvant radiotherapy

### 6.1 What are the indications for radiotherapy after breast conserving surgery?

#### Short Summary

##### Invasive breast cancer

The strongest overview was the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) (Clarke *et al* 2005) who conducted a systematic review of individual patient data (IPD) from the relevant trials, and provided data up to the year 2000 with 15 years of follow-up. A heterogeneous group of studies were assessed of patients receiving breast conserving surgery (BCS) with and without radiotherapy (RT). A range of participants were included, for example patients with tumours of less than 1 cm and elderly patients. Some of the studies provided an additional boost of radiotherapy to the tumour bed. A number of associated reviews were not as strong as the EBCTCG review and these have been included where additional data was provided (Liljegren 2002, Rutqvist *et al* 2003, Vinh-Hung & Verschraegen 2004). One recent randomised controlled trial (Ford *et al* 2006) from the St George's study (with earlier IPD reported in Clarke 2005) and another retrospective cohort study from the US SEER database (Vinh-Hung *et al* 2003) were also included.

Two systematic reviews reported cosmetic outcomes (Liljegren *et al.* 2002, Mul *et al* 2007). These were also reported in one RCT (Johansen *et al* 2002) and one non-randomised study (Duetsch & Flickinger 2003). Four studies reported quality of life outcomes using five different instruments. Three were recruited from RCTs (Lee *et al* 2008, Rayan *et al* 2003, Whelan *et al* 2000) and the fourth was a survey (Back *et al* 2005).

Three reviews (one narrative, Kuerer *et al* 2004, and two systematic reviews Cuncins-Hearn *et al* 2004, Sarin 2005) of non-randomised studies assessed a range of Accelerated Partial Breast Irradiation (APBI) techniques including intra-operative and postoperative brachytherapy. Another review (Kunkler *et al* 2006) discussed whether radiotherapy could be omitted after surgery.

Four guidelines were included, two Canadian (Shelley & Trudeau 2002, Whelan *et al* 2003), one American (Morrow *et al* 2002) and one recent German DEGRO guideline (Sautter-Bihl *et al* 2007).

Most studies from RCTs and well conducted meta-analyses/systematic reviews were consistent in the finding that postoperative radiation decreased the risk of local recurrence. The EBCTCG meta-analysis of breast conserving surgery trials showed a moderate reduction in breast cancer deaths and overall mortality after 15 years. Subgroup analyses by age, tumour characteristics and nodal status in the EBCTCG revealed further treatment effects of radiotherapy. Quality of Life (QoL) was generally high among patients receiving radiotherapy. Patient satisfaction with breast conserving surgery was also high.

#### PICO question

POPULATION	INTERVENTION	COMPARISON	OUTCOME
------------	--------------	------------	---------

Patients with operable invasive breast cancer who have received breast conserving surgery	RT to the breast after breast conserving surgery including: <ul style="list-style-type: none"> <li>• Electrons</li> <li>• Implant</li> </ul>	Breast conserving surgery alone	<ul style="list-style-type: none"> <li>• Recurrence</li> <li>• Disease Free Survival (DFS)</li> <li>• Overall Survival (OS)</li> <li>• Quality of life</li> <li>• Patient acceptability</li> <li>• Cosmesis</li> </ul>
---	--	---------------------------------	--

The search strategy developed from this table and used to search the literature for this question can be found in Appendix A

### Evidence Summary

The literature search was limited to the last 10 years (1997-2007). The strongest overview was the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) (Clarke *et al* 2005) who conducted a systematic review of Individual Patient Data (IPD) from the relevant trials, and provided data up to the year 2000 with 15 years of follow-up. A heterogeneous group of studies were assessed of patients receiving Breast Conserving Surgery (BCS) with and without radiotherapy (RT). A range of participants were included, e.g., patients with tumours of less than 1 cm, elderly patients. Some of the studies provided an additional boost of RT to the tumour bed. A number of associated reviews were not as strong as the EBCTCG review and these have been included where additional data was provided (Liljegren 2002, Rutqvist *et al* 2003, Vinh-Hung & Verschraegen 2004). One recent RCT (Ford *et al* 2006) from the St George's study (with earlier IPD reported in Clarke 2005) and another retrospective cohort study from the US SEER database (Vinh-Hung *et al* 2003) were also included.

Two systematic reviews reported cosmetic outcomes (Liljegren 2002, Mul *et al* 2007). The former used the same studies as the EBCTCG, so only cosmetic outcomes were reported in the evidence table. Cosmesis outcomes were also reported in one RCT (Johansen *et al* 2002) and one non-randomised study (Duetsch & Flickinger 2003).

Four studies reported quality of life outcomes using five different instruments. Three were recruited from RCTs (Lee *et al* 2008, Rayan *et al* 2003, Whelan *et al* 2000) and the fourth was a survey (Back *et al* 2001).

Three reviews (one narrative Kuerer *et al* 2004, and two systematic reviews Cuncins-Hearn *et al* 2004, Sarin 2005) of non-randomised studies assessed a range of Accelerated Partial Breast Irradiation (APBI) techniques including intra-operative and postoperative brachytherapy. Another review (Kunkler *et al* 2006) discussed whether RT could be omitted after surgery.

Four guidelines were included, two Canadian (Shelley & Trudeau 2002, Whelan *et al* 2003), one American (Morrow *et al* 2002) and one recent German DEGRO guideline (Sautter-Bihl *et al* 2008).

The systematic reviews of RCTs included a variety of post-operative interventions in addition to RT, the adjuvants used were boost to the scar, chemotherapy or tamoxifen. The RCTs compared BCS alone vs. BCS and RT. Wide local excision and adjuvant therapy were used in Ford *et al* (2006). In the cosmesis study (Johansen *et al* 2002), BCS patients received RT and a boost dose to the scar and tumour bed of either photons or electrons. Adjuvant chemotherapy was offered to high risk patients. Two QoL studies (Whelan *et al* 2000, Rayan *et al* 2003) included a boost dose to the tumour site. The QoL study by Lee *et al* (2008) included women after mastectomy or BCS receiving conventional or hypofractionated RT to the breast or chest wall, and a proportion with RT to the supraclavicular nodes.

Most studies from RCTs and well conducted meta-analyses/systematic reviews are consistent in the findings that post operative radiation decreases the risk of local recurrence, but has no effect on overall survival. Subgroup analyses revealed further treatment effects. QoL was generally high among patients receiving RT.

Local recurrence, breast cancer mortality and overall mortality were assessed from level 1 evidence using pooled meta-analyses of both IPD and RCT data. One retrospective cohort (level 2) from the US SEER database was also included (Vinh-Hung & Verschraegen 2003).

### **Local Recurrence**

From a logrank analysis of IPD (Clarke *et al* 2005) of 10 randomised trials the reduction in local recurrence by allocation to RT was highly significant ( $p < 0.00001$ ), the 5-year risk of local recurrence was 7% with radiotherapy, and 26% without radiotherapy. This corresponds to an absolute reduction of 19% in 5-year risk. Similar findings were reported by Liljegren (2002) using the most up to date trial data (not IPD) at the time (published between 1996-2001) from 5 of the studies in Clarke *et al* (2005) as well as an additional later trial (Holli 2001). They reported that the addition of postoperative radiotherapy reduced the risk of local recurrence by 2/3. The dose-intensity of radiotherapy and surgery had a positive impact on local control. Patients at low risk of local recurrence were > 55 years of age, with stage I tumours and favourable histology treated with adequate resection margins.

The meta-analysis (Vinh-Hung *et al* 2004) reported the pooled relative risk of ipsilateral breast tumour recurrence estimated from 15 trials (9422 randomised patients' data available for analysis) as 3.00 (95% CI 2.65-3.40). There was statistically significant heterogeneity between these studies.

Ford *et al* (2006) in the most recent RCT also reported a statistically significant reduction in locoregional recurrence in the RT arm [0.45 (95% CI 0.31-0.64;  $P = 0.0001$ ), Kaplan Meier] with 26.8% of recurrences for the RT arm and 49.8% for no RT. This was independent of node status, ER status or T stage.

### *Node status*

A subgroup analysis by node status (Clarke *et al* 2005) found the addition of radiotherapy produced a substantial absolute reduction in local recurrence risk [16.1% (SE1.0) for node-negative disease, and 30.1% (SE2.8) for node-positive disease].

### Age

Most local recurrences were in the conserved (ipsilateral) breast. The absolute effects of post-BCS radiotherapy on local recurrence were greater in younger women than in older women (test for trend in absolute benefits  $2p=0.00002$ ) (Clarke *et al* 2005).

### Tumour characteristics

The 5-year local recurrence risk without radiotherapy was higher in women with tumours that were large or with direct extension to the skin or chest wall (T2/T3/T4 tumours) or poorly differentiated. The absolute reduction in this risk from radiotherapy was correspondingly greater, however, ER status did not appear to affect these risks (Clarke *et al* 2005).

### Summary of local recurrence

In trials of RT after BCS radiotherapy reduced the risk of local recurrence irrespective of age, tumour grade, tumour size and Estrogen Response (ER) status (Clarke *et al* 2005). The authors suggest that the avoidance of local recurrence (mostly during the first 5 years) appears to be relevant to breast cancer mortality (after the first 5 years) using data from a further analysis of trials of post BCS radiotherapy. Another finding was that the avoidance of recurrence in the conserved breast and the avoidance of other local recurrences (e.g. in the chest wall or regional lymph nodes) were relevant to 15 year breast cancer mortality.

### Breast cancer mortality

From a pooled logrank analysis there was a significant overall reduction in breast cancer mortality (breast cancer death rate ratio 0.83 SE 0.05, 95% CI 0.75–0.91,  $2p=0.0002$ ). The absolute risk reduction of the addition of RT following BCS was 5.4% (SE 1.7) at 15 years (35.9% vs. 30.5%+ RT) (Clarke *et al* 2005).

An analysis of breast cancer deaths by Ford *et al* (2006) did not show any effect of radiation ( $p=0.44$ ).

### Overall mortality

In the post-BCS radiotherapy trials the radiotherapy regimes produced a moderate reduction in 15 year mortality (15 year gain of RT 5.3% (SE 2.3%,  $2p=0.005$ ). The absolute reduction in 15-year overall mortality was similar in magnitude to 15-year breast cancer mortality. There is a lack of data beyond this time period as women are still being followed-up (Clarke *et al* 2005).

Ford *et al* (2006) reported no significant differences between groups for disease-free ( $p=0.63$ ) or overall survival ( $p=0.59$ ), with a Hazard Ratio of 0.91 (95%CI 0.64-1.28;  $P=0.59$ ) for overall survival with RT. There were also no statistically significant differences in overall survival between groups when stratified for node positive vs. node negative; ER positive vs. ER negative; T1 vs. T2; pre-menopausal vs. post-menopausal status.

In the meta-analysis by Vinh-Hung & Verschraegen (2004) the pooled relative mortality risk of no RT vs. RT estimated from 13 trials with survival or mortality data (8206 randomised patients' data available for analysis) was 1.086 (95% CI 1.003-1.175). This equates to an 8.6% excess mortality if no RT is administered.

The weaker retrospective cohort by Vinh-Hung (2003) found the omission of radiotherapy compared to delivery of radiotherapy was associated with an overall increased mortality hazard ratio of 1.346 (95% confidence interval: 1.204-1.504) which increased with time. However, this may be an over-estimate as patients with high grade tumours were less likely to receive RT in more recent time periods. The findings were not generalizable.

### **Cosmesis**

Four studies reported on the cosmetic effects of RT: one systematic review by Liljegren (2002) included cosmetic/QOL outcomes, one systematic review of case reports (Mul *et al* 2007), one RCT (Johansen *et al* 2002) and one prospective non-randomised study (Deutsch & Flickinger 2003).

Johansen *et al* (2002) reported that 73% of patients regarded the cosmetic result as excellent or good. A univariate analysis found that treatment with a direct anterior electron field produced more morbidity and inferior cosmetic outcomes compared with tangential photon treatment. Anterior electron fields also led to significantly more grade 2 and 3 late reactions compared to tangential photons. On multivariate analysis cosmetic outcome was significantly associated with electron therapy (OR 2.3 CI 1.4-4.1;  $p=0.002$ ). Increasing breast size was associated with increased breast retraction and breast fibrosis after tangential RT on multivariate analysis (OR 1.73 CI 1.17-2.56,  $p=0.006$ ). Treatment characteristics that were independently associated with a fair/poor cosmetic outcome on multivariate analysis were the use of a direct anterior electron field (OR = 2.15, CI 1.25-3.70) and adjuvant systemic therapy (OR = 2.13, CI 1.22-3.71).

The non-randomised study by Deutsch & Flickinger (2003) reported 48.3% of women had an excellent cosmetic result (no skin changes or deformity and very slight, or no, differences in size); and 41.5% had a good result (no skin changes and little difference in size between the breasts; or skin changes with no difference in size between the breasts). 10.2% of women had a fair or poor cosmesis with skin pigmentation and a difference in size or breast distortion. An excellent or good cosmetic result versus a fair or poor result was associated with white race ( $p = 0.0056$ ), smaller separation between the tangential fields ( $p = 0.01$ ), the use of a boost dose ( $p = 0.0025$ ), and no use of tamoxifen ( $p = 0.025$ ). This study was likely to be biased since the same physician treated patients and assessed cosmesis.

Mul *et al* (2007) reported the rare side effect bullous pemphigoid (a blistering below the skin) which may occur after percutaneous treatment with RT.

The systematic review of 2 earlier RCTs (Liljegren 2002) concluded that the negative effect of postoperative radiotherapy on cosmesis and quality of life was small and occurred during early follow-up but not in later follow-up two to three years after treatment.

### **Quality of Life**

Quality of life was assessed using five different instruments in 4 studies (three RCTs Whelan *et al* 2000, Rayan *et al* 2003, Lee *et al* 2008; and one survey Back *et al* 2005). Three studies used the EORTC QLQ-30 (Back, Lee, Rayan) and two studies used the EORTC QLQ BR-23 breast cancer module (Lee, Rayan).

Whelan *et al* (2000) reported that breast irradiation therapy had an effect on quality of life during early treatment, with irradiated patients reporting increased breast symptoms compared with controls. After 2 years no differences were found between groups for rates of skin irritation, breast pain, and being upset by the appearance of the breast.

A small RCT of post-menopausal women, with node-negative breast cancer taking tamoxifen, (Rayan *et al* 2003) applied tangential field irradiation. RT did not significantly contribute to breast pain or adversely impact the QOL up to 12 months after treatment.

An update search identified a small Australian RCT (Lee *et al* 2008). The findings indicated that quality of life improves after RT treatment to reach baseline levels by 7 months of treatment. Breast symptoms and fatigue were found to be predictors of quality of life and treatment may be best targeted at these symptoms.

A short term non-randomised study by Back *et al* (2005), of women receiving tangential RT, reported a minimal impact of RT on patient functioning at 6 weeks post-treatment.

The three studies using the EORTC QLQ-30 questionnaire (Back, Lee, Rayan) and the two using the EORTC QLQ BR-23 breast cancer module (Lee, Rayan) all report that by the end of the study period QoL had reached pre-treatment levels.

### **Accelerated Partial Breast Irradiation**

Two systematic type reviews (Cuncins-Hearn *et al* 2004, Sarin 2005) assessing studies incorporating intra-operative and post operative APBI techniques both recommend that there is not sufficient evidence at this time for optimal use of these techniques. Longer term data from RCTs are awaited. This view is supported by Kuerer *et al* (2004).

### **Guidelines**

Four guidelines were identified (Morrow *et al* 2002, Sautter-Bihl *et al* 2007, Shelley & Trudeau 2002, Whelan *et al* 2003). All recommend post operative RT after BCS however the role of fractionation schedules and other adjuvant therapies eg, chemotherapy are less clear. Intra-operative and brachytherapy techniques are not recommended at this time.

Design: Systematic review of individual patient data

Level 1++

Country: Multi-national

Aim: To update previous meta-analyses of the individual patient data from randomised trials of the effects of radiotherapy and extent of surgery on local disease control and cause-specific mortality in early breast cancer. Specifically to quantitate the relationship between local control and long term mortality.

**Inclusion criteria** Randomised trials of Breast Conserving Surgery (BCS) with or without post surgery radiotherapy (RT). (Other studies involving mastectomy were also included in the overview).

**Exclusion criteria**

Trials considered to be confounded, e g., no difference in treatment groups in the use of systemic therapy.

**Population** 7311 women in 10 trials

**Interventions**

Update of individual patient data from randomised trials by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) with results up to the year 2000. The randomised trials compare local treatments of various types of surgery or radiotherapy (RT) or both. The intervention category relevant to this topic was RT versus no RT with the same BCS surgery (generally with axillary clearance).

**Outcomes**

Breast cancer recurrence (ipsilateral locoregional, contralateral or distant). Includes residual breast tissue, scar area, chest wall, ipsilateral regional lymph nodes.

Cause-specific mortality

Overall mortality

Incidence of second primary cancers before breast cancer recurrence.

**Follow up** –This is an ongoing systematic overview of randomised trials with an update every 5 years. The current publication (2005) used a pooled analysis of individual patient data from the included studies rather than the primary studies themselves. Findings from 15 years of follow-up were reported.

**Results**

Trials included in the meta-analysis are listed in the following table:

*Isolated local recurrence*

Trial	Year started	Events/ woman years	
		BCS+RT	BCS
<b>RT to conserved breast only: N+ 14%</b>			
NSABP B-06	1976	125/6862	285/4991
Upsala-Orebro	1981	10/1636	43/1511
St George's London	1982	12/1202	31/1047
Ontario COG	1984	53/3543	155/2754
INT Milan 3	1987	19/2478	60/2005

West Midlands UK	1985	42/2398	104/1929
CRC UK	1986	33/1604	77/1454
Subtotal	5 yr risk	105/7220 (7.7%)	294/6023
<b>Total</b>	Overall 5 yr risk	363/28 469 (7.3%)	1000/23 489 (25.9%)

A number of analyses were conducted after stratification by trial, time since randomization and nodal status (positive or negative). The main outcomes of local recurrence, breast cancer mortality and overall mortality were also stratified by age at randomization (<40, 40-49, 50-59, 60-69, > 70 years).

### Local recurrence

Results of a meta-analysis of 10 trials were provided as a Forest plot in the paper.

Results from 2 subgroups of trials were shown:

- a) RT to conserved breast only; 14% node positive patients
- b) RT to conserved breast and other sites; 24% node positive patients

There was a reduction in isolated local recurrences after RT compared with no RT in every trial. The difference was significant in each subgroup (RT to breast only and RT to breast and other sites) as well as overall studies.

The ratio of local recurrences between groups (RT vs. no RT) were:  
 RT to conserved breast only                      0.31 (SE 0.04) 2p <0.00001

RT to conserved breast and other sites      0.32 (SE 0.06) 2p <0.00001  
 Overall studies    0.31 (SE 0.03) 2p <0.00001

This corresponds to a proportional reduction in local recurrences of 70% in patients receiving post-operative RT. No significant heterogeneity was present between the 11 strata or subgroups analysed.

The overall 5 year risk of local recurrence was 7.3% with RT and 25.9% without post-operative RT, corresponding to an 18.6% (25.9%-7.3%) absolute reduction in 5 year risk.

**Breast cancer mortality**

A second Forest plot was reported in the paper of deaths from breast cancer after 15 years, with the same sub-groupings. The findings of each subgroup and overall results are reported in the following table:

	Deaths/women		Ratio of annual death rates	P value
	BCS+RT	BCS		
RT to conserved breast only: N+ 14%	499/2683	587/2662		
15 year risk	28%	33.2%	0.84 (SE 0.06)	2p=0.004
RT to conserved breast and other sites: N+ 24%	254/990	302/976		
10 year risk	28.2%	35.1%	0.81 (SE 0.08)	2p=0.02
Total events (N + 14% and N+ 24%)	753/3683	889/3638		
Overall 15 year risk	30.5%	35.9%	0.83 (SE 0.05)	2p=0.0002

There was a significant overall reduction in breast cancer mortality when studies were pooled (breast cancer death rate ratio 0.83 SE 0.05, 95% CI 0.75–0.91, 2p=0.0002).

The corresponding values between groups (RT vs no RT) for the 2 subgroups were:

RT to conserved breast only                              0.84 (SE 0.06) 2p =0.004  
 RT to conserved breast and other sites              0.81 (SE 0.08) 2p =0.02

The absolute risk reduction of the addition of RT following BCS was 5.4% (SE 1.7) at 15 years (35.9% vs. 30.5% + RT).

*Effect of BCS and RT by node status*

The results of local recurrence and breast cancer mortality were plotted (%)

isolated recurrence vs. time since randomization; and % breast cancer mortality vs. time since randomization) by node status (6097 women with BCS were node negative; and 1214 with BCS were node positive). The risk of local recurrence at 5 years was greater for women with node positive disease than node negative disease. Radiotherapy provided a larger 5 year gain in node positive than node negative women (ARR 30.1% vs. 16.1%). Data is shown in the following table. The numbers were too small to provide sufficient statistical power.

	Events by year 5		5 year risk (actuarial %)		Absolute reduction in 5 year risk (%) for addition of RT
	BCS +RT	BCS	BCS +RT	BCS	
Node negative	216/3071	637/3026	6.7	22.9	16.1% (1.0)
Node Positive	66/602	221/612	11.0	41.1	30.1% (2.8)

The authors suggest that the avoidance of a local recurrence mainly during the first 5 years influenced the breast cancer mortality rate after the first 5 years.

#### *Subgroup analyses*

These were conducted on available data from all trials by age and tumour characteristics. For women with node-negative disease, in trials of RT after BCS, radiotherapy produced similar proportional reductions in local recurrence risk irrespective of age, tumour grade, tumour size and Estrogen Response (ER) status. Data are shown in the following table which was provided in the original paper.

	5 year risk of local recurrence (%) in RCTs of RT after BCS (node negative)	
Subgroup	RT vs. control	Absolute reduction (SE)
<b>Age (years)</b>		
<50	11 vs 33	22 (2)
50-59	7 vs 23	16 (2)
60-69	4 vs 16	12 (1)
≥ 70	3 vs 13	11 (2)
<b>Tumour grade</b>		
Well differentiated	4 vs 14	
Moderately differentiated	9 vs 26	
Poorly differentiated	12 vs 34	
<b>Tumour size (T)</b>		

<b>category)</b>	5 vs 20	15 (1)
1-20mm (T1)	14 vs 35	21 (3)
21-50mm (T2)	-	-
> 50mm (T3 or T4)		
<b>ER status</b>		
ER poor	12 vs 30	18 (3)
ER positive	6 vs 25	19 (2)
<b>All women</b>	7 vs 23	16 (1)

### Age

The 5-year local recurrence risks of different subgroups of patients with node-negative disease are shown in the Table. Most local recurrences were in the conserved (ipsilateral) breast. The absolute effects of post-BCS radiotherapy on local recurrence were greater in younger women than in older women. The 5-year risk reductions by age group are shown below:

<i>Age</i>	<i>5-year risk reduction</i>
< 50 years	22%
50-59	16%
60-69	12%
> 70	11%

Test for trend in absolute benefits  $2p=0.00002$ .

### Tumour characteristics

The 5-year local recurrence risk without radiotherapy was higher in women with tumours that were large or with direct extension to the skin or chest wall (T2/T3/T4 tumours) or poorly differentiated. The absolute reduction in this risk from radiotherapy was correspondingly greater, however, ER status did not appear to affect these risks.

### Overall mortality

The radiotherapy regimes produced a moderate reduction in 15 year mortality (15 year gain of RT 5.3% (SE 2.3%,  $2p=0.005$ ). In the post-BCS radiotherapy trials the absolute reduction in 15-year overall mortality were similar in magnitude to 15-year breast cancer mortality. However there is little follow-up beyond year 15 and many women have not yet been followed to year 15.

### Author conclusions

Avoidance of a local recurrence in the conserved breast after BCS and avoidance of a local recurrence elsewhere (e.g., the chest wall or regional nodes) after mastectomy were of comparable relevance to 15-year breast cancer mortality. Differences in local treatment that substantially affect local recurrence rates would, in the hypothetical absence of any other causes of death, avoid about one breast cancer death over the next 15 years for every four local recurrences avoided, and should reduce 15-year overall mortality.

Updated 2018

Vinh-Hung V, Verschraegen C (2004) Breast-conserving surgery with or without radiotherapy: Pooled-analysis for risks of ipsilateral breast tumor recurrence and mortality. *Journal of the National Cancer Institute* **96**, 115-121.

Design: Systematic review and pooled analysis Level 1++

Country: Belgium

Aim: The objective of the study was to investigate whether radiotherapy or its omission after breast-conserving surgery has measurable consequences on local tumour growth and patient survival.

**Inclusion criteria** Randomized clinical trials of invasive breast cancer that compared radiotherapy versus no radiotherapy after breast-conserving surgery (lumpectomy or local excision) with or without systemic treatment.

**Exclusion criteria** None

**Population** 18 randomised trials identified. Eleven were published as full articles, most of these were included in Clarke (2005) as individual patient data to 2000. Four were abstracts and 3 were unavailable since they were ongoing.

**Interventions**

Breast-conserving surgery (lumpectomy or local excision) with or without postoperative radiotherapy

**Outcomes**

Ipsilateral breast tumour recurrence as a first event  
Survival analysis from death by any cause

**Follow up -**

**Results**

**Mortality**

The pooled relative mortality risk of no RT vs. RT estimated from 13 trials with survival or mortality data (8206 randomised patients' data available for analysis) was 1.086 (95% CI 1.003-1.175). This equates to an 8.6% excess mortality if no RT is administered. A re-analysis of a subset of 9 trials, that excluded the studies reported as abstracts only, found a relative mortality risk of 1.083 (95% CI 0.993-1.180).

**Local recurrence**

The pooled relative risk of ipsilateral breast tumour recurrence estimated from 15 trials (9422 randomised patients' data available for analysis) was 3.00 (95% CI 2.65-3.40). There was statistically significant heterogeneity across these studies. Relative risks from individual studies ranged from 2.32 (95% CI 1.56-3.45) to 4.89 (95% CI 2.45-9.76). A re-analysis of a subset of 9 trials that excluded the studies reported as abstracts only found a relative risk of ipsilateral breast tumour recurrence of 3.09 (95% CI 2.69-3.56).

Data are shown in the following table:

Outcome	BCS + RT	BCS no RT	Relative risk
Relative mortality risk (13 trials)	755/4109 (deaths)	824/4097 (deaths)	1.086 (95% CI 1.003-1.175)
Relative risk of ipsilateral breast tumour recurrence (15 trials)	279/4691	875/4731	3.00 (95% CI 2.65-3.40)

### Author conclusions

Omission of RT after BCS was associated with a 3 fold increase of ipsilateral breast tumour recurrence and a marginally statistically significant excess mortality risk of 8.6% (95% CI 0.3%-17.5%) relative to the delivery of RT alone.

**General comments –**

Updated 2018

Mul VE, van Geest AJ, Pijls-Johannesma MC, Theys J, Verschueren TA, Jager JJ, Lambin P, Baumert BG (2007) Radiation-induced bullous pemphigoid: a systematic review of an unusual radiation side effect.[see comment]. [Review] [41 refs]. *Radiotherapy & Oncology* **82**, 5-9.

Design: Systematic review of case reports

Level 1-

Country: Holland

**Inclusion criteria** Studies reporting histologically confirmed bullous pemphigoid (BP) and treatment with radiotherapy (RT). Languages: Dutch, English, French, Italian, German. Searches to April 2006.

**Exclusion criteria** Pemphigus vulgaris and other forms of pemphigus. Bullous diseases with no histopathology diagnosis.

**Population** 21 references identified of BP and breast cancer from 289 potentially relevant articles.

#### **Interventions**

Percutaneous radiotherapy to the breast

#### **Outcomes**

Bullous pemphigoid described as a severe pruritis in combination with a bullous eruption (blistering below the skin surface)

#### **Follow up -**

#### **Results**

An association between RT and BP was reported in 27 patients. The majority developed BP after RT and a median dose of 50 Gy. Four patients developed BP during RT after a minimal dose of 20 Gy.

#### **Conclusions**

In all reported cases, there is a clear relationship of BP with RT. Therefore, BP may be considered as an RT-induced side effect. RT can induce a BP following a minimal dose of 20 Gy.

**General comments** –Very rare event caused by RT to the breast affecting the appearance.

## Accelerated Partial Breast Irradiation

Kuerer HM, Julian TB, Strom EA, Lyerly HK, Giuliano AE, Mamounas EP, Vicini FA (2004) Accelerated partial breast irradiation after conservative surgery for breast cancer.[see comment]. [Review] [57 refs]. *Annals of Surgery* **239**, 338-351.

Design: Review of recent selected studies

Level 4

Country: USA

Aim: APBI has very recently come to the forefront as a potential local treatment option for women with breast cancer. This review aims to give an overview of the biologic rationale for APBI techniques, and benefits and limitations of APBI techniques.

**Inclusion criteria** Breast-conserving surgery with and without postoperative irradiation; all studies involving partial breast irradiation, including brachytherapy, for breast cancer; and currently accruing and planned APBI trials

**Exclusion criteria** None reported

### Population

### Interventions

APBI techniques after BCS

### Outcomes

Early results of treatment in terms of toxicity, complications, cosmesis, and local control.

### Follow up -

### Results

#### Local recurrence

There is some overlap with studies in the Sarin review. Of the eight studies reported excluding Fentiman (1996) where 56% of patients had involved margins, local recurrence rates were 0-4.4%.

Approximately 3% of patients treated with breast-conserving surgery experience an ipsilateral breast local recurrence away from the site of the lumpectomy in groups with or without postoperative standard whole-breast irradiation. Results of phase I-II studies involving approximately 500 patients treated with APBI after breast-conserving surgery have been published. Many of the studies have limited long-term follow-up and potential selection biases, but early results suggest that toxicity, cosmesis, and local control are comparable to outcomes seen after breast-conserving surgery followed by standard whole-breast irradiation.

### Author conclusions

Recent advances in radiation delivery and published series of partial breast irradiation support large randomized trials comparing APBI with standard whole-breast irradiation after breast-conserving surgery.

Cuncins-Hearn A, Saunders C, Walsh D, Borg M, Buckingham J, Frizelle F, Maddern G (2004) A systematic review of intraoperative radiotherapy in early breast cancer. [Review] [34 refs]. *Breast Cancer Research & Treatment* **85**, 271-280.

Design: Systematic review

Level 1-

Country: Australia

Aim: To assess safety and efficacy of IORT in EBC

**Inclusion criteria** All studies of any form of BC surgery (local excision, lumpectomy, segmentectomy, quadrantectomy) and any form of IORT.

Mastectomy was also included.

**Exclusion criteria** high dose IORT

**Population** 7 studies (incl 1 RCT, five of the seven were Level IV evidence)

### **Interventions**

Any IORT study including boost.

### **Outcomes**

Safety, efficacy

DFS

Overall survival

Cosmesis

### **Follow up -**

### **Results**

#### **Local recurrence**

From 5 studies local recurrence ranged from 0-29% (However the upper limit (29%) was from a study with only 7 patients).

#### **Overall survival**

From 3 studies: 86-100%

#### **DFS**

Not reported in IORT studies

#### **Cosmesis**

Cosmesis was measured differently across the studies and long-term IORT data is not available. Preliminary data suggest that IORT gives a similar short-term cosmetic outcome to BCT.

### **Author conclusions**

Further research is required to clarify several issues such as identification of the most appropriate subgroups of patients for IORT, a comparison of the currently available mobile IORT technologies, establishing whether IORT is most appropriate as a boost replacement dose or replacement for all postoperative radiotherapy, the examination of how biological repair processes may differ between the two treatment modalities and determining

precisely where local recurrences originate with respect to the original tumour site.

**General comments –**

There was little overlap between this review and the Sarin (2005) review since the inclusion criteria were broader and older studies were used.

Updated 2018

Sarin R (2005) Partial-breast treatment for early breast cancer: emergence of a new paradigm. [Review] [51 refs]. *Nature Clinical Practice Oncology* **2**, 40-47.

Design: Critical Review

Level 1-

Country: India

Aim: To review the clinical, biologic and technical aspects of an emerging paradigm of partial-breast irradiation with BCS

**Inclusion criteria** Studies of surgery and radiotherapy techniques for Accelerated Partial Breast Irradiation (APBI)

**Exclusion criteria** None reported

**Population** Studies using the techniques listed below in the next section. Case selection is critical for good clinical outcomes since the location of tumour, size of tumour, proximity to the skin, and breast size determine the type of technique used for optimum outcomes. The American Brachytherapy Society (ABS) and American Society of Breast Surgeons (ASBS) recently defined conservative patient selection criteria and treatment guidelines in 2003.

**Interventions**

APBI techniques including intra-operative or postoperative implantation of needles or catheters for continuous low dose rate (LDR), pulsed low dose rate (PDR) or fractionated high dose rate brachytherapy. Techniques include the inflatable balloon device known as Mammosite, external beam 3D conformal RT (3DCRT), external electron beam. Intra-operative RT (IORT) with a large single radiation dose to the tumour bed is being evaluated in Milan with the ELIOT trial using electrons from a mobile linear accelerator. In the TARGIT trial an Xray device, Intrabeam, is used.

**Outcomes**

Ipsilateral recurrence  
 Contralateral incidence  
 Cosmesis

**Follow up** –Long term results from RCTs are not yet available. Several prospective and retrospective studies are available with median follow-up from 4 to 12 years. The best results have been achieved with careful case selection.

**Results**

Only studies post 2000 were included in the tables.

**Ipsilateral recurrence and contralateral incidence**

Five year APBI results from quality assured LDR or HDR interstitial implants in optimally selected patients:

Institution	N of patients	Median follow-	5 year actuarial ipsilateral breast	Contralateral breast
-------------	---------------	----------------	-------------------------------------	----------------------

		up (years)	recurrence rates. Anywhere in Outside the breast tumour bed		cancer incidence
Ochsner Clinic (2 studies)	160	7	2.5%	1.2%	NA
NIO Budapest phase I/II (1 study)	45	6 7	4.4%	4.4%	0
William Beaumont (2 studies)	199	5.4	1.2%	0.6%	1%
Virginia Commonwealth University (2 studies)	59	4.2	5.1%	2.6%	0
Orebro (1 study)	49	4.6	4%	2%	NA
RTOG 9517 phase II (1 study)	99	3.7	3% (4 yr)	NA	3%
All studies	611	4-7	1-5%	0.6-4.4%	0-3%

### Cosmesis

With a radiobiologically optimal dose most APBI studies report good to excellent cosmesis in 85-100% of women.

Fat necrosis occurred in 0-25% of women at 3-5 years follow-up.

Severe late radiation sequelae have occurred with radiobiologically unacceptable schedules.

Long term cosmetic outcome and complications with Mammosite and single fraction IORT are awaited. Adverse cosmetic outcome is associated with higher implant volume and doxorubicin-based adjuvant chemotherapy.

### Author conclusions

There is enough evidence against the use of APBI for inappropriately selected women or with suboptimal techniques, which may lead to unacceptable breast recurrences and late sequelae. Long term clinical outcome data in appropriately selected women (ABS guidelines) is ongoing and, along with RCT clinical evidence, together can establish the role of APBI in breast cancer treatment.

Additional information from systematic reviews or analyses by other authors who have further examined some of the EBCTCG included randomised trials and other studies:

**Kunkler IH**, Prescott RJ, Williams LJ, King CC (2006) When may adjuvant radiotherapy be avoided in operable breast cancer?. [Review] [57 refs]. *Clinical Oncology (Royal College of Radiologists)* **18**, 191-199.

Randomised trials in which the omission of radiotherapy has been tested after breast-conserving surgery, with or without adjuvant systemic therapy, show a significant four- to five-

fold reduction in local recurrence. No subgroup of women, managed by breast-conserving surgery, has been identified where radiotherapy may be omitted.

The PRIME trial which evaluates the role of radiotherapy in a population of low risk, older women is ongoing. Adjuvant radiotherapy after breast-conserving surgery or mastectomy significantly reduces the incidence of local recurrence. Adjuvant radiotherapy improves survival after mastectomy in women at high risk of recurrence (> 20% risk of recurrence at 10 years), when combined with adjuvant systemic therapy. Postoperative radiotherapy is the standard of care among women with T3 tumours, and those with four or more involved axillary nodes treated by mastectomy. The role of radiotherapy is unclear in women at intermediate risk of recurrence (i.e. <15% 10-year risk of recurrence after surgery and systemic therapy alone), with one to three involved nodes or node negative with other risk factors. Clinical trials to assess the role of postmastectomy radiotherapy (PMRT) in this setting are needed. There is no evidence presently that PMRT is needed for women with pT1-2, pNO tumours without other risk factors.

**Rutqvist LE**, Rose C, Cavallin-Stahl E (2003) A systematic overview of radiation therapy effects in breast cancer. *Acta Oncologica* **42**, 532-545. Level 1-

Abstract: A systematic review of radiation therapy trials in several tumour types was performed by The Swedish Council of Technology Assessment in Health Care (SBU). The synthesis of literature on radiation therapy for breast cancer was based on data from 29 randomized trials, 6 meta-analyses and 5 retrospective studies. Forty articles were included and involved 41 204 patients. The conclusions reached for breast conserving surgery can be summarized as follows:

- There are conflicting data whether breast conservation surgery plus radiotherapy is comparable to modified radical mastectomy on local recurrence rates.
- There is strong evidence that breast conservation surgery plus radiotherapy is comparable to modified radical mastectomy alone for disease-free survival and overall survival.
- There is strong evidence that postoperative radiotherapy to the breast following breast conservation surgery statistically significantly reduces ipsilateral breast recurrences and diminishes the need for salvage mastectomies.
- There is strong evidence that the omission of postoperative radiotherapy to the breast following breast conservation surgery has no impact on overall survival. One meta-analysis using Bayesian statistics, which included three randomized studies, found a survival advantage.
- There is strong evidence that the addition of a radiation boost to the tumour bed after breast conservation surgery and conventional radiotherapy significantly decreases the risk of ipsilateral breast recurrences but has no impact on overall survival after short follow-up.

Randomized controlled trial

Ford HT, Coombes RC, Gazet JC, Gray R, McConkey CC, Sutcliffe R, Quilliam J, Lowndes S (2006) Long-term follow-up of a randomised trial designed to determine the need for irradiation following conservative surgery for the treatment of invasive breast cancer. *Annals of Oncology* **17**, 401-408

Design: RCT Level 1++  
Country:UK (St George's Hospital), setting: Single hospital  
Update of RCT included in EBCTCG (2005) and Vinh-Hung (2004) reviews

**Inclusion criteria**

**Exclusion criteria**

**Population** number of patients: Post-operative RT (n=208); no post-operative RT (n=192)  
Age < 70 years at recruitment  
T1 or T2 breast cancer

**Interventions**

Wide local excision and adjuvant therapy [oestrogen receptor (ER) positive: tamoxifen; ER negative: CMF chemotherapy].

**Outcomes**

Local recurrence  
Distant recurrence  
Deaths

**Follow up** up to 20 years (median 13.7 years)

**Results**

*Local recurrence*

Statistically significant reduction in recurrence in ipsilateral breast in RT arm (p=0.0001). Kaplan-Meier rates for each arm are shown in the table below. A Forest plot stratified by subgroups for node status, ER status, T stage (1 or 2) and pre or post menopausal status found no significant differences between groups for local recurrence.

*Distant disease-free survival*

110 (27.5%) patients developed distant metastases, which was not related to treatment with or without RT. Kaplan-Meier rates for each arm are shown in the table below. There was no significant difference between groups for occurrence of distant metastases (HR = 0.91 95%CI 0.64-1.33; p=0.63). When stratified in a Forest plot by node status, ER status and T stage there were no significant differences between groups. There was a significant difference between pre-menopausal and post-menopausal status (P=0.02) suggesting that RT had a greater effect in post-menopausal women.

*Overall survival*

There was no significant difference in overall survival between groups (p=0.59). The hazard ratio for deaths in women is shown in the table below.

The authors reported a strong association of local recurrence in the breast with distant metastases:

119 patients had a local recurrence, and 51 (42.8%) of these also had a distant recurrence;

281 patients had no local recurrence, and 59 (21%) of these also had a distant recurrence.

The authors suggested that patients with a local recurrence were more likely to develop distant metastases. This was tested with Cox regression analysis with local recurrence as a time-dependent variable and showed a risk ratio of 5.28 ( $P < 0.0001$ ). This strong relationship is dependent on the intensity of post-treatment follow-up and investigation.

Outcome	BCS + RT	BCS no RT	Result
Local recurrence (20 year Kaplan-Meier)	28.6% (95%CI 19.6 – 37.6%)	49.8% (95%CI 40.8 – 58.9%)	Reduction in locoregional recurrence: 0.45 (0.31-0.64; P=0.0001)
Deaths (Hazard ratio at 20 years)	39.5%	43.3%	HR for RT vs no RT: 0.91 (95%CI 0.64-1.28; P=0.59)
Overall survival	60.5% (SE 4.7%)	56.7% (SE 6.1%)	
Development of metastases (20 year Kaplan-Meier)	33.8% (95%CI 25.1 – 42.5%)	32.2% (95%CI 24.7 – 39.7%)	HR for RT vs no RT: 0.91 (95%CI 0.64-1.33; P=0.63)

### Conclusions

Post-operative radiotherapy produced a reduction in locoregional recurrence, but did not influence the incidence of distant metastases or time of death.

### General comments -

Observational Studies (eg. Prospective Cohort or Retrospective Cohort or Case Series):

## BCS ± RT

Vinh-Hung V, Voordeckers M, Van de SJ, Soete G, Lamote J, Storme G (2003) Omission of radiotherapy after breast-conserving surgery: survival impact and time trends. *Radiotherapy & Oncology* **67**, 147-158.

Design: Retrospective cohort (SEER)

Level 2 +

Country: USA, setting: Multi-centre

Aim: To evaluate the survival impact of omission of radiotherapy after breast-conserving surgery and changes over time.

### Inclusion criteria

Women diagnosed between 1988-1998;

Ages 40-69 years;

Primary non-inflammatory, histologically confirmed invasive carcinoma confined to breast;

Tumour diameter < 50 mm;

No previous cancer, no known internal mammary node involvement or distant metastases.

### Exclusion criteria

Non hospital or non clinic based record, unknown race, unknown month of diagnosis, size of primary tumour not specified, discrepancy between nodal status and reported nodal involvement.

**Population** number of patients = 27491 patient records

### Interventions

Treatment was breast-conserving surgery (partial mastectomy, lumpectomy, wedge resection, quadrantectomy, segmental resection, tylectomy), with axillary dissection, with or without post-surgery radiation.

No details provided about how RT was delivered.

### Outcomes

Survival

Death from any event was recorded.

**Follow up** 10 years

### Results

Radiation therapy was omitted in 3586 patients (13%).

Patients with histologically high grade tumours were less likely to be omitted from RT than patients with low grade tumours in 1988 than in 1997, i.e., in more recent years a higher proportion of patients with grade 3-4 tumours did not receive RT.

There was an increased overall mortality hazard ratio associated with the omission of radiotherapy compared to delivery of radiotherapy:

Hazard ratio = 1.346 (95% CI 1.204-1.504).

The time profile suggested an increase in mortality over time associated with the omission of radiotherapy. The baseline mortality hazard ratio of 1.14-1.17 (14-17% excess relative mortality risk), increased to a projected hazard ratio of 2.26 (more than doubling the relative mortality risk) for omission of radiotherapy.

### **Author conclusions**

In the selected population of patients aged 40–69 years with complete treatment records available, and who also had extensive axillary dissection, the omission of radiotherapy was independently associated with increased mortality. The most conservative estimate of a baseline effect yields a hazard ratio of 1.14–1.17, corresponding to a 14–17% increase of relative mortality. The time trend indicated an exponential increase associated with the omission of radiotherapy in patients who presented more unfavourable factors. Even by discarding the latest registration year, the estimation still yields a hazard ratio of 2.16; more than doubling the relative mortality of no-radiotherapy as compared to radiotherapy. The data do not give support to omitting radiation or give rationale to clinical trials that would omit radiation.

### **General comments –**

There was an increasing trend from 1988 to 1998 to omit radiotherapy for patients with tumours of histological grade 3–4, in comparison to patients receiving radiotherapy. Patients meeting the inclusion criteria were selected from the database, and there was a significant difference between the trial arms for patients with grade 3-4 tumours receiving RT (28.3%) and those not receiving RT (34.7%). The odds of not receiving RT for a high grade tumour increased with time. This may lead to an overestimate of the hazard ratio for this population.

Since only 15% of the database records were selected, the findings are not generalizable.

## COSMESIS

Johansen J, Overgaard J, Rose C, Engelholm SA, Gadeberg CC, Kjaer M, Kamby C, Juul-Christensen J, Blichert-Toft M, Overgaard M, Danish Breast Cancer Cooperative Group (DBCG) and the DBCG Radiotherapy Committee. (2002) Cosmetic outcome and breast morbidity in breast-conserving treatment--results from the Danish DBCG-82TM national randomized trial in breast cancer. *Acta Oncologica* **41**, 369-380.

Design: RCT (1982-1990)

Level 1++

Country: Denmark, setting: Multi-centre

Aim: To assess factors that may impact on late effects after BCS.

**Inclusion criteria** Recurrence free and alive

**Exclusion criteria**

**Population** number of patients = 266/343 (78%) recurrence free patients from the BCS arm

**Interventions**

Breast conservation compared with mastectomy. BCS is the focus of this paper. BCS patients received RT (50 Gy in 25 fractions over 5 weeks) and a boost dose (10Gy) to the scar and tumour bed of either photons or electrons. Adjuvant chemotherapy was offered to high risk patients.

**Outcomes**

Cosmesis, assessment made by patients and clinician.

Includes: asymmetry and contour, dyspigmentation, telangiectasia, fibrosis, oedema, pain, sensibility, body image, need to change clothing habits, plastic surgery

**Follow up** Median 6.6 years (3.5-10.5)

**Results**

194/266 (73%) of patients regarded the cosmetic result as excellent or good. This compared with 125/266 (47%) when assessed by oncologists.

*Cosmesis*

Morbidity assessments showed that breast fibrosis, skin telangiectasia, and breast retraction were significantly associated with a less satisfactory cosmetic result.

On univariate analysis, treatment with a direct anterior electron field produced more morbidity and inferior cosmetic outcomes compared with tangential photon treatment.

Photons 78% excellent/good outcome

Electrons 66% excellent/good outcome

P=0.04 (patient outcomes)

55% vs. 35% for physician assessment (p=0.002)

Anterior electron fields also led to significantly more grade 2 and 3 late reactions compared to tangential photons:

Grade  $\geq 2$  dyspigmentation 32% vs 9% ( $p < 0.001$ )

Grade  $\geq 2$  telangiectasia 42% vs 3% ( $p < 0.001$ )

Grade  $\geq 2$  breast fibrosis 29% vs 18% ( $p < 0.05$ )

On multivariate analysis cosmetic outcome remained significantly associated with electron therapy (OR 2.3 CI 1.4-4.1;  $p = 0.002$ ).

Increasing breast size was associated with increased breast retraction and breast fibrosis after tangential RT on multivariate analysis (OR 1.73 CI 1.17-2.56,  $p = 0.006$ ).

Treatment characteristics that were independently associated with a fair/poor cosmetic outcome on multivariate analysis were the use of a direct anterior electron field (OR = 2.15, CI 1.25-3.70) and adjuvant systemic therapy (OR = 2.13, CI 1.22-3.71).

#### **Author conclusions**

Patient satisfaction with BCS was high despite a high frequency of observed breast changes related to treatment with electrons, resected breast volume, and adjuvant systemic therapy. The prevalence of breast morbidity reported by patients was low.

#### **General comments -**

Updated 2018

Deutsch M, Flickinger JC (2003) Patient characteristics and treatment factors affecting cosmesis following lumpectomy and breast irradiation. *American Journal of Clinical Oncology-Cancer Clinical Trials* **26**, 350-353.

Design: Prospective Cohort (June to Nov 1999)

Level 2 -

Country: USA, setting: Single University centre

Aim: To evaluate factors influencing cosmetic outcome in women following lumpectomy and breast irradiation.

**Inclusion criteria** All women previously treated by one physician who were followed-up in a 6 month period (June-Nov 1999).

**Exclusion criteria** Bilateral breast cancer and loco-regional recurrence. Patients with previous or subsequent cosmetic surgery.

**Population** number of patients = 265 women with a unilateral breast cancer. Median age 61 years (28-85)

### Interventions

Women treated with lumpectomy with or without axillary dissection (84 lumpectomy alone; 181 lumpectomy and AXD) and post-operative breast irradiation. Irradiation with two tangential fields. A boost to operative area given in 217/265 (81.9%). Majority treated with X-rays, but Cobalt-60 was used in 83 patients. Systemic therapy administered to 188 patients [127 (47.9%) tamoxifen alone; 32 had tamoxifen and chemotherapy]. Sixty (22.6%) patients were treated with chemotherapy with or without tamoxifen. Seventy seven (29.1%) had no adjuvant systemic therapy. Cosmetic outcome assessed by the same physician who treated the patients.

### Outcomes

Cosmetic outcome factors including skin pigmentation changes, distortion of the breast, asymmetry, and differences in size between the two breasts.

**Follow up** 3-249 months (median 61)

### Results

On multivariate analysis:

- Skin pigmentation changes were significantly associated with axillary dissection ( $p = 0.0049$ ) and black race ( $p = 0.001$ ).
- An increased interval from surgery was associated with a decreased incidence of pigmentation changes ( $p = 0.0058$ ).
- Smaller size of the treated breast was associated with a longer interval from surgery ( $p < 0.0001$ ) and an increased separation between opposed tangential fields ( $P < 0.0001$ ).

128/265 (48.3%) women had an excellent cosmetic result (no skin changes or deformity and very slight or no differences in size).

110/265 (41.5%) patients had a good result (no skin changes and little difference in size between the breasts, or skin changes with no difference in size between the breasts).

27/265 (10.2%) had a fair or poor cosmesis with skin pigmentation and a difference in size or breast distortion.

An excellent or good cosmetic result versus a fair or poor result was associated with white race ( $p = 0.0056$ ), smaller separation between the tangential fields ( $p = 0.01$ ), the use of a boost dose ( $p = 0.0025$ ), and no use of tamoxifen ( $p = 0.025$ ).

**Author conclusions**

The majority of women treated with lumpectomy and breast irradiation will have a good or excellent cosmetic outcome.

**General comments –**

There does not appear to be a description of the instrument used to rate cosmetic outcome as excellent, good, fair or poor. The same physician who treated the patients also assessed cosmesis, likely to be very biased.

Updated 2019

## QUALITY OF LIFE

Whelan TJ, Levine M, Julian J, Kirkbride P, Skingley P (2000) The effects of radiation therapy on quality of life of women with breast carcinoma: Results of a randomized trial. *Cancer* **88**, 2260-2266.

Design: RCT (1984-1989)

Level 1++

Country: Canada, setting: Multi-centre

Aim: To evaluate the effect of breast irradiation after lumpectomy on quality of life, including cosmetic outcome, of patients in a clinical trial.

**Inclusion criteria** Breast carcinoma treated by lumpectomy and axillary lymph node dissection, tumour <4 cm diameter, local excision microscopically complete, and no evidence of histological involvement of axillary lymph nodes.

### Exclusion criteria

**Population** number of patients = 837 randomized

416 received RT

421 no RT

### Interventions

BCS and radiation therapy with Cobalt -60 to a dose of 40 Gy in 16 daily fractions to the whole breast over 3 weeks.

A boost dose of 12.5 Gy in 5 daily fractions was also given to the primary site.

A modified version of the Breast Cancer Chemotherapy Questionnaire (BCQ) containing 17 items (questions) was administered by a nurse.

### Outcomes

Breast Cancer Chemotherapy Questionnaire (BCQ) scores (modified version).

Irritation of the skin of the breast, breast pain, and appearance of the breast to the patient were assessed 3 monthly for the first 2 years of the study.

### Follow up

BCQ administered at baseline, 1 month and 2 months after randomisation.

Data available for 91% of patients after 2 years.

### Results

*Short term QOL*

*Effect on individual domains*

Mean change scores from baseline to 1 month and from baseline to 2 months were measured for each domain.

At 1 month the differences in mean change scores between RT and control groups were statistically significant for the fatigue, physical symptoms, and inconvenience domains. No statistically significant differences were reported for the emotional dysfunction, social, and attractiveness domains. The overall difference in score between groups was significant favouring no RT (RT = -0.07; no RT +0.21; p=0.0001). A similar pattern was observed for the overall change scores between baseline and 2 months after randomization ((RT = -0.05; no RT +0.30; p=0.0001).

A comparison of patients with a mean score reduction of  $\geq 0.5$  at 2 months was made between the 2 arms:

93/344 (27%) in the RT group experienced a reduction in scores

60/376 (16%) in the control group experienced a reduction in scores.

The difference was statistically significant ( $P = 0.0003$ ).

#### *Long term QOL*

Approximately 75% of patients responded to the 3 items (fatigue, physical symptoms, and inconvenience domains) over the 2 years since randomization.

The 3-month (12 week) assessment was performed at a median of 7 weeks after the last radiation treatment (25–75%, range 5.3– 8.7 weeks).

#### *Skin irritation*

Radiation increased the occurrence of skin irritation.

At 3 months 28% in the radiation group and 14% in the control group ( $P = 0.0001$ ) were affected. The number of patients reporting skin irritation decreased over time in both groups ( $P = 0.0001$  for trend). At 24 months 7% in each group reported this symptom.

#### *Breast pain*

A similar pattern was observed for breast pain. Radiation therapy increased the occurrence of breast pain. At 6 months after randomization 33% of patients in the radiation group and 20% in the control group reported this symptom ( $P = 0.0002$ ). Breast pain also decreased over time ( $P = 0.0001$  for trend) with approximately 15% of patients in each group reporting breast pain at 24 months.

#### *Appearance*

Dissatisfaction with the appearance of the breast was reported less frequently, with no difference between groups.

4.8% of patients in each group reported being dissatisfied at 2 years ( $P = 0.62$ ).

#### **Author conclusions**

Breast irradiation therapy had an effect on quality of life during treatment. After treatment, irradiated patients reported increased breast symptoms compared with controls. However, no difference was detected between groups at 2 years in the rates of skin irritation, breast pain, and being upset by the appearance of the breast.

#### **General comments -**

Rayan G, Dawson LA, Bezjak A, Lau A, Fyles AW, Yi Q-L, Merante P, Vallis KA (2003) Prospective comparison of breast pain in patients participating in a randomized trial of breast-conserving surgery and tamoxifen with or without radiotherapy. *International Journal of Radiation Oncology, Biology, Physics* **55**, 154-161.

Design: RCT (1992-2000; Companion study over last 2 years of trial)  
Level 1++

Country: Canada, setting: Single hospital

Aim: To determine whether breast pain affects quality of life (QOL) after breast-conserving surgery and tamoxifen (TAM) with or without adjuvant breast radiotherapy (RT).

#### **Inclusion criteria**

Women aged  $\geq 50$  years treated with breast-conserving surgery (BCS) with negative excision margins and stage T1-T2 N0 breast cancer.

#### **Exclusion criteria**

Previous diagnosis of breast cancer and disease free for  $< 10$  years

A diagnosis of another malignancy (except non-melanoma skin cancer or carcinoma in situ of the cervix)

Disease free for  $< 5$  years

Bilateral breast cancer.

**Population** number of patients = 86 patients  
(41 received RT plus TAM and 45 received TAM alone)  
Median age was 70 years (range 51-80).

#### **Interventions**

RT protocol consisted of 40 Gy in 16 fractions over 3 weeks to the whole breast and a tumour site boost of 12.5 Gy in 5 fractions over 1 week OR

A dose of 50 Gy in 25 fractions to the whole breast and no boost dose.

A coplanar pair of opposed tangential fields using 6-MV photons or Cobalt-60 radiation was administered to the whole breast. The boost was delivered with a mixed beam of photons and electrons.

Questionnaires were completed by participants within 1 week of randomization in the randomized clinical trial (baseline) and at 3, 6, and 12 months.

#### **Outcomes**

The short-form McGill Pain Questionnaire (SF-MPQ)

European Organization for Research and Treatment of Cancer (EORTC) QOL (QLQ-C30)

EORTC breast cancer module (QLQ-BR23)

#### **Follow up**

##### *Compliance*

The compliance rates for QLQ-C30 and QLQ-BR23 (physical function scale, pain symptom scale, global health status/ QOL, and breast symptom scale) were high (88–100%) at baseline and subsequent time points.

Compliance rates were similar for the other functional and symptom scales of the QLQ-C30 and QLQBR23 (88–100%), an exception was the sexual function scale of the QLQ-BR23. Compliance rates for the five items of the sexual function scale ranged from 69% to 88%.

Compliance with the SF-MPQ was lower - rates ranging from 58% to 100%.

## **Results**

### *QLQ-C30 scores*

Mean scores for each function and symptom measured by the scale were compared for each treatment group. There were no statistically significant differences in mean scores at baseline or follow-up at 3, 6 or 12 months with the exception of one parameter, role function, which was higher in the RT group than the group without RT ( $p=0.02$ ). The most commonly reported symptoms were fatigue and sleep disturbance. The scores for dyspnea, appetite and financial impact improved over time on both groups.

### *QLQ-BR23 scores*

Mean scores for each function and symptom measured by the scale were compared for each treatment group. There were no statistically significant differences in mean scores at baseline or follow-up at 3, 6 or 12 months. Arm and breast symptoms improved in both groups over the year. Women were not concerned about body image, with high scores during the study period. The scores for sexual functioning were low, however this was an older group of women (median age 70 years).

There was no statistically significant difference in pain or breast symptoms between groups. By 12 months breast and arm symptoms improved in both groups compared to baseline, and there was again no statistically significant difference between groups.

### *SF-MPQ scores*

At 3 months the RT group reported more breast pain than the tamoxifen only group, but the difference was not significant ( $p=0.47$ ). At 12 months breast pain scores had decreased in both groups but the difference was not significant ( $p=0.71$ )

Scores for acute RT toxicity did not correlate with breast pain or QOL scores at 12 months.

## **Author conclusions**

These results suggest that breast RT does not significantly contribute to breast pain or adversely impact the QOL up to 12 months after treatment in postmenopausal patients with node-negative breast cancer who take TAM.

## **General comments -**

Back M, Ahern V, Delaney G, Graham P, Steigler A, Wratten C (2005) Absence of adverse early quality of life outcomes of radiation therapy in breast conservation therapy for early breast cancer. *Australasian Radiology* **49**, 39-43.

Design: Prospective longitudinal cohort (Nov 1998- Mar 2001) Level 3

Country: NSW, Australia, setting: Multi-centre

Aim: To assess the impact of RT on acute toxicity and quality of life (QOL).

**Inclusion criteria**

Women with EBC or DCIS treated with BCS (wide excision) followed by adjuvant tangential RT.

**Exclusion criteria** Women receiving systemic cytotoxic chemotherapy

**Population** number of patients = 195 women

Mean age 56 years (range 36-81)

Node dissection 71%

Postoperative complication 15%

Postoperative oedema 21%

Cosmesis (good/excellent) 76%

**Interventions**

European Organization of Research and Treatment of Cancer Quality of Life Questionnaire (EORTC QLQ-30) and Perceived Adjustment to Chronic Illness Scale (PACIS) QoL instruments.

Eight formal assessments over a 14-month period from the commencement of adjuvant RT (weeks 0, 2, 4, 6 during RT; weeks +2, +6, +26 and +52 post-RT). Assessments included physician review, clinical examination, QoL survey, patient symptom diary and cosmesis grid photography.

**Outcomes**

EORTC QLQ-30 and PACIS questionnaires

Lethargy

Global QoL.

**Follow up**

Lethargy and global QoL at baseline and week 6 after RT treatment.

175 women had completed follow-up at the time of the analysis.

**Results**

15% received RT to the nodes

77% received a tumour site boost of RT

*Lethargy*

Of 175 women, 34.3% described lethargy as a significant disruption to normal activity during RT. At 6 weeks 7.5% reported significant lethargy.

Univariate analysis found breast discomfort to be associated with lethargy (p=0.027)

### QoL

Scores were compared at baseline and 6 weeks.

- No negative effects on QoL were noted over the time period of RT.
- EORTC demonstrated no difference in scores between baseline and 6 weeks ( $P = 0.79$ )
- PACIS demonstrated a significant improvement in functioning ( $P < 0.001$ ) from baseline to week 6.
- On univariate analysis older patient age ( $p=0.02$ ), breast discomfort ( $p=0.01$ ), nodal dissection ( $p=0.02$ ) and lethargy ( $p<0.001$ ) were associated with higher than mean PACIS scores at 6 weeks

### Author conclusions

This study confirms the minimal impact of RT on patient functioning at 6 weeks post-treatment.

### General comments –

Study includes women with invasive breast cancer and ductal carcinoma in situ. Short term study.

Updated 2018

An update search identified a further study on quality of life after treatment with radiotherapy (Lee *et al* 2008)

Lee TS, Kilbreath SL, Refshauge KM, Pendlebury SC, Beith JM, Lee MJ. Quality of life of women treated with radiotherapy for breast cancer. *Support Care Cancer* 2008;16(4):399-405.

Design: RCT

Level 1+

Country: Australia, setting: Single centre

Aim: To describe the quality of life of women undergoing radiotherapy for breast cancer.

**Inclusion criteria** Women post breast cancer surgery and receiving RT to the breast or chest wall

**Exclusion criteria**

Women receiving RT to the axilla

**Population** number of patients =64 consecutive sample

Mean age 54 ± 12 years

T I-II n=44

T III n=7

No axillary surgery n=16

Full AXD n=24

Mastectomy n=13

Lumpectomy n=48

**Interventions**

Women received BCS or mastectomy

RT to breast or chest wall

Doses 50 Gy in 25 fractions or 42.5 Gy in 16 fractions in 2 fields OR

50 Gy in 25 fractions and a supraclavicular fossa field (3 fields)

In this study women were randomized to a control and stretch group throughout the RT period.

**Outcomes**

EORTC QLQ-C30

QLQ-BR23

**Follow up**

Baseline, post RT and 7 months

**Results**

- There were no differences in scores over all time points on the EORTC QLQ-C30 and QLQ-BR23 questionnaires between the control and stretch groups.
- Global health status scores were high
- Trend towards an improvement in QoL between completion of RT and 7 month follow-up
- Fatigue increased during RT but returned to baseline at 7 months
- Breast symptoms increased from baseline to completion of RT, then

returned to baseline at 7 months

- A higher dose of RT (50 Gy vs 42.5 Gy) and more fractions (25 vs. 16) were associated with lower QoL (2 way analysis of variance)
- Fatigue after completion of RT and at 7 months was predictive of lower quality of life at the same time point (linear regression)

**Author conclusions**

Women retain a high quality of life and return to baseline function by 7 months after radiotherapy. Treatment may best be targeted to alleviate fatigue and breast symptoms during radiotherapy.

**General comments**

Updated 2018

## GUIDELINES

Whelan T, Olivotto I, Levine M, Health Canada 's Steering Committee on Clinical Practice Guidelines for the Care and Treatment of Breast Cancer. (2003) Clinical practice guidelines for the care and treatment of breast cancer: breast radiotherapy after breast-conserving surgery (summary of the 2003 update). *CMAJ Canadian Medical Association Journal* **168**, 437-439.

Design: Guideline

Level 4

Country: Canada

### Inclusion criteria

A literature search was conducted using MEDLINE from 1966 to October 2001 and CANCERLIT from 1983 to September 2001 for a systematic review of English Language articles. A nonsystematic review of the literature was continued through to April 2002.

**Exclusion criteria** Non-English language articles

### Population

### Interventions

Breast radiotherapy after BCS

### Outcomes

Local control, survival, quality of life, adverse effects of irradiation and cosmetic results.

### Follow up

### Results

**Recommendations** (taken from section 6 of the clinical practice guidelines):

- Women who undergo BCS should be advised to have postoperative breast irradiation. Omission of radiation therapy after BCS increases the risk of local recurrence.
- Contraindications to breast irradiation include pregnancy, previous breast irradiation (including mantle irradiation for Hodgkin's disease) and inability to lie flat or to abduct the arm. Scleroderma and systemic lupus erythematosus are relative contraindications.
- A number of different fractionation schedules for breast irradiation have been used. Although the most common fractionation schedule in Canada to date has been 50 Gy in 25 fractions, recent data from a Canadian trial demonstrate that 42.5 Gy in 16 fractions is as good as this more traditional schedule.
- Irradiation to the whole breast rather than partial breast irradiation is recommended.
- There is insufficient evidence to recommend breast irradiation with brachytherapy implants

or intraoperative radiation therapy. Further evaluation of these treatments in randomized trials is required.

- Additional irradiation to the lumpectomy site (boost irradiation) reduces local recurrence but can be associated with worse cosmesis compared with no boost. A boost following breast irradiation may be considered in women at high risk of local recurrence.
- Physicians should adhere to standard treatment regimens to minimize the adverse effects of breast irradiation.
- When choices are being made between different treatment options, patients must be made aware of the acute and late complications that can result from radiation therapy.
- Breast irradiation should be started as soon as possible after surgery and not later than 12 weeks after, except for patients in whom radiation therapy is preceded by chemotherapy. However, the optimal interval between BCS and the start of irradiation has not been defined.
- The optimal sequencing of chemotherapy and breast irradiation is not clearly defined for patients who are also candidates for chemotherapy. Most centres favour the administration of chemotherapy before radiation therapy. Selected chemotherapy regimens are sometimes used concurrently with radiation therapy. There is no evidence that concurrent treatment results in a better outcome, and there is an increased chance of toxic effects, especially with anthracycline-containing regimens.
- Patients should be offered the opportunity to participate in clinical trials whenever possible.

Shelley W, Trudeau M (2002) Breast irradiation in women with early stage invasive breast cancer following breast conserving surgery. Practice Guideline Report #1-2. Cancer Care Ontario.

Design: Guideline

Level 4

Country: Canada

### **Inclusion criteria**

MEDLINE and CANCELIT were searched for the years 1966-1999. Bibliographies of articles identified by the searches, recent reviews, relevant articles and personal files were reviewed. For the update entries to MEDLINE (through to December 2001), the Cochrane Library (through to Issue 4, 2001) and abstracts published in the proceedings of the annual meetings of the American Society of Clinical Oncology and the American Society of Radiation Oncology were searched for evidence relevant to this practice guideline. The most recent literature search was performed in January 2002.

### **Exclusion criteria**

#### **Population**

Adult patients with early-stage (stages I and II) invasive breast cancer who have had breast-conserving surgery.

#### **Interventions**

#### **Outcomes**

#### **Follow up**

#### **Results** (taken from the published guideline)

*Breast irradiation versus no breast irradiation:* Four randomized controlled trials and one meta-analysis compared breast irradiation versus no breast irradiation following breast-conserving surgery. Results indicated a significant decrease in local recurrence rates for patients receiving radiotherapy. In the four trials with a median follow-up of five years or longer, the relative risk reduction with breast irradiation ranged from 73 to 89%. The absolute differences ranged from 16% ( $p < 0.001$ ) to 29% ( $p < 0.0001$ ). Despite the effect on local recurrence, no difference in survival was detected in any of the five trials. Most of the patients with breast recurrence in these trials underwent mastectomy. Additional evidence from two randomized trials that examined the efficacy of breast irradiation following breast-conserving surgery, and from a meta-analysis and randomized trial that examined adverse effects of irradiation were identified and reviewed by the Breast Cancer DSG for the update. No changes were made to the recommendations at that time.

#### **Recommendations** (from the published guideline)

- Women with early stage (stages I and II) breast cancer who have undergone breast-conserving surgery (defined as excision of the tumour with clear resection margins) should be offered postoperative

breast irradiation.

- The optimal fractionation schedule for breast irradiation has not been established and the role of boost irradiation is unclear. Outside of a clinical trial, two commonly used fractionation schedules are suggested: 50 Gy in 25 fractions to the whole breast, or 40 Gy in 16 fractions to the whole breast with a local boost to the primary site of 12.5 Gy in five fractions. Shorter schedules (e.g., 40 or 44 Gy in 16 fractions) have also been used routinely in some centres. The enrolment of patients in ongoing clinical trials is encouraged.
- Women who have undergone breast-conserving surgery should receive local breast irradiation as soon as possible following wound healing. A safe interval between surgery and the start of radiotherapy is unknown, but it is reasonable to start breast irradiation within 12 weeks of definitive surgery.
- For women who are candidates for chemotherapy, the optimal sequencing of chemotherapy and radiotherapy is unknown. It is reasonable to start radiotherapy after the completion of chemotherapy, or concurrently if anthracycline-containing regimens are not used.

Country: USA

Review and literature summary

**Inclusion criteria**

9 RCTs comparing breast conserving surgery (BCS) alone with BCS and radiotherapy (RT).

**Exclusion criteria**

**Population**

**Interventions** The trials are varied in patient selection criteria, the extent of surgery and radiotherapy, and use of adjuvant systemic therapy. All were included in the EBCTCG overview (Clarke 2005).

**Outcomes**

**Follow up**

**Results**

**RCTs:**

- Older women, (>55 years of age) with small primary infiltrating ductal tumours (< 1-2 cm) and negative axillary nodes without an extensive intraductal component (EIC) or lymphatic invasion, had the lowest risk of breast recurrence when radiation was omitted in a subset analysis.
- A further analysis suggested that tamoxifen could not replace radiation therapy even in women with the most favourable tumors.
- Radiation therapy appeared to benefit all women with early-stage invasive breast cancer (including primary tumours < 2cm, histological Grade 1 and negative axillary nodes), although the magnitude of the benefit varied depending on patient selection.

An update search identified another guideline (Sautter-Bihl *et al* 2007).

Sautter-Bihl ML, Budach W, Dunst J, Feyer P, Haase W, Harms W, et al. DEGRO practical guidelines for radiotherapy of breast cancer I: breast-conserving therapy. *Strahlenther Onkol* 2007 Dec;183(12):661-6.

Design: Guideline (March 2007) Level 4  
Country: Germany (DEGRO)

**Inclusion criteria**

Guideline compiled by an expert panel of the German Society of Radiation Oncology

**Results**

**Recommendations** (from the published article)

- For invasive carcinoma postoperative RT of the breast is indicated after BCS (Level 1a evidence)
- External beam RT improves local control and increased survival (1a evidence)
- Accelerated partial-breast irradiation as a sole intraoperative or postoperative procedure instead of whole-breast RT is experimental and should not be performed except in studies (Level 3 evidence)

## Health Economics Summary

The only economic evaluation conducted in the UK (Prescott *et al.* 2007) was based on an RTC performed in Scotland and England, with a follow-up of 15 months, which assessed whether omission of RT after BCS improved quality of life (QoL) and was more cost-effective than administering RT after BCS. The study focused on EBC women aged 65 or older, at low risk of local recurrence. The RCT appeared to be appropriately conducted, with study groups being comparable at baseline and analyses conducted using an intention-to-treat approach. The follow-up period was 15 months. The type of economic evaluation was a cost-utility analysis (i.e. cost savings per QALY lost with non-RT vs RT were estimated). The study was conducted from the UK NHS perspective. The cost analysis appeared to be appropriate and reflected UK clinical practice. The results showed that no-RT for EBC patients aged 65 or older at low risk of local recurrence is likely to be cost-effective compared to RT after BCS, with a 94% of probability at a £30,000 threshold, given that omitting RT would not result in a significant loss of QALYs. In total, £215,160 could be saved per QALY lost with no-RT compared to the RT option. The authors highlighted that longer-term follow-up data still needs to be collected.

Hayman *et al.* (2000) conducted a cost-utility analysis to assess the incremental cost-effectiveness of adding RT following BCS compared to BCS alone for EBC patients aged 60, diagnosed with clinical stage I or II BC and who underwent lumpectomy and axillary dissection, from a societal perspective. They used a Markov model with 1 year cycles and a 10 year time horizon. The clinical parameters were derived from one of the identified RCTs (the National Surgical Adjuvant Breast and Bowel Project: NSABP) for being this the RTC representing best USA clinical practice and population. Utilities for the estimation of QALYs were obtained from a survey conducted on 97 BC patients treated with lumpectomy+RT using the standard gamble technique. In sensitivity analysis, utilities derived from a sample of 20 medical oncology nurses were used. Expert judgement was used to estimate the utilities of BC patients in metastatic states. The cost analysis appeared to be appropriately conducted, although health care resources used were not reported separately from the unit costs. The authors concluded that adjuvant RT after BCS for EBC patients seemed to be cost-effective, since the ICER obtained was \$28,000 per QALY, much lower than the commonly accepted threshold for USA studies (i.e. \$50,000 per QALY). The cost-effectiveness seemed to be minimally affected by changes in most of the parameters; the most influential parameters were the costs of RT and the utility scores associated with a reduction in the fear of local recurrence.

Liljegren *et al.* (1997) conducted a cost-utility analysis to assess the cost-effectiveness of routine post-operative RT compared to BCS alone in women < 80 with a unifocal BC, with stage I cancer, from a societal perspective and considering a 5-year time horizon. A decision tree was developed, which may not have been the most appropriate choice since usually Markov models are used in EBC to take account of the recurrent nature of local relapse and survival related to EBC. The clinical effectiveness was obtained from a RCT with a median of 5-year follow-up (range: 3 to 10 years), which reported recurrences and survival, although the authors did not report whether patient groups were comparable at analysis; therefore, although the RCT seemed to be appropriate in terms of randomisation and analysis (an intention-to-treat analysis was conducted), there may be potential biases that cannot be assessed due to the lack of information in the paper. Expert judgement was used to obtain the utility scores for the QALY estimation; the instrument used for that was not reported. The

cost analysis appeared to be appropriately conducted, although health care resources used were not reported separately from the unit costs.

The authors concluded that the costs per avoided recurrence and per QALY gained with postoperative RT after sector resection and axillary dissection for EBC patients with stage I tumour are high and vary considerably depending on the utility values considered. Moreover, they highlight the need to identify risk factors for local recurrence and quality of life for these patients, since cost-effectiveness of postoperative RT depends on these factors.

The last economic evaluation was published as two congress abstracts, by Alvegard *et al* (2005) and by Persson *et al* (2005), therefore limited information was available as to confidently assess the methodological quality of this study. A cost-utility analysis was conducted to assess the cost-effectiveness of post-operative RT after BCS in stage I-II BC patients considering a 10 year time horizon. A stochastic decision analytic model was developed and the clinical effectiveness was derived from the RCT SweBCG 91-RT. Time horizons of 5, 15 and 20 years seemed to have been considered. The authors concluded that postoperative RT is cost-effective in pre- and post-menopausal BC women with stage I and II undergoing BCS in Sweden only as an adjunct to no medical adjuvant treatment. As an adjunct to novel adjuvant medical treatment, RT is cost-effective in high-risk groups only.

## Health Economics Evidence Tables

Prescott RJ, Kunkler IH, Williams LJ, King CC, Jack W, van der Pol M, Goh TT, Lindley R and Cairns J. A randomised controlled trial of postoperative radiotherapy following breast-conserving surgery in a minimum-risk older population. The PRIME trial. Health Technology Assessment 2007; Vol 11(31)

### **Design:**

#### Type of economic evaluation:

Cost-utility analysis. Discounting of health benefits and costs over 1 year was conducted, using a 3.5% discount rate. Incremental cost-effectiveness ratios were estimated and uncertainty was assessed by means of bootstrapping the differences in costs and benefits, and by presenting cost-effectiveness acceptability curves (CEACs), in addition to one-way sensitivity analyses.

#### Clinical effectiveness:

RCT, with randomisation balanced by participating centre, to assess whether omission of radiotherapy (RT) after breast conserving surgery (BCS) improved quality of life (QoL) and was more cost-effective. Patients in the RCT seemed to be comparable at baseline. The follow-up period was 15 months. QALYs were estimated based on the EuroQol 5-D questionnaire.

#### Cost estimation:

NHS perspective. Cost categories included were: RT treatment, NHS transport, treatment of recurrence, medication, endocrine therapy, primary and secondary care. Cost of follow-up visits excluded since they were common to both treatment arms. Cost data sources were identified; forms and patient diaries were mainly used to collect cost data. Health care resource utilisation was reported separately from unit costs. The price year was £2004-05

**Country:** Scotland and England (UK), **setting:** NHS

### **Inclusion criteria**

EBC patients aged  $\geq 65$ , receiving endocrine therapy; medically suitable for treatment and follow up; histologically confirmed unilateral breast cancer of tumour, node, metastasis (TNM) stages T0-2, N0, M0 and with no axillary node involvement on histological assessment (i.e. at low risk of local recurrence); who had BCS with complete excision on histological assessment; able and willing to give informed consent.

### **Exclusion criteria**

Past history of pure in situ carcinoma of either breast or previous or concurrent malignancy within the past 5 years other than non-melanomatous skin cancer or carcinoma in situ of cervix; grade III cancer with lymphatic/vascular invasion.

### **Population**

255 patients were randomised to either BCS alone (128 patients) or BCS + RT (127 patients), although only 253 patients had complete baseline data.

### **Interventions**

BCS and adjuvant endocrine therapy without RT

BCS and adjuvant endocrine therapy with RT (normally 45-50Gy over 4-5 weeks, with or without a boost of 10-15 Gy, although the type of RT depended on local practice).

**Results –**

Based on the results of the cancer-specific quality of life questionnaires (EORT QLQ-C30 and EORT QLQ-BR23), overall, there were not significant differences in outcomes in either treatment group, but for significantly higher mean levels of insomnia in the non-RT group ( $p = 0.01$ ), besides a higher level of sexual functioning ( $p = 0.05$ ) and small but higher systemic therapy side effects on this group ( $p = 0.03$ ). There were not significant differences between treatment groups in terms of anxiety levels and depression. In terms of the functional status (mobility, housework and self-care) as measured by the Clackmannan Scale, there was no evidence of a treatment effect. In terms of acute morbidity, scores related to acute skin reactions were significantly worse for patients receiving RT ( $p < 0.0001$ ); no significant differences were found in terms of the scores recorded for lung reactions; fibrosis was significantly higher among RT patients (44% versus 6% at 1 year after surgery;  $p < 0.0001$ ); RT patients presented a significantly higher level of pain at 8 months ( $p = 0.03$ ), although at 12 months the levels of pain were similar between the two groups. No loco-regional recurrences were reported for any of the groups at 15 months. The number of deaths in the RT and the no RT groups were 4 and 1, respectively, at 15 months.

OUTCOME OF INTEREST	RT group	Non-RT group
Total costs (£2004-05): mean (95% CI)	3,500 (3066, 3934)	1,893 (759, 3027)
Cost difference (£2004-05): mean (95% CI)	-	-1,607 (2741, 474)
Unadjusted QALYs	0.95 (0.90, 0.99)	0.92 (0.88, 0.95)
Difference in unadjusted QALYs	-	-0.03 (-0.09, 0.03)
Difference in adjusted QALYs	-	-0.01 (-0.05, 0.04)
ICER (£ saved per QALY lost)	-	215,160

A threshold analysis conducted to identify the critical value for the recurrence rate at which RT would become cost-effective considering a 15 month time horizon (and assuming that diagnostic and treatment for recurrence would cost £20,000 and that recurrence decreases QoL by 9% and has no impact in life expectancy), it was estimated that an increase of at least 5.5% in local recurrences would be required in order to make RT cost-effective at a £30,000 threshold.

**Authors' conclusions –**

The authors concluded that no RT for this patient population is likely to be cost-effective compared to RT after BCS, with a 94% of probability at a £30,000 threshold, given that omitting RT would not result in a significant loss of QALYs. As the authors reported, the

costs differences would have been even larger, and therefore no RT would have been even more cost-effective, if a societal perspective would have been taken into account, since patients incur in substantial costs (travel and accommodation) when attending RT sessions. However, they highlighted the fact that the evidence for the longer term has yet to be determined.

**General comments –**

The RCT seemed to have been appropriate, although the sample size was not very large and several protocol changes occurred during the development of the clinical studies. It was reported that the treatment groups were comparable at baseline. The follow-up period was considerably short and did not allow for enough time to observe differences in terms of local recurrences between the treatment arms. The cost analysis seemed to have been appropriate. Bootstrapping was conducted, which allowed the assessment of uncertainty surrounding cost-effectiveness results. The patient population considered at analysis is very specific and therefore the results here obtained should not be generalised outside similar patient populations.

**Non-UK Economic Evaluations: full studies**

Hayman JA, Hillner BE, Harris JR and Weeks JC. Cost-effectiveness of routine radiation therapy following conservative surgery for early-stage breast cancer. *Journal of Clinical Oncology* 1998; 16(3):1022-1029.

**Design:**

Type of economic evaluation:

Cost-utility analysis. A Markov model was used, with cycles of 1 year and a 10 year time horizon, to assess the incremental cost-effectiveness of adding RT following BCS compared to BCS alone for EBC patients. Discounting of health benefits and costs was conducted using a 3% discount rate. A societal perspective was adopted. Sensitivity analyses were conducted on all the model parameters.

Clinical effectiveness:

A review of the literature seemed to have been conducted, although it was not stated whether it was systematic or not; the clinical parameters were derived from one of the identified RCTs (the National Surgical Adjuvant Breast and Bowel Project: NSABP) for being this the RTC representing best USA clinical practice and population, according to the authors.

Utilities for the estimation of QALYs were obtained from a survey conducted on 97 BC patients treated with lumpectomy+RT using the standard gamble technique. In sensitivity analysis, utilities derived from a sample of 20 medical oncology nurses were used. Expert judgement was used to estimate the utilities of BC patients in metastatic states.

Cost estimation:

The costs included were direct medical costs (i.e. consultation and follow-up visits, RT, salvage surgery and salvage chemotherapy administration), and patients' costs (i.e. time and transportation). BCS costs were not included since they were assumed to be the same across groups. The sources of costs and the unit costs used in the model were clearly identified; however, health care resource utilisation was not reported separately. The price year was 1995.

**Country:** USA, **setting:** societal

**Inclusion criteria**

Patients aged 60, diagnosed with clinical stage I or II BC, having already chosen to undergo BCS and having undergone a lumpectomy and axillary dissection.

**Exclusion criteria**

None stated

**Population**

A hypothetical cohort of 60-year old women with EBC

**Interventions**

BCS alone (i.e. lumpectomy plus axillary dissection) versus BCS followed by RT

**Results –**

OUTCOME OF INTEREST	BCS + RT	BCS alone
Years of life	7.81	7.81
Δ Years of life	0	-
QALYs	7.19	6.84
Δ QALYs	0.35	-
Total costs per patient (\$1995)	27,200	17,400
Δ cost per patient	9,800	-
ICER (\$1995 per QALY)	28,000	-

The ICER was insensitive to: small changes in survival associated with RT and changes in the assumption regarding the percentage of patients undergoing mastectomy followed by reconstruction versus BCS + RT as salvage treatment after local recurrence. The results were sensitive to: changes in the utility values (if anxiety derived from fear to local recurrence without RT was not considered in the analysis, the ICER increased to \$149,100 per QALY gained); changes in the costs of RT (between \$20,600 and \$35,600 per QALY when the cost of RT was decreased and increased, respectively, by 20%). If the provider's perspective was undertaken (i.e. costs of time and transportation were excluded), the ICER obtained was \$25,800 per QALY gained.

**Authors' conclusions –**

The authors concluded that adjuvant RT after BCS for EBC patients seems to be cost-effective, since the ICER obtained was \$28,000 per QALY, much lower than the commonly accepted threshold for USA studies (i.e. \$50,000 per QALY). The cost-effectiveness seemed to be minimally affected by changes in the parameters, with modifications in the costs of RT and in the health benefit derived from a reduction in the fear of local recurrence being the most influential parameters.

**General comments –**

The applicability of this study to the EBC guideline is limited since the study was conducted in USA, and the patient population and clinical practice seemed to be representative of USA, which may differ substantially from a UK context (specially in terms of clinical practice). Additionally, only women aged 60 were included, which limits the generalisability of the results to patients with different ages. The cost results may be biased in favour of RT since it was assumed that patients with local recurrence would undergo mastectomy followed by immediate reconstruction, which would lead to higher costs for the non-RT option. On the other hand, quality of life would have been biased in

favour of the non-RT group due to this assumption. The authors highlighted the limitations of the utility values used in the analysis (obtained from patients that had not experience recurrence; therefore, they may be biased, although the bias was reported to be minor after comparing the utilities with those obtained from the nurses); in addition, the limitation of considering only 60 year-old patients.

Liljegren, G., et al., The cost-effectiveness of routine postoperative radiotherapy after sector resection and axillary dissection for breast cancer stage I. Results from a randomized trial. *Annals of oncology* 1997; 8(8): p. 757-763.

**Design:**

Type of economic evaluation:

Cost-utility analysis. A decision tree was constructed to assess the cost-effectiveness of routine post-operative RT compared to BCS alone considering a 5-year time horizon. Local recurrences and QALYs were used as measures of health benefit, and a societal perspective was adopted. Costs and health benefits were discounting using a 5% discount rate.

Clinical effectiveness:

The clinical effectiveness was obtained from a RCT with a median of 5-year follow-up (range: 3 to 10 years), which reported recurrences and survival. Expert judgement was used to obtain the utility scores for the QALY estimation; the instrument used for that was not reported.

Cost estimation:

The cost categories included were: medical costs, including cost of primary treatment and of local recurrence (i.e. surgery, anaesthesia, hospital stay, radiotherapy, laboratory tests and X-ray investigations) and follow-up (i.e. mammograms, X-ray investigation, laboratory tests, cytology tests and outpatient visits); travel expenses and productivity losses due to absence from work. The cost data sources appeared to be appropriate. Resource quantities were not reported separately from the costs. The price year was 1993.

**Country:** Sweden, **setting:** societal

**Inclusion criteria**

Women < 80 with a unifocal BC, with stage I cancer: specimen histopathologically free from multifocal in situ and a maximum tumour diameter of 20mm on the preoperative mammogram; axillary nodes histopatologically free from metastases.

**Exclusion criteria**

None stated

**Population**

381 patients: 184 randomised to the RT group and 197 randomised to the non-RT group.

**Interventions**

Sector resection of the tumour bearing part of the breast, including the underlying pectoral fascia and axillary dissection, with or without postoperative RT to the breast only.

RT was administered as 54Gy in 27 fractions, five fractions a week, with no boost to the tumour bed.

Perioperative X-ray was conducted to ensure complete tumour excision, and axillary was dissected a levels I and II.

## Results –

Only results with QALYs and costs discounted at a 5% rate are presented below; the study also reported QALYs with 0% discount rate.

OUTCOME OF INTEREST	BCS + RT	BCS alone
Local recurrences developed during follow up	6	37
Local recurrence rate	0.023	0.184
All patients:		
QALYs	4.231	4.184
Total costs in SEK 1993 (£)	SEK 120,633 (£9,651)	SEK 66,187 (£5,295)
ICER: SEK (£) per avoided local recurrence in all patients	SEK 337,727 (£27,018)	-
ICER: SEK (£) per avoided local recurrence in intermediate/high risk patients	SEK 209,666 (£16,773)	-
ICER: SEK (£) per avoided local recurrence) in low risk patients	SEK 1,229,780 (£98,382)	-
ICER: SEK (£) per QALY all patients	SEK 1,125,721 (£90,058)	-
ICER: SEK (£) per QALY intermediate/high risk patients	SEK 532,609 (£42,609)	-
ICER: SEK (£) per QALY low risk patients	Dominated	-

The results of the sensitivity analysis showed the results were sensitive to modifications in the cost of RT

## Authors' conclusions –

The authors concluded that the costs per avoided recurrence and per QALY gained with postoperative RT after sector resection and axillary dissection for EBC patients with stage I tumour are high and vary considerably depending on the utility values used. Moreover, they highlight the need to identify risk factors for local recurrence and quality of life for these patients, since cost-effectiveness of postoperative RT depends on these factors.

## General comments –

A decision tree may not have been the most appropriate type of model to use within the context of EBC. A more appropriate approach may have been to use a Markov model, which is the type model usually considered when recurrences and survival are taken into account in EBC interventions. It was not reported whether patient groups were comparable at analysis; therefore, although the RCT seemed to be appropriate in terms of randomisation and analysis (an intention-to-treat analysis was conducted), there may be potential biases that cannot be assessed due to the lack of information in the paper. Utility scores may not represent actual

preferences since these were obtained from the judgement of health professionals in the BC context. The time horizon for the decision tree may not be long enough to capture all the health benefits related to RT if local recurrences for the non-RT group happen in the long term.

**Non-UK Economic Evaluations: congress abstracts**

Alvegard TA, Borg S, Ferras-Nunez J, Franzen S, Genell A, Malstrom PO, Persson U, Wallgren A, Ostlund A. The cost-effectiveness of post-operative radiotherapy after breast conservation surgery in stage I-II breast cancer in Sweden. *Journal of Clinical Oncology*, 2005. 23(16): p. 79S-79S.\*

Persson U, Borg S, Ferras-Nunez J, Franzen S, Genell A, Malmstrom P, Wallgren A, Ostlund A, Alvegard T. The cost-effectiveness of post-operative radiotherapy after breast conservation surgery in stagel-II breast cancer in Sweden. *Value in Health*, 2005. 8(6): p. A36-A36.\*

\*Note: These two congress abstracts correspond to the same study.

**Design:**

Type of economic evaluation:

Cost—utility analysis. A stochastic decision analytic model was used to assess the cost-effectiveness of post-operative RT after BCS in stage I-II BC patients considering a 10 year time horizon.

Clinical effectiveness:

Obtained from the RCT SweBCG 91-RT

Cost estimation:

Costs included health care costs, pharmaceuticals, hospice and home care. Some sources were identified and seemed appropriate, but limited information was provided in the abstract. The price year was not reported.

**Country:** Sweden, **setting:** health service, although unclear

**Inclusion criteria**

Women aged 75 or younger who had received BCS and axillary dissection in Sweden between 1991 and 1997 with a median follow up of 5 years.

**Exclusion criteria**

None stated

**Population**

1187 women in the RCT, although the population used for the model may have been hypothetical and it was not identified within the abstract.

**Interventions**

BCS alone versus BCS followed by RT

**Results –**

OUTCOME OF INTEREST	BCS + RT	BCS alone
10 year risk of local and regional recurrence	8.4	24.1
QALYs	7.73	7.60

Δ QALYs	0.13	-
Treatment costs (SEK)	101,453	97,467
Treatment costs (€)	11,300	10,800
ICER (SEK per QALY)	32,000	-
ICER (€ per QALY)	3,600	-

Consideration of longer time horizons (15 and 20 years) resulted in RT being a cost-saving strategy for preventing relapses.

**Authors' conclusions –**

The authors concluded that postoperative RT is cost-effective in pre- and post-menopausal BC women with stage I and II undergoing BCS in Sweden only as an adjunct to no medical adjuvant treatment. As an adjunct to novel adjuvant medical treatment, RT is cost-effective in high-risk groups.

**General comments –**

Little information was provided in the abstract; therefore, the limitations of the study cannot be appropriately assessed.

Updated 2018

## 6.2 When should patients with DCIS who have undergone complete excision or wide local excision (WLE) be given radiotherapy?

### Short Summary

When radiotherapy is compared to no radiotherapy following breast conserving surgery for DCIS there are RCTs that provide strong evidence that radiotherapy after breast conserving surgery to treat patients with DCIS is associated with a lower rate of ipsilateral breast recurrence compared to breast conserving surgery alone, and reduces the risk of such recurrence by approximately half (Bijker *et al.* 2006; Emdin *et al.* 2006; Fisher *et al.* 1998; (Bijker *et al.* 2006; Emdin *et al.* 2006; Fisher *et al.* 1998; Houghton *et al.* 2003; Holmberg *et al.* 2008; Houghton *et al.* 2003).

Evidence from three systematic reviews of mixed primary study designs and two large retrospective analyses, (Boyages *et al.* 1999; Fonseca *et al.* 1997; Shelley *et al.* 2006; Baxter *et al.* 2005; Smith *et al.* 2006) provide evidence that the addition of radiotherapy to breast conserving surgery reduces the risk of local recurrence.

There is strong evidence that the use of radiotherapy following breast conserving surgery to treat patients with DCIS is associated with longer disease-free survival than breast conserving surgery alone (Bijker *et al.* 2006; Emdin *et al.* 2006; Fisher *et al.* 1998). Evidence from two RCTs suggest no difference in overall survival between in patients with DCIS treated with breast conserving surgery plus radiotherapy versus breast conserving surgery alone (Fisher *et al.* 1998; Bijker *et al.* 2006). One retrospective study found no statistically significant difference in 10-year overall survival between patients treated for DCIS with local excision alone, local excision plus radiotherapy and local excision plus radiotherapy plus boost (Omlin *et al.* 2006).

There is evidence that small lesion size (<2cm), widely clear surgical margins (≥1cm), low nuclear grade and the absence of necrosis are favourable risk factors with a risk of breast cancer recurrence after 10 years of 4%-10% in patients with all four factors, and with a very small absolute risk reduction arising from radiotherapy. Guidelines associated with these two systematic reviews concluded that the evidence does not support identification of a group of patients with DCIS who can be treated routinely with breast conserving surgery without radiotherapy.

### PICO

Population	Intervention	Comparison	Outcome
Patients with DCIS including those with microinvasive tumours who have received WLE	Radiotherapy	No Radiotherapy	<ul style="list-style-type: none"> <li>• Local Recurrence Rate</li> <li>• Disease Free Survival</li> <li>• Overall Survival</li> <li>• Cosmetic Result</li> <li>• Psychological Morbidity</li> </ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

### Evidence Summary

There was a good body of high quality evidence available to address the issue of when should patients with DCIS who have undergone complete excision or wide local excision be given radiotherapy, consisting of randomised trials and systematic reviews and a small number of relevant observational studies.

The four RCTs have good applicability to this question, but do not assess cosmetic outcomes, psychological morbidity or cost-effectiveness. The non RCT studies have in general, reasonable applicability to this question and do assess quality of life outcomes, though as none were UK based studies these may be influenced by subtle cultural factors.

There is very little variability in radiotherapy regimens across the RCTs, with 50 Gy in 25 fractions being the commonest regimen but the exact type of breast conserving operation performed varies somewhat between RCTs.

There is consistency in the RCTs in relation to their direction of effect, favouring the use of RT, adjuvant to breast conserving surgery. The strength of the effect of RT from the RCTs is largely similar to that summarised in the systematic reviews.

## 1. Radiotherapy versus no radiotherapy following breast conserving surgery for DCIS:

### Local recurrence

Four RCTs provide strong evidence that radiotherapy after breast conserving surgery to treat patients with DCIS is associated with a lower rate of ipsilateral breast recurrence compared to breast conserving surgery alone, and reduces the risk of such recurrence by approximately half (Bijker *et al.* 2006; Emdin *et al.* 2006; Fisher *et al.* 1998; Houghton *et al.* 2003) (Figure 1). In addition three of these trials observed lower rates of ipsilateral recurrence in the radiotherapy arm when considering either invasive ipsilateral recurrence or non-invasive ipsilateral recurrence (Bijker *et al.* 2006; Fisher *et al.* 1998; Houghton *et al.* 2003) whereas the SweDCIS trial found no statistically significant difference for these subtypes of recurrent tumours (Emdin *et al.* 2006).

Three systematic reviews of mixed primary study designs, summarise the risk of local recurrence in patients with DCIS treated either with breast conserving surgery alone or breast conserving surgery plus RT (Table 1) and support the finding of the RCTs: that the addition of RT to breast conserving surgery reduces the risk of local recurrence.

Two recent, large retrospective analyses also found that breast conserving surgery plus radiotherapy is superior to breast conserving surgery alone in reducing local recurrence (Baxter *et al.* 2005; Rakovitch *et al.* 2007; Schouten van der Velden *et al.* 2007; Smith *et al.* 2006). A smaller observational study provided a similar result and suggested also that radiotherapy plus boost confers a further benefit in reducing local recurrence to that of conventional radiotherapy (Omlin *et al.* 2006).

### Table 1: Systematic reviews: rates of local recurrence following treatment for DCIS

Study	Size	Follow-up	Rate of local recurrence	
			BCS alone	BCS + RT
(Shelley <i>et al.</i> 2006) (cites a previous meta-analysis by Yin <i>et al.</i> 1997)	24 studies; 2407 patients	5 years	No data	10.6% (95% CI 5.6%-16.9%)
(Boyages <i>et al.</i> 1999)	36 studies; 2600 patients	5 years*	22.5% (95% CI 16.9%-28.2%)	8.9% (95% CI 6.8%-11.0%)
(Fonseca <i>et al.</i> 1997)	16 studies; 794 patients	5 years*	23% (range 8%-63%)	9% (range 4%-21%)

\* Approximated by reported mean follow-up periods

### Disease-free survival

Three RCTs provide strong evidence that the use of radiotherapy following breast conserving surgery to treat patients with DCIS is associated with longer disease-free survival than breast conserving surgery alone (Bijker *et al.* 2006; Emdin *et al.* 2006; Fisher *et al.* 1998) (Figure 2). The UKCCCR trial did not analyse survival due to low event rates (Houghton *et al.* 2003). (Houghton *et al.* 2003). An update of the original RCT (Emdin *et al.* 2006) reported no statistically significant difference in distant metastasis-free survival (Holmberg *et al.* 2008); where a total of 18 events of metastatic breast disease and breast cancer deaths occurred in the RT arm and a total of 15 in the control group (RR=1.2; 95% CI, 0.60 to 2.4).

### Overall survival

Two RCTs analysed overall survival in patients with DCIS treated with breast conserving surgery plus radiotherapy versus breast conserving surgery alone (Fisher *et al.* 1998; Bijker *et al.* 2006). Both trials found no difference in overall survival between the randomised arms (Figure 3).

One retrospective study found no statistically significant difference in 10-year overall survival between patients treated for DCIS with local excision alone, local excision plus RT and local excision plus RT plus boost (Omlin *et al.* 2006).

### Cosmesis and quality of life

Evidence from two observational studies suggests that in patients treated with breast conserving surgery plus radiotherapy, a good cosmetic result is achievable (Mills *et al.* 1997;

Claus *et al.* 2006). Clinicians rated the cosmetic result as good or excellent in 97% of cases in one series (Mills *et al.* 1997) whereas in another larger series 50% of patients perceived a good or excellent result (Claus *et al.* 2006).

Evidence from one case-control study and one observational study suggests that patients treated for DCIS with breast conserving surgery, with or without adjuvant radiotherapy have good physical health at 4-5 years follow-up (Amichetti *et al.* 1999; Claus *et al.* 2006). The same studies suggest also that in this patient group, breast conserving surgery plus radiotherapy has an adverse impact on emotional, psychological and sexual outcomes, but with uncertainty around the clinical significance of this effect (Amichetti *et al.* 1999; Claus *et al.* 2006).

### **Factors for predicting no benefit from radiotherapy**

Evidence from two good quality systematic reviews does not define clearly and consistently a low risk group of patients in whom adjuvant radiotherapy has no benefit after breast conserving surgery.

The reviews, both undertaken to inform Canadian guidelines, report on primary studies (of predominantly observational design) that examined factors which may have potential to identify patients with an acceptably low risk of recurrence when treated with breast conserving surgery without RT (Olivotto 1998; Shelley *et al.* 2006).

Olivotto (1998) identified small lesion size (<2cm), widely clear surgical margins (≥1cm), low nuclear grade and the absence of necrosis as favourable risk factors; reporting a risk of breast cancer recurrence after 10 years of 4%-10% in patients with all four factors, and with a very small absolute risk reduction arising from RT.

A second systematic review cited studies that developed the Van Yuys Prognostic Index (VNPI), which includes the four factors reported above, and also patient age (Shelley *et al.* 2006). Using VNPI it is possible to identify a group of patients with DCIS and favourable risk factors in whom there is little benefit from RT, but further observational studies have omitted RT in highly selected patients treated only with BCS and experienced high local failure rates (Shelley *et al.* 2006).

Both guidelines associated with these two systematic reviews concluded that the evidence does not support identification of a group of patients with DCIS who can be treated routinely with breast conserving surgery without RT.

An observational study of breast conserving surgery alone or with RT (Omlin *et al.* 2006) identified, in addition to RT, younger age and positive/unknown margin status as independent risk factors for local failure (Omlin *et al.* 2006).

A large retrospective analysis (Smith *et al.* 2006) found, at a median follow-up of 5 years, that in patients of age 66 years or more, advanced age was protective with regard to breast cancer events, but large tumour size, comedo histology and high grade were predictive factors for breast cancer events. Using these factors to define groups according to risk, the absolute risk reduction arising from RT in addition to breast conserving surgery alone was statistically significant both in the low risk sub group (ARR 7%) and the high risk subgroup (ARR 10%);  $p < 0.001$  in each case (Smith *et al.* 2006).

One observational study aimed to measure the utility (i.e. a measure of value, or desirability) attributed by patients and non patients for different hypothetically proposed outcomes that can

follow treatment for DCIS by either lumpectomy or lumpectomy plus RT (Hayman *et al.* 2005). Participants had strongest utility for being free of invasive recurrence. For outcomes that follow treatment with breast conserving surgery plus RT, patients had higher utility for being recurrence-free than did non-patients.

Rakovitch *et al.* (2007) evaluated the risk of local recurrence risk among women with multifocal DCIS who were treated with breast conserving surgery and to determine whether multifocality is an independent risk factor for local recurrence in a retrospective study. Among women treated with breast conserving surgery only, 21% developed local recurrence as compared with 9% of women treated with breast conserving surgery and radiotherapy. The 5 year actuarial local recurrence free survival rates were 85% for women treated with breast conserving surgery alone and 93% for those treated with BCS plus radiotherapy. Median time to local recurrence was 4.2 years (Range; 0.3-16.7 years) following BCS Alone and 3.0 years (Range; 0.6-8.7) following BCS + RT. On univariate analysis, administration of radiation (HR: 0.48 (95% CI; 0.30-0.75), P=0.002), presence of comedonecrosis (HR: 1.7 (95% CI; 1.02-2.85), P=0.04) and resection margins of 4mm or smaller (HR: 1.89 (1.20-2.98), P=0.006), were significantly associated with the development of local recurrence. Administration of radiation and positive or close resection margins ( $\leq 4$ mm) were associated with the development of an invasive recurrence. On multivariate analysis multifocality (HR: 1.8 (95% CI; 1.2-2.8), P=0.01), radiotherapy (HR 0.46 (95% CI; 0.29-0.74), P=0.001), margin width 4mm or smaller (HR: 1.7 (95% CI; 1.0-2.9), P=0.04) and high nuclear grade (HR: 1.6 (95% CI; 1.0-2.7), P=0.04) were predictors of local recurrence. For women treated with breast conserving surgery alone, the 5 year actuarial local recurrence free survival rates were 82% for women with multifocal disease and 87% for those with unifocal disease. At ten years the recurrence-free survival rate was significantly lower; 59% for women with multifocal disease compared to 80% for women with unifocal disease (p=0.02). There was no significant impact of multifocality among women that received radiation therapy.

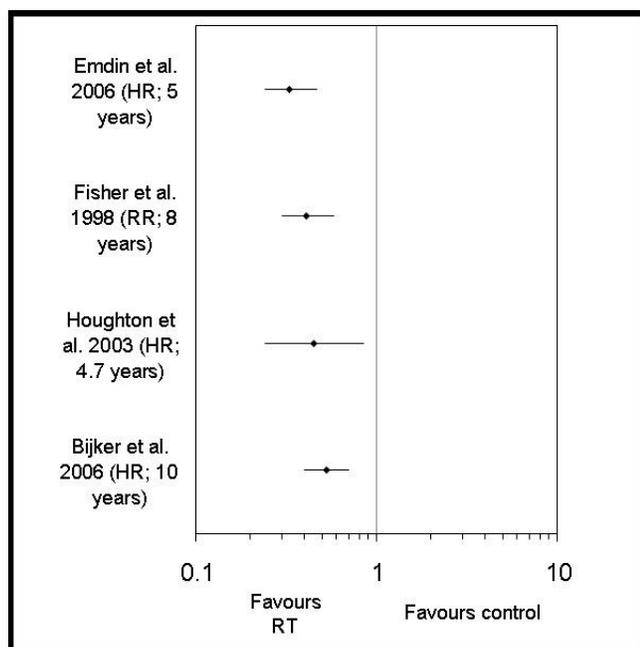

## **2. Adjuvant tamoxifen in patients who are not treated with radiotherapy**

### **Local recurrence**

One RCT provided a subgroup analysis of the effect of adjuvant tamoxifen versus no adjuvant therapy in 1053 patients treated for DCIS with primary complete local excision, who did not receive radiotherapy (Houghton *et al.* 2003). Within this subgroup there was no statistically significant difference between randomised arms in the incidence of ipsilateral invasive recurrence or ipsilateral DCIS (Figure 4).

This study did not analyse the rate of contralateral breast events alone in this subgroup. Analysing events in either breast together, there was no statistically significant difference in the incidence of total breast tumours (invasive plus DCIS) or invasive tumours alone. However there were statistically significantly fewer recurrent DCIS tumours in the tamoxifen arm compared to the control arm (Figure 4). This study did not analyse survival.

## Further details from randomised trials

NB: For further details of non RCT studies, see related evidence table.

### EORTC 10853

The EORTC 10853 trial randomised 1010 patients treated initially with complete local excision for DCIS to either 50 Gy RT in 25 fractions in 5 weeks or no further treatment (Bijker *et al.* 2006).

The trial reported a statistically significant advantage for patients treated with RT in terms of local recurrence-free survival, which in addition, held true when invasive recurrences or DCIS recurrences were considered individually. The 10-year estimated local recurrence-free survival rate was 85% in the RT group versus 74% in the control group; Hazard ratio (HR; RT:control) 0.53 [95% CI 0.40-0.70],  $p < 0.0001$ , log-rank test. The 10-year estimated local recurrence-free survival rate (DCIS recurrence only) was 93% in the RT group versus 86% in the control group; HR (RT:control) 0.52 [95% CI 0.34-0.77],  $p = 0.0011$ , log-rank test. The 10-year estimated local recurrence-free survival (invasive recurrence only) was 92% in the RT group versus 87% in the control group; HR (RT:control) 0.58 [95% CI 0.39-0.86],  $p = 0.0065$ , log-rank test.

The trial demonstrated a statistically significant advantage arising from adjuvant RT in terms of disease-free survival at 10 years' follow-up, whereas there was no difference at 10 years follow up for overall survival. The 10-year estimated rate of disease-free survival was 76% in the RT group versus 70% in the control group; HR (RT:control) 0.72 [95% CI 0.57-0.91],  $p = 0.0066$ , log-rank test. The 10-year estimated rate of overall survival was 95% in the RT group versus 95% in the control group; HR (RT:control) 1.18 [95% CI 0.70-1.96],  $p = 0.53$ , log-rank test.

### NSABP B-17

The NSABP B-17 trial randomised 818 patients with DCIS detected either by physical examination or mammography to either lumpectomy (excision, with tumour free margin) plus 50 Gy RT in 2 Gy fractions or lumpectomy alone (Fisher *et al.* 1998).

The trial demonstrated an advantage in disease-free survival at 8 years' follow-up arising from adjuvant RT, but with little difference in overall survival between randomised groups. The estimated 8-year rate of disease-free survival was 75% in the RT group versus 62% in the control group;  $p = 0.00003$ , log-rank test; Relative risk (RR; Control:RT) 1.74 [95% CI 1.34-2.26],  $p = 0.00003$ , log-rank test. There was no statistically significant difference in the 8-year estimated rate of overall survival in the RT group (95%) versus the control group (94%); RR (control:RT) 1.07 [95% CI 0.82-1.39],  $p = 0.84$ , log-rank test.

RT also resulted in a lower rate of local recurrence. The estimated 8-year rate of all ipsilateral local recurrence as the first event was 12.1% in the RT group versus 26.8% in the control group; RR (Control: RT) 2.44 [95% CI 1.72-3.45],  $p < 0.000005$ , log-rank test. The estimated 8-year rate of invasive ipsilateral local recurrence as first event was 8.2% in the RT group versus 13.4% in the control group; RR (control: RT) 3.45 [95% CI 2.00-5.95],  $p < 0.000005$ , log-rank test. The estimated 8-year rate of non-invasive ipsilateral local recurrence as first

event was 3.9% in the RT group versus 13.4% in the control group; RR (Control: RT) 1.87 [95% CI 1.19-2.93],  $p < 0.007$ , log-rank test.

## **SweDCIS**

The SweDCIS trial randomised 1067 patients treated with sector resection for histologically proven DCIS occupying one quadrant or less of the breast to either 50 Gy RT in 25 fractions over 5 weeks or no further treatment (Emdin *et al.* 2006).

At 5 years' follow up there were statistically significantly fewer cases of local recurrence in the RT group compared to the control group. The estimated 5-year rate of ipsilateral local recurrence was 7% in the RT group versus 22% in the control group; HR (RT:control) 0.33 [95% CI 0.24-0.47],  $p < 0.0001$ , log-rank test. There was no statistically significant difference in the proportion of ipsilateral recurrences that presented as invasive tumours: 47.7% in the RT group versus 41.0% in the control group; difference: 6.7% [95% CI -10.0% to 23.3%].

Disease-free survival over the entire follow-up period was statistically significantly longer in the RT group compared to the control group ( $p < 0.001$ , log-rank test). For example the estimated 5-year disease-free survival was 87% in the control group versus 72% in the control group. This study did not analyse overall survival.

An update study by Holmberg 2008 showed that there were 64 ipsilateral events in the RT arm and 141 in the control group corresponding to a risk reduction of 16.0 percentage points at 10 years (95% CI, 10.3% to 21.6%) and a relative risk of 0.40 (95% CI, 0.30 to 0.54). Out of the 64 ipsilateral events; 59.4% (in the RT arm) and 45.4% (in the control arm) were invasive. There was no statistically significant difference in distant metastasis-free survival. A total of 18 events of metastatic breast disease and breast cancer deaths occurred in the RT arm and a total of 15 in the control group (RR=1.2; 95% CI, 0.60 to 2.4). There was an effect modification by age, yielding a low effect of RT in women younger than 50, but substantial protection in women older than 60 years. The age effect was not confounded by focality, lesion size, completeness of excision, or detection mode. There was no group as defined by study stratification variables that had a low risk without radiotherapy. There were signs of increasing effect of RT by age although this was not significant ( $p = 0.07$  for interaction between RT and age-group). There were no indications of effect modification on RT for any other factors examined.

## **UKCCCR**

The UKCCCR trial aimed to examine the individual effects of adjuvant RT and adjuvant tamoxifen in 1694 patients with predominantly screen-detected DCIS, all of whom were treated initially with complete local excision (Houghton *et al.* 2003).

The study had a 2X2 factorial design by which 912 patients chose to enter randomisation to one of four treatment combinations of RT, tamoxifen, RT plus tamoxifen, or no adjuvant therapy. A further 664 patients made a choice whether to undergo RT or forego RT and accepted randomisation to either tamoxifen or no tamoxifen. A further 118 patients made a choice whether to receive tamoxifen or forego tamoxifen and accepted randomisation to either RT or no RT.

### **a) Radiotherapy versus control**

1030 patients were randomly allocated to either RT or control, of whom a proportion received tamoxifen in addition (55% and 53% respectively). There were statistically significantly fewer ipsilateral breast cancer events in patients randomised to RT compared to those randomised to control, which held true when analysing invasive events and DCIS events individually. The rate of ipsilateral (DCIS + invasive) breast events was 6% in the RT arm versus 14% in the control arm; HR 0.38 [95% CI 0.25-0.59],  $p < 0.0001$ , stratified log-rank test. The rate of new ipsilateral invasive events was 3% in the RT arm versus 6% in the control arm; HR 0.45 [95% CI 0.24-0.85],  $p = 0.01$ , stratified log-rank test. The rate of new ipsilateral DCIS events was 3% in the RT arm versus 7% in the control arm; HR 0.36 [95% CI 0.19-0.66],  $p = 0.0004$ , stratified log-rank test.

#### **b) Tamoxifen in the patient subgroup that did not receive radiotherapy**

This trial also provided a subgroup analysis of new breast events in patients randomised to tamoxifen or control, stratified by whether or not they received RT. In the subgroup of patients who did not receive RT there was no statistically significant difference between randomised arms in the incidence of ipsilateral invasive recurrence or ipsilateral DCIS. The rate of ipsilateral invasive breast events was 5% in the tamoxifen arm versus 4% in the control arm; HR 1.32 [95% CI 0.81-2.14],  $p = 0.26$ , stratified log-rank test. The rate of ipsilateral DCIS events was 6% in the tamoxifen arm versus 9% in the control arm; HR 0.73 [95% CI 0.51-1.06],  $p = 0.10$ , stratified log-rank test.

This study did not analyse the rate of contralateral breast events alone in the subgroup of patients that did not receive RT, but analysed new breast events that occurred in either breast together in this subgroup: there was no statistically significant difference in the incidence of total breast tumours (invasive plus DCIS) or invasive tumours alone. The rate of total breast events (invasive + DCIS; ipsilateral + contralateral tumours) was 12% in the tamoxifen arm versus 15% in the control arm; HR 0.80 [95% CI 0.61-1.05],  $p = 0.11$ , stratified log-rank test. The rate of total invasive (ipsilateral + contralateral tumours) was 5% in the tamoxifen arm versus 5% in the control arm; HR 1.11 [95% CI 0.72-1.72],  $p = 0.64$ , stratified log-rank test. However there were statistically significantly fewer recurrent DCIS tumours in the tamoxifen arm compared to the control arm: respective rates were 6% versus 10%; HR 0.68 [95% CI 0.47-0.97],  $p = 0.03$ , stratified log-rank test. This study did not analyse survival.

## Evidence Tables

Fisher, Dignam, Wolmark, Mamounas, Costantino, Poller, Fisher, Wickerham, Deutsch, Margolese, Dimitrov & Kavanah . Lumpectomy and radiation therapy for the treatment of intraductal breast cancer: findings from National Surgical Adjuvant Breast and Bowel Project B-17. Journal of clinical oncology : official journal of the American Society of Clinical Oncology 16[2], 441-452. 1998.

### Design

Design: Randomized controlled trial (therapy), evidence level: 1+  
Country: USA, setting: Secondary care

### Inclusion criteria

818 patients with DCIS detected either by physical examination or mammography; including those with diffuse calcifications on mammography, where excised tissue margins showed histologically no tumour.

### Exclusion criteria

Positive margin of excised tissue;  
Clinically or histologically involved axillary nodes;  
History of previous cancer, excluding carcinoma in situ of the cervix or basal cell carcinoma of the skin

### Population

number of patients = 818.

### Interventions

Aim: to examine the effect of RT after lumpectomy to treat patients with DCIS.

RT group (n=413): underwent lumpectomy (excision, with tumour free margin) plus 50 Gy RT in 2 Gy fractions.

No RT group (n=405): underwent lumpectomy alone.

### Outcomes

Ipsilateral local recurrence;  
Second ipsilateral primary tumour;  
Contralateral breast cancer;  
Regional or distant metastasis;  
Death.

### Follow up

Clinical examination was performed every 6 months and mammography each year.

Mean duration 90 months (range 67-130 months).

### Results

Survival:

Estimated 8-year rate of disease-free survival:

RT group: 75%

No RT group: 62%; p=0.00003, log-rank test.

Relative risk (RR; No RT:RT) 1.74 [95% CI 1.34-2.26], p=0.00003, log-rank test.

Estimated 8-year rate of overall survival:

RT group: 95%

No RT group: 94%

RR (No RT:RT) 1.07 [95% CI 0.82-1.39], p=0.84, log-rank test.

Local recurrence:

Estimated 8-year rate of all ipsilateral local recurrence as first event:

RT group: 12.1%

No RT group: 26.8%

RR (No RT: RT) 2.44 [95% CI 1.72-3.45], p<0.000005, log-rank test.

Estimated 8-year rate of invasive ipsilateral local recurrence as first event:

RT group: 8.2%

No RT group: 13.4%

RR (No RT: RT) 3.45 [95% CI 2.00-5.95], p<0.000005, log-rank test.

Estimated 8-year rate of non-invasive ipsilateral local recurrence as first event:

RT group: 3.9%

No RT group: 13.4%

RR (No RT: RT) 1.87 [95% CI 1.19-2.93], p<0.007, log-rank test.

Other events:

Estimated 8-year rate of all events as first event (combined) excluding ipsilateral recurrence:

RT group: 12.5%

No RT group: 11.0%

RR (No RT:RT) 0.99 [95% CI 0.64-1.52], p=0.96, log-rank test.

Individual relative risks of regional recurrence, non-breast cancer primary tumour, contralateral breast cancer tumour and distant breast cancer metastasis (RT:No RT; p values from log-rank test):

Regional recurrence: 1.81 [95% CI 0.33-9.86], p=0.79

Non-breast cancer primary: 1.26 [95% CI 0.56-2.85], p=0.72

Contralateral tumour: 1.32 [95% CI 0.65-2.67], p=0.55

Distant metastasis: 0.90 [95% CI 0.18-4.47], p=0.99

### **General comments**

Proportion of patients with pure DCIS or microscopic invasion is not known.

Age distribution similar between randomised groups.

Randomisation was stratified for age (<=49 or >49 years), tumour type (DCIS or DCIS +

LCIS), method of detection (mammography, clinical examination or both) and axillary dissection (performed or not performed).

Axillary dissection was obligatory at study outset but became optional during the study period.

18 patients (RT: 12, No RT: 6) were ineligible but are included in the analysis. 4 patients (2 in each group) were lost to follow-up and were not included in the analyses. Study does not report whether analysis is by intention-to-treat.

Study reports its relative risk outcomes as either RT:No RT or the reciprocal, No RT:RT.

Bijker, Meijnen, Peterse, Bogaerts, Van, Julien, Gennaro, Rouanet, Avril, Fentiman, Bartelink & Rutgers . Breast-conserving treatment with or without radiotherapy in ductal carcinoma-in-situ: ten-year results of European Organisation for Research and Treatment of Cancer randomized phase III trial 10853--a study by the EORTC Breast Cancer Cooperative Group and. J Clin Oncol 24[21], 3381-3387. 2006.

## **Design**

Design: Randomized controlled trial (therapy), evidence level: 1++  
Country: European States, setting: Secondary care

## **Inclusion criteria**

1010 patients treated initially with complete local excision for DCIS with no histological evidence of DCIS at the surgical margin. Other criteria:

Tumour diameter  $\leq 5$ cm;

No evidence of invasive disease or Paget's disease;

## **Exclusion criteria**

Age  $> 70$  years;

Pregnancy;

Previous/concomitant malignancy except for treated basal cell carcinoma of skin or treated carcinoma in situ of the cervix;

WHO performance status  $\geq 2$ ;

Mental or social condition precluding follow-up

## **Population**

number of patients = 1010, median age = 53 years.

## **Interventions**

Aim: to examine the effect of RT after complete local excision of DCIS.

RT group (n=507): underwent 50 Gy RT in 25 fractions in 5 weeks. No boost was advised.

No RT group (n=503): underwent no further treatment.

## **Outcomes**

Invasive and non-invasive recurrence in the treated breast;

Regional recurrence;

Metastasis;

Death;

Contralateral breast cancer.

## **Follow up**

Patients were followed at 6-monthly intervals until the 10th postoperative year and then at annually intervals. Bilateral mammograms were performed every year.

Median duration 10.5 years.

## Results

### Local recurrence:

4-year estimated local recurrence-free survival was 91% in the RT group versus 84% in the No RT group; HR (RT:No RT) 0.62 [95% CI 0.44-0.87],  $p=0.005$ , log-rank test.

4-year estimated local recurrence-free survival (DCIS recurrence only) was 95% in the RT group versus 92% in the No RT group; HR (RT:No RT) 0.65 [95% CI 0.41-1.03],  $p=0.06$ , log-rank test.

4-year estimated local recurrence-free survival (invasive recurrence only) was 96% in the RT group versus 92% in the No RT group; HR (RT:No RT) 0.60 [95% CI 0.37-0.97],  $p=0.04$ , log-rank test.

10-year estimated local recurrence-free survival was 85% in the RT group versus 74% in the No RT group; HR (RT:No RT) 0.53 [95% CI 0.40-0.70],  $p<0.0001$ , log-rank test.

10-year estimated local recurrence-free survival (DCIS recurrence only) was 93% in the RT group versus 86% in the No RT group; HR (RT:No RT) 0.52 [95% CI 0.34-0.77],  $p=0.0011$ , log-rank test.

10-year estimated local recurrence-free survival (invasive recurrence only) was 92% in the RT group versus 87% in the No RT group; HR (RT:No RT) 0.58 [95% CI 0.39-0.86],  $p=0.0065$ , log-rank test.

### Regional recurrence:

10-year estimated regional recurrence free-survival was 99% in the RT group versus 97% in the No RT group; HR (RT:No RT) 0.46 [95% CI 0.20-1.07],  $p=0.064$ , log-rank test.

### Contralateral breast cancer:

4-year estimated contralateral breast cancer-free survival was 97% in the RT group versus 99% in the No RT group; HR (RT:No RT) 2.57 [95% CI 1.24-5.33];  $p=0.01$ , log-rank test.

10-year estimated contralateral breast cancer-free survival was 92% in the RT group versus 96% in the No RT group; HR (RT:No RT) 1.41 [95% CI 0.87-2.30],  $p=0.16$ , log-rank test.

10-year estimated contralateral (as DCIS) breast cancer-free survival was 98% in the RT group versus 98% in the No RT group; HR 1.10 (RT:No RT) [95% CI 0.47-2.59],  $p=0.82$ , log-rank test.

10-year estimated contralateral (as invasive tumour) breast cancer-free survival was 94% in the RT group versus 97% in the No RT group; HR (RT:No RT) 1.48 [95% CI 0.83-2.65],  $p=0.18$ , log-rank test.

**Distant metastasis:**

4-year estimated distant metastasis-free survival was 99% in the RT group versus 98% in the No RT group; HR (RT:No RT) 0.98 [95% CI 0.44-2.18]; p=0.96, log-rank test.

10-year estimated distant metastasis-free survival was 96% in the RT group versus 96% in the No RT group; HR (RT:No RT) 1.14 [95% CI 0.63-2.08]; p=0.66, log-rank test.

**Overall survival:**

4-year overall survival was 99% in the RT group and 99% in the No RT group; HR (RT:No RT) 0.97 [95% CI 0.44-2.16], p=0.94, log-rank test.

10-year overall survival was 95% in the RT group versus 95% in the No RT group; HR (RT:No RT) 1.18 [95% CI 0.70-1.96], p=0.53, log-rank test.

**Disease-free survival:**

4-year disease-free survival was 86% in the RT group versus 82% in the No RT group; HR (RT:No RT) 0.82 [95% CI 0.61-1.10], p=0.2, log-rank test.

10-year estimated disease-free survival was 76% in the RT group versus 70% in the No RT group; HR (RT:No RT) 0.72 [95% CI 0.57-0.91], p=0.0066, log-rank test.

**General comments**

Cited data originate in part from earlier trial publication: Julien et al. (2000).

Trial was performed in 46 centres in 13 countries.

41 patients were randomised although they did not meet the inclusion criteria; generally we would expect poorer prognosis in these patients as a result. 30 patients received treatment as per the opposite arm to their randomised arm and 5 patients received RT outside of the stipulated 12 weeks from surgery. 25 patients received a boost of RT to the site of surgery. 8 patients were lost to follow-up; 3 in the No RT group and 5 in the RT group. All analyses were by intention-to-treat.

Re: population: the trial included a central pathology review: sufficient data was available in 863 (85%) patients. Invasive tumour was found or suspected in 40 cases and benign proliferative lesions or LCIS in 48 cases; therefore an estimated 91% of randomised patients had pure DCIS.

Emdin, Granstrand, Ringberg, Sandelin, Arnesson, Nordgren, Anderson, Garmo, Holmberg & Wallgren . SweDCIS: Radiotherapy after sector resection for ductal carcinoma in situ of the breast. Results of a randomised trial in a population offered mammography screening. Acta Oncol 45[5], 536-543. 2006.

### **Design**

Design: Randomized controlled trial (therapy), evidence level: 1++  
Country: Sweden, setting: Secondary care

### **Inclusion criteria**

1067 patients treated with sector resection for histologically proven DCIS occupying one quadrant or less of the breast.

### **Exclusion criteria**

Paget's disease of the nipple;  
Invasive carcinoma or intracystic carcinoma in situ;  
Pregnancy;  
Previous or concurrent malignancy excluding treated basal cell skin carcinoma or carcinoma in situ of the cervix;  
Doubtful surgical margin (see comment)

### **Population**

number of patients = 1067, mean age = 56 years.

### **Interventions**

Aim: to examine the effect of RT following breast conserving surgery for DCIS. All patients underwent breast sector resection with a 1cm macroscopic surgical margin and mandatory specimen X-ray. Following surgery patients were randomised as follows:

RT group (n=534): received 50 Gy RT in 25 fractions over 5 weeks or 54 Gy in two series with a gap of two weeks. No boost was given.

No RT group (n=533): received no further treatment.

### **Outcomes**

Ipsilateral breast recurrence;  
Ipsilateral regional recurrence;  
Contralateral breast cancer;  
Distant metastasis;  
Death (any cause);  
Death due to breast cancer.

### **Follow up**

Biannual clinical examination plus annual mammography for five years; thereafter annual clinical examination and mammography.

Median duration 5.2 years

## Results

Estimated 5-year rate of ipsilateral local recurrence:

RT group (44 events): 7%

No RT group: (117 events): 22%

HR (RT: No RT) 0.33 [95% CI 0.24-0.47],  $p < 0.0001$ , log-rank test.

Proportion of ipsilateral recurrences that presented as invasive tumours:

RT group: 21/44 = 47.7%

No RT group: 48/117 = 41.0%

Difference: 6.7% [95% CI -10.0% to 23.3%]

Estimated 5-year rate of contralateral breast cancer:

RT group (26 events): 3.3%

No RT group: (22 events): 3.2%

HR (RT: No RT) 1.16 [95% CI 0.62-2.14],  $p = 0.64$ , log-rank test.

Proportion of cases of contralateral breast cancer that presented as invasive tumours:

RT group: 23/26 = 88.5%

No RT group: 15/22 = 68.2%

Difference: 20.1% [95% CI -3.0% to 42.5%]

Estimated 5-year rate of combined distant metastasis or deaths due to breast cancer:

RT group (9 events): 1.3%

No RT group (9 events): 0.5%

HR 1.02 [95% CI 0.40-2.56],  $p = 0.97$

Disease-free survival over the entire follow-up period was statistically significantly longer in the RT group compared to the No RT group ( $p < 0.001$ , log-rank test); e.g. estimated 5-year disease-free survival:

RT group: 87%

No RT group: 72%

## General comments

Multi-centre trial with 58 contributing centres.

Completeness of surgical excision was assessed by operative findings, pathology report and specimen X-ray. Cases of doubtful margin were not randomised.

47 patients received treatment that violated the protocol for their randomised arm. No patients were lost to follow-up. 19 patients in the RT group plus 14 patients in the No RT group received systemic anti-oestrogen therapy. All analyses were by intention-to-treat.

Histological re-evaluation by three pathologists was planned for a sample of 20% ( $n = 212$ ) of randomised patients. Of these, 93% (198) had slides available. Of these, 163 (83%) were classified as pure DCIS; the remainder were either benign, atypical ductal hyperplasia, invasive/microinvasive ductal carcinoma, LCIS or inconclusive.

Holmberg, L., Garmo, H., Granstrand, B., Ringberg, A., Arnesson, L.A., Sandelin, K., Karlsson, P., Anderson, H., Emdin, S. (2008) Absolute Risk Reductions for Local Recurrence After Postoperative Radiotherapy After Sector Resection for Ductal Carcinoma In Situ of the Breast. *Journal of Clinical Oncology* 26;8:1247-1252

Design: Randomised Controlled Trial      Evidence Level: 1++ (from original RCT Emdin et al. 2006)

Country: Sweden

Aim: To evaluate the effects of radiotherapy following sector resection for DCIS in patient groups defined by age, lesion size, focality, completeness of excision and mode of detection.

Inclusion criteria:

Women who underwent breast conserving surgery for histologically proven DCIS occupying a quadrant or less of the breast and with a clinically negative examination of the axilla.

Exclusion criteria:

Paget's disease of the nipple, invasive carcinoma or intracystic carcinoma in situ, ongoing pregnancy, history of previous or concurrent malignancy (except basal cell carcinoma and treated carcinoma in situ of the uterine cervix).

Population: 1067 randomised to RT or control

21 patients excluded due to protocol violations prior to receiving RT

Interventions: Patients were randomised to receive radiotherapy or control following a sector resection where macroscopic lateral and medial margins of at least one centimetre were aimed for.

Outcomes: New ipsilateral breast events and distant metastasis-free survival. The data were analysed according to intention to treat.

The absolute risk reduction of the cumulative incidence proportion of local recurrence.

Results:

There were 64 ipsilateral events in the RT arm and 141 in the control group corresponding to a risk reduction of 16.0 percentage points at 10 years (95% CI, 10.3% to 21.6%) and a relative risk of 0.40 (95% CI, 0.30 to 0.54). Out of the 64 ipsilateral events; 59.4% (in the RT arm) and 45.4% (in the control arm) were invasive

- There was no statistically significant difference in distant metastasis-free survival. A total of 18 events of metastatic breast disease and breast cancer deaths occurred in the RT arm and a total of 15 in the control group (RR=1.2; 95% CI, 0.60 to 2.4).
- There was an effect modification by age, yielding a low effect of RT in women younger than 50, but substantial protection in women older than 60 years. The age effect was not confounded by focality, lesion size, completeness of excision, or detection mode. There was no group as defined by study stratification variables that had a low risk without radiotherapy. There were signs of increasing effect of RT by age although this was not significant ( $p = 0.07$  for interaction between RT and age-group).

- There were no indications of effect modification on RT for any other factors examined.

Authors Comment:

RT substantially reduces the risk of local recurrence after a sector resection for DCIS.

General comments:

Author Comment: The findings by age were not likely to have been confounded by the use of exogenous hormones or hormone therapy. Hormone replacement therapy was considered strictly contraindicated in all women with a previous breast cancer in situ at the time in Sweden. Tamoxifen was used by less than 4% in the cohort and none of the women underwent hormone ablation.

Houghton, George, Cuzick, Duggan, Fentiman, Spittle, UK Coordinating Committee on Cancer Research, Ductal Carcinoma in situ Working Party, DCIS trialists in the UK, Australia & and . Radiotherapy and tamoxifen in women with completely excised ductal carcinoma in situ of the breast in the UK, Australia, and New Zealand: randomised controlled trial. Lancet 362[9378], 95-102. 2003.

## **Design**

Design: Randomized controlled trial (therapy), evidence level: 1-  
Country: UK, Australia, New Zealand, setting: Secondary care

## **Inclusion criteria**

1694 patients with unilateral or bilateral screen-detected or DCIS who were candidates for breast conserving surgery; including:

- Symptomatic patients in whom DCIS was confirmed in the same way as in screening clinics;
- Patients with microinvasion <1mm in diameter, provided histologically clear margins were obtained. This group comprised 59 patients (3%).

Age distribution largely reflects screened population: modal age group 50-54 years; 90% of patients were of age >50 years i.e. older than the other RCT populations.

## **Exclusion criteria**

LCIS or atypical ductal hyperplasia;  
Doubtful histological margins;  
Paget's disease of the nipple;  
Patients with reduced life expectancy due to concomitant illness or malignancy;  
Patients considered unsuitable for any of the treatment options.

A total of 7 patients were excluded (from an original study size of 1701) after randomisation.

## **Population**

number of patients = 1694.

## **Interventions**

Aim: to investigate the individual effects of radiotherapy and tamoxifen as adjuvant treatment for DCIS following complete local excision.

All patients underwent complete local excision.

2X2 factorial design:

912 patients chose to enter randomisation to one of four treatments:

RT + tamoxifen:	242
Tamoxifen alone:	224
RT alone:	220
No treatment:	226

782 patients chose 2-way randomisation:

664 patients made a choice re: RT and were randomised to either tamoxifen or no tamoxifen:

RT + Tamoxifen:	30
Tamoxifen alone:	298
RT alone:	31
No treatment:	305

118 patients made a choice re: tamoxifen and were randomised to either RT or no RT:

RT + Tamoxifen:	44
Tamoxifen alone:	45
RT alone:	16
No treatment:	13

Tamoxifen comprised 20mg daily for 5 years.

RT comprised 50 Gy in 25 fractions over 5 weeks.

### **Outcomes**

Ipsilateral breast recurrence;

Contralateral breast cancer;

New cancer (non-breast);

Death; breast cancer related or not.

Time-to-event analysis was by the life table method and the stratified log-rank test.

### **Follow up**

Yearly bilateral mammography for the first 7 years and every 2 years thereafter.

Median duration 56.2 months (range 2.4-118.3 months).

### **Results**

1. Effect of tamoxifen (1576 patients in the randomised tamoxifen comparison)

New ipsilateral invasive events:

Tamoxifen: 45 (6%)

Control: 35 (4%)

HR 1.31 [95% CI 0.84-2.03], p=0.23, stratified log-rank test.

New ipsilateral DCIS events:

Tamoxifen: 57 (7%)

Control: 77 (10%)

HR 0.74 [95% CI 0.52-1.04], p=0.08, stratified log-rank test.

All ipsilateral (DCIS + invasive) events:

Tamoxifen: 102 (13%)

Control: 114 (15%)

HR 0.90 [95% CI 0.69-1.17], p=0.42, stratified log-rank test.

New contralateral invasive events:

Tamoxifen: 10 (1%)

Control: 15 (2%)

HR 0.66 [95% CI 0.30-1.46], p=0.30, stratified log-rank test.

New contralateral DCIS events: no data

All contralateral (DCIS + invasive) breast events:

Tamoxifen: 11 (1%)

Control: 21 (3%)

HR 0.52 [95% CI 0.25-1.07], p=0.07, stratified log-rank test.

All invasive (ipsilateral + contralateral) events:

Tamoxifen: 55 (7%)

Control: 50 (6%)

HR 1.11 [95% CI 0.76-1.63], p=0.59, stratified log-rank test.

All DCIS (ipsilateral + contralateral) events:

Tamoxifen: 58 (7%)

Control: 84 (11%)

HR 0.68 [95% CI 0.49-0.96], p=0.03, stratified log-rank test.

All events (invasive + DCIS; ipsilateral + contralateral):

Tamoxifen: 114 (14%)

Control: 137 (18%)

HR 0.83 [95% CI 0.64-1.06], p=0.13, stratified log-rank test.

2. Effect of RT (1030 patients in the randomised RT comparison)

New ipsilateral invasive events:

RT: 15 (3%)

Control: 30 (6%)

HR 0.45 [95% CI 0.24-0.85], p=0.01, stratified log-rank test.

New ipsilateral DCIS events:

RT: 14 (3%)

Control: 38 (7%)

HR 0.36 [95% CI 0.19-0.66], p=0.0004, stratified log-rank test.

All ipsilateral (DCIS + invasive) breast events:

RT: 29 (6%)

Control: 69 (14%)

HR 0.38 [95% CI 0.25-0.59], p<0.0001, stratified log-rank test.

New contralateral invasive events:

RT: 9 (2%)

Control: 6 (1%)

HR 1.50 [95% CI 0.53-4.22], p=0.44, stratified log-rank test.

New contralateral DCIS events: no data.

All contralateral (DCIS + invasive) breast events in patients in the RT comparison:

RT: 9 (2%)

Control: 11 (2%)

HR 0.82 [95% CI 0.34-1.18],  $p=0.65$ , stratified log-rank test.

All invasive (ipsilateral + contralateral) events:

RT: 24 (5%)

Control: 36 (7%)

HR 0.62 [95% CI 0.37-1.04],  $p=0.07$ , stratified log-rank test.

All DCIS (ipsilateral + contralateral) events:

RT: 14 (3%)

Control: 44 (9%)

HR 0.31 [95% CI 0.17-0.56],  $p<0.0001$ , stratified log-rank test.

All events (ipsilateral + contralateral; invasive + DCIS):

RT: 38 (7%)

Control: 82 (16%)

HR 0.43 [95% CI 0.29-0.63],  $p<0.0001$ , stratified log-rank test.

3. Subgroup analysis: New breast events in patients randomised to tamoxifen or control, stratified by whether or not they had RT

a) Patients not receiving RT (n=1053)

Ipsilateral invasive:

Tamoxifen: 37 (5%)

Control: 29 (4%)

HR 1.32 [95% CI 0.81-2.14],  $p=0.26$ , stratified log-rank test.

Ipsilateral DCIS:

Tamoxifen: 20 (6%)

Control: 68 (9%)

HR 0.73 [95% CI 0.51-1.06],  $p=0.10$ , stratified log-rank test.

Total invasive (ipsilateral + contralateral tumours):

Tamoxifen: 42 (5%)

Control: 39 (5%)

HR 1.11 [95% CI 0.72-1.72],  $p=0.64$ , stratified log-rank test.

Total DCIS (ipsilateral + contralateral tumours):

Tamoxifen: 51 (6%)

Control: 75 (10%)

HR 0.68 [95% CI 0.47-0.97],  $p=0.03$ , stratified log-rank test.

Total breast events (invasive + DCIS; ipsilateral + contralateral tumours):

Tamoxifen: 94 (12%)

Control: 117 (15%)

HR 0.80 [95% CI 0.61-1.05], p=0.11, stratified log-rank test.

b) Patients receiving RT (n=523)

Ipsilateral invasive tumours:

Tamoxifen: 8 (1%)

Control: 6 (1%)

HR 1.25 [95% CI 0.43-3.61], p=0.68, stratified log-rank test.

Ipsilateral DCIS:

Tamoxifen: 7 (1%)

Control: 9 (1%)

HR 0.75 [95% CI 0.28-2.02], p=0.57, stratified log-rank test.

Total invasive (ipsilateral + contralateral tumours):

Tamoxifen: 13 (2%)

Control: 11 (1%)

HR 1.11 [95% CI 0.50-2.48], p=0.80, stratified log-rank test.

Total DCIS (ipsilateral + contralateral tumours):

Tamoxifen: 7 (1%)

Control: 9 (1%)

HR 0.75 [95% CI 0.28-2.02], p=0.57, stratified log-rank test.

Total breast events (invasive + DCIS; ipsilateral + contralateral tumours):

Tamoxifen: 20 (3%)

Control: 20 (3%)

HR 0.95 [95% CI 0.51-1.77], p=0.88, stratified log-rank test.

### **General comments**

'Complete excision': defined by radiology of the surgical specimen and free margins on histological examination. Re-excision was performed where necessary.

Randomisation was performed by each contributing centre, blocked in groups of four and stratified for screening assessment centre.

Power calculation performed; additional patients were recruited because patients/clinicians favoured the 2-way randomisation.

Analysis of the individual effect of tamoxifen included only patients randomised to tamoxifen (not those who chose tamoxifen). The analysis was repeated, stratified by whether RT was given in addition.

Analysis of the individual effect of RT included only patients randomised to RT (not those who chose RT). No results are provided stratified by whether tamoxifen was given in

addition. Approximately 54% of patients in either arm of the RT comparison received tamoxifen in addition.

Of 794 patients randomised to tamoxifen, 86 (11%) did not fully comply with the regimen. Study does not measure adverse effects of tamoxifen or RT.

Survival was not analysed as there were few deaths (45 in total).

Study may be underpowered where sub groups are small; the largest subgroup arising through choice of treatment is patients who chose with their clinicians to not be randomised to radiotherapy or control (n=664).

## Systematic review of combined study designs

{Olivotto, 1998 8448 /id}

### Design

Design: Systematic review of combined study designs (therapy), evidence level: 2 +  
Country: Canada, setting: Secondary care

### Inclusion criteria

RCTs, meta-analyses, practice guidelines and literature reviews; patients with DCIS.

### Exclusion criteria

Non-English language papers.

### Population

-

### Interventions

Aim: to systematically review evidence for management of patients with DCIS; in order to inform recommendations in a Canadian clinical guideline.

Cited data relate to selection of patients for RT, assuming primary treatment with breast conserving surgery.

### Outcomes

Outcomes cited here are pathologic prognostic factors to predict local recurrence following treatment for DCIS, in the context of patient selection for the omission of RT.

### Follow up

Not known; review cites data on the risk of recurrence at 10 years follow-up.

### Results

Relevant findings from the systematic review:

The "Consensus conference on the classification of ductal carcinoma in situ" concluded that the most useful clinical factors to predict local recurrence in patients treated for DCIS are: nuclear grade, necrosis, margin width and lesion size.

The EORTC 10853 RCT and the NSABP B-17 RCTs demonstrated reduced risk of ipsilateral invasive and non-invasive breast cancer recurrence even for patients with clear margins of excision.

Evidence from observational studies and the pathology review of the NSABP B-17 RCT indicates that four pathological factors tend to identify patients with a lower risk of recurrence when treated with breast conserving surgery without RT:

Small lesion size (<2cm);

Widely clear margins ( $\geq 1$ cm);

Low nuclear grade;  
Absence of necrosis.

Patients with all four favourable risk factors may have a risk of breast cancer recurrence after 10 years of 4%-10%. In such cases the further absolute risk reduction arising from RT is very small. However omission of RT remains controversial (the Canadian clinical guideline recommends that breast conserving surgery for DCIS be usually followed by RT).

### **General comments**

Literature search:

English-language literature published between 1976 and 2001, identified primarily through MEDLINE and CANCELIT databases;

Key words: "breast neoplasms," "carcinoma in situ,"

Subject headings "carcinoma, intraductal, non-infiltrating";

Text words: "duct," "dcis" and "ductal carcinoma"

The search was restricted to RCTs, meta-analyses, practice guidelines and literature reviews.

References in review articles and textbooks were also used.

Quality assessment:

The quality of the evidence was categorised into 5 levels, according to the reference cited below, but no further details are provided.

Sackett (1989) Rules of evidence and clinical recommendations on the use of antithrombotic agents. Chest 1989;95(Suppl):2S-4S

Data cited here originate from 1 consensus conference, 2 RCTs (EORTC 10853 and NSABP B-17, including a paper of a related pathology review) and 3 non-randomised studies which address factors associated with local control/recurrence.

It is unclear how relevant observational studies were identified and study quality assessment is not made explicit and is rarely evident. However the review is structured according to recommendations for practice in Canada and as such is fit for purpose.

Shelley, McCready & Holloway . Management of ductal carcinoma in situ of the breast: A clinical practice guideline. Cancer Care Ontario . 2006.

## **Design**

Design: Systematic review of combined study designs (therapy), evidence level: 2+  
Country: Canada, setting: Secondary care

## **Inclusion criteria**

1. RCT, or meta-analysis design
2. Outcomes: overall or disease-free survival, local recurrence (invasive or non-invasive), breast conservation, distant recurrence, toxicity, or quality of life.
3. Results reported in full papers or abstracts.
4. Evidence-based clinical practice guidelines

NB: The systematic review continued to include observational studies, for topics where the authors demonstrated an absence of RCT evidence.

## **Exclusion criteria**

Non English language papers;  
Publications prior to 1983.

## **Population**

-

## **Interventions**

Aim: to provide a clinical guideline for the management of patients with DCIS based upon a systematic review of the evidence.

## **Outcomes**

Review reports important outcomes for the management of patients with DCIS, including survival and disease recurrence.

Information cited from the review in this report relates to 3 areas

1. A meta-analysis by Yin et al (1997) that is not otherwise included in this report: Yin XP, Li XQ, Neuhauser D, Evans JT. Assessment of surgical operations for ductal carcinoma in situ of the breast. *Int J Tech Ass Health Care*. 1997;3:420-9.
2. Additional prognostic information from RCTs (whose main results are already included) about risk of recurrence of DCIS, in the context of selecting patients in whom RT may be omitted following breast conserving surgery.
3. Observational studies aimed at deriving prognostic factors in the context of selecting patients in whom RT may be omitted following breast conserving surgery.

## **Follow up**

Variable across included studies.

## Results

1. Result of a meta-analysis of 24 published observational studies (2407 patients in total; number of patients for cited result not known):

Risk of local recurrence at 5 years follow-up in patients treated for DC IS by breast conserving surgery and RT: 10.6% [95% CI 5.6%-16.9%].

2. Additional prognostic information from RCTs

### EORTC 10853

Prognostic factor analysis in a subset of 775 patients with DCIS without invasion who underwent a central pathology review.

Median follow-up 5.4 years.

Multifactorial analysis of: treatment group, age, method of detection, nuclear grade, necrosis, architecture, size, margin status, histologic grade, and Van Nuy's classification. Age  $\leq$  40 years, clinical detection, cribriform or solid/comedo architecture, close, involved or unknown margins, and no postoperative RT were all risk factors for local recurrence.

Multivariate analysis not performed for each treatment group but, in the single factor analysis, all subgroups had an observed lower incidence of local recurrence in the RT group compared to the No RT group. Two subgroups in the RT group had local recurrence rates  $\geq$ 20% i.e. those  $\leq$  40 years of age, a 23% recurrence rate, and those with involved, close, or unspecified resection margins, a 20% recurrence rate.

### NSABP B-17

623 patients underwent central pathology review.

Analysis at 8 years follow-up.

Factors examined: comedo necrosis, histologic type, margin status, lymphoid infiltrate, nuclear grade, focality, cancerisation, stroma, and tumour size.

In a multifactorial analysis, only the presence of moderate to marked comedo necrosis was a significant predictor of breast recurrence. The average annual hazard rates for recurrence were lower for all nine pathologic characteristics in the RT group compared to the No RT group.

Subgroups according to the Van Nuys classification: recurrence rates were lower in all three groups in patients who received RT.

In these two RCTs there was no subgroup of patients identified in whom a low rate of recurrence was observed, with or without RT.

3. Prognostic information from observational studies

Four observational studies by Silverstein (1995, 1996, 1999, 2003) of patients with DCIS informed the development of the Van Nuys prognostic index:

Silverstein (1995) defined three groups (Van Nuys classification) to examine risk of local recurrence patients with DCIS as follows:

I: Nuclear grade I-II, comedo necrosis absent;  
 II: Nuclear grade I-II, comedo necrosis present;  
 III: Nuclear grade III.

In 425 patients treated with either mastectomy, BCS plus RT or BCS alone, 8-year disease-free survival was as follows:

I: 93%

II: 84% (I versus II, p=0.05)

III: 61% (II versus III, p=0.003).

Failure was most commonly due to local recurrence.

[i.e. higher local recurrence in the high risk group defined by the Van Nuys classification]

Silverstein (1996) derived the Van Nuys Prognostic Index (VNPI; scale range 3-9) in 333 patients treated with either BCS alone or BCS plus RT. The VNPI utilised the Van Nuys Classification (as above) and also tumour size (<1.5, 1.6-4.0, >4.1 mm) and margin width (>10, 1-9, <1 mm) and derived low risk (score 3-4), intermediate risk (score 5-7) and high risk (score 8-9) groups.

**8-year risk of ipsilateral breast recurrence (invasive plus non invasive; %), by VNPI group and by treatment received:**

	<b>BCS</b>	<b>BCS + RT</b>
<b>VPNI group</b>		
Low (3-4)	3	0
Intermediate (5-7)	32	15
High (8-9)	100	65

This finding was suggestive of little additional benefit of RT in patients in the low risk VNPI group; a benefit in the intermediate risk group; and in the high risk group benefit, but with a remaining high risk of local recurrence.

Silverstein (1999) studied the effect of BCS alone and BCS plus RT in 469 patients stratified according to surgical margin width:

Relative risk of recurrence at 8 years (RT:BCS+RT) by margin size:

>10 mm 1.14 [95% CI 0.10-12.64] p=0.92

1-10 mm 1.49 [95% CI 0.76-2.90] p=0.24

<1mm 2.54 [95% CI 1.25-5.18] p=0.01

This finding was suggestive of no benefit of RT except in patients with margins <1mm in size.

Silverstein (2003) re-defined the VNPI in 706 patients treated with either BCS alone or BCS plus RT; the index comprised tumour size, margin width, the pathological criteria described above and also age:

At 12 years follow-up there was no statistically significant difference in local recurrence-free survival in patients in the low risk VNPI group (score 4-6) in patients treated by BCS alone versus those treated with BCS plus RT; rates in both groups >90% (from graph in original paper), p=NS.

In patients with a VNPI of 7-9 RT was associated with a statistically significant reduction

in the rate of local recurrence over the 12 years of follow up, of between 12% and 15%;  $p=0.02$ .

In patients with a VNPI of 10-12, RT was also associated with a statistically significant reduction in the rate of local recurrence over the 12 years of follow up;  $p=0.001$ ; although the rate of local recurrence was high, even in patients treated with RT e.g. 30% at 5 years follow-up (from graph in original paper).

These results are suggestive of no advantage of RT existing only in the low risk group, however in the highest risk group RT does not reduce the rate of local recurrence to an acceptable level.

These four studies suggest that a low risk group of patients with DCIS exists in whom there is little benefit from RT. However further observational studies have omitted RT in highly selected patients treated only with BCS and experienced high local failure rates (17% at 10 years in Lagios et al. 1989 and 12% at 3 years in Wong et al. 2006).

Based upon the evidence cited above the authors of this systematic review (undertaken for a Canadian clinical guideline) concluded that it is not possible to safely identify a group of patients with DCIS, treated with BCS, who do not require adjuvant RT.

### **General comments**

Literature Search Strategy :

MEDLINE to March 2006, using MeSH terms ("carcinoma, intraductal, noninfiltrating") and treatment-specific MeSH terms ("radiotherapy", "mastectomy", or "tamoxifen").

Excerpta Medica database (EMBASE) up to March 2006, using a disease-specific Excerpta Medica Tree (EMTREE) term ("intraductal carcinoma") and the same treatment-specific EMTREE term as for the MEDLINE search.

Issue 5 (2004) of the Cochrane Library, the Physician Data Query database ([http://www.cancer.gov/search/clinical\\_trials/](http://www.cancer.gov/search/clinical_trials/))

Conference proceedings from the American Society of Clinical Oncology (1998 to 2005)

American Society for Therapeutic Radiology and Oncology (1998 to 2005)

San Antonio Breast Cancer Symposium (2001 to 2005).

Canadian Medical Association Infobase (<http://mdm.ca/cpgsnew/cpgs/index.asp>) and the National Guidelines Clearinghouse (<http://www.guideline.gov/>)

Relevant articles and abstracts were selected and reviewed by three reviewers, and the reference lists from these sources were searched for additional trials, as were the reference lists from relevant review articles.

One original paper by Silverstein used to read values from graphs, where indicated.

Boyages, Delaney & Taylor . Predictors of local recurrence after treatment of ductal carcinoma in situ: a meta-analysis.[see comment]. Cancer 85[3], 616-628. 1999.

### **Design**

Design: Systematic review of combined study designs (therapy), evidence level: 3  
Country: Australia, setting: Secondary care

### **Inclusion criteria**

Studies (no design restrictions) of treatment of patients with DCIS by:  
Mastectomy;  
Breast conserving surgery;  
Breast conserving surgery plus RT.

### **Exclusion criteria**

Pooled data;  
Data available only in abstracts or books.

### **Population**

number of patients = 2600.

### **Interventions**

Aim: to examine the rate of local recurrence in patients treated for DCIS, and to analyse predictive factors for local recurrence.

Treatment groups considered:  
Mastectomy (data not cited);  
Breast conserving surgery;  
Breast conserving surgery plus RT.

### **Outcomes**

Local recurrence;  
Risk factors for local recurrence (data not cited).

### **Follow up**

Not reported in all primary studies.

Average follow up by treatment group:  
Breast conserving surgery alone: 68 months  
Breast conserving surgery plus RT: 62 months

### **Results**

Pooled rates of local recurrence by treatment group:

Breast conserving surgery alone:  
22.5% [95% CI 16.9%-28.2%]; 17 studies, n=1148

Breast conserving surgery plus RT:

8.9% [95% CI 6.8%-11.0%]; 19 studies, n=1452

Proportion of recurrent tumours presenting as invasive tumours:

Breast conserving surgery alone: 93/217=43%

Breast conserving surgery plus RT: 63/126=50%

### **General comments**

Studies were identified by a MEDLINE search and by reference lists in papers; no further details provided.

Statistical methods are reported, including assessment of study heterogeneity.

'Average' follow-up reported since authors refer to 'median or mean'.

Some of the included studies are dated; 6 were published prior to 1983.

No details are provided for the precise type of breast conserving surgery performed in each primary study, nor the dose of RT given. Studies were known to vary in terms of design, length of follow-up and selection of participants. For these reasons, study is graded as level 3 evidence.

Fonseca, Hartmann, Petersen, Donohue, Crotty & Gisvold . Ductal carcinoma in situ of the breast (DARE structured abstract). Ann Intern.Med 127, 1013-1022. 1997.

### Design

Design: Systematic review of combined study designs (therapy), evidence level: 3  
Country: Multinational, setting: Secondary care

### Inclusion criteria

Women with DCIS

### Exclusion criteria

Personal communications and case reports.

### Population

number of patients = 794.

### Interventions

Aim: to review data on the natural history of DCIS and different treatment approaches.

Cited data are of patients with DCIS who were treated with breast conserving surgery alone or breast conserving surgery plus RT.

### Outcomes

Local recurrence;  
Survival (no data cited).

### Follow up

Breast conserving surgery alone: mean 65 months.  
Breast conserving surgery plus RT: mean 64 months

### Results

#### Characteristics of included studies:

	<b>BCS</b>	<b>BCS + RT</b>
<b>Number of studies</b>	10	6
<b>Number of patients</b>	461	333
<b>Mean follow-up (months)</b>	65	64

Mean rate (range) of local (invasive + non-invasive) recurrence:

BCS: 23% (8%-63%)

BCS + RT: 9% (4%-21%)

Mean rate of local invasive recurrence:

BCS: 9%

BCS + RT: 6%

### **General comments**

The review included RCTs and retrospective case series (observational) studies. Data were presented narratively.

Literature search described in brief: used the search terms 'carcinoma in situ', 'ductal carcinoma in situ', 'intra-ductal breast cancer' and 'DCIS'; MEDLINE database only; English language papers only; papers published since 1966. The authors do not state how the data were extracted for the review, and the number of studies included is unclear. However, the authors gave details of 11 studies for lumpectomy and 7 for lumpectomy plus RT. Personal communications and case reports were excluded. Authors include a statement that papers were reviewed critically - no further details.

No details provided of the included studies re: design, age of the women. No details provided of assessment of study validity.

Data cited here excludes that of the NSABP B-17 trial, which has been included for this question as a primary study.

Degree of primary study heterogeneity not known.

Appraisal of this review cites the DARE (University of York) structured abstract, available online at:

## Case control study

Claus, Petruzella, Carter & Kasl . Quality of life for women diagnosed with breast carcinoma in situ. J Clin Oncol 24[30], 4875-4881. 2006.

### Design

Design: Case control study (therapy), evidence level: 2+  
Country: USA, setting: Secondary care

### Inclusion criteria

795 patients with breast cancer in situ (87% of whom had DCIS; 13% LCIS) and 702 healthy controls identified in Connecticut between 1994 and 1998.

### Exclusion criteria

Of 2067 patients identified for an older study, 570 were excluded in this analysis due to:  
Refusal to participate;  
Deceased;  
Too ill;  
Lost to follow-up;  
New pathology rendered ineligible (i.e. invasive breast cancer or previous history of in situ breast cancer).

### Population

, mean age = 55 years.

### Interventions

Aim: to assess the quality of life (QOL) in patients treated for breast cancer in situ (predominantly DCIS) compared to selected healthy controls.

Analysis groups were as follows:

CASES (n=795)

Lumpectomy only (n=282)

Lumpectomy + RT (n=397)

Mastectomy only (n=111)

(5 patients reported no treatment)

CONTROLS (n=702) were randomly selected based on telephone numbers and frequency-matched for age in 5 year intervals.

### Outcomes

1. Health related QOL: 36 item Medical Outcomes Study Short Form (MOS SF-36); 8 scales for physical functioning, role function-physical, bodily pain, social functioning, mental health, role function-emotional, vitality and general health perceptions; scale range 0-100; 100 representing best QOL.

Two additional summary scales:

Physical component summary scale;

Mental component summary scale.

The Medical Outcomes Sexual Problems Measure List was also added

2. Centre for Epidemiologic Studies Depression scale (CES-D): 20 item scale used to measure depressive symptoms over the last week (maximum score 60, representing highest risk of depression; score >16 generally regarded as an indicator of depression).

3. Cut Down, Annoyed, Guilty, Eye-opener (CAGE) screening questionnaire (scored 0-4); used to evaluate alcohol consumption.

Outcomes evaluated by descriptive statistics, t, Chi square, Fisher's exact, and ANOVA.

Estimates of MOS SF-36 and CES-D were adjusted for age, race, education, menstrual status, comorbidity, marital status.

### **Follow up**

Survey performed at a mean follow-up of 5 years from diagnosis.

### **Results**

The majority (>85% of both cases and controls reported having good, very good or excellent health at 5 years after diagnosis.

Case participants and controls did not differ in reported levels of limitations due to physical health problems, bodily pain, social functioning, or overall physical functioning (MOS Physical component summary scale). This was true for all cases together and also each individual treatment group within the cases.

With regard to alcohol consumption there was no statistically significant difference in score between cases and controls (0.23 versus 0.28 respectively;  $p=0.13$ ).

Statistically significantly lower MOS SF-36 scores were reported for case participants for the following dimensions: general mental health, role limitations due to emotional problems, vitality and general health perceptions, as well as for the MOS mental component summary scale. CES-D score for cases was statistically significantly higher (indicating higher levels of depressive symptoms) than for controls. These differences were mainly due to poorer scores in the subset of cases who underwent lumpectomy plus RT, relative to controls. In the case of the SF-36 item: role limitations due to emotional problems; the the difference between cases and controls was due to lower scores in the lumpectomy group.

Case participants who underwent lumpectomy with radiation reported lower levels of emotional functioning, general health perceptions, vitality, sexual interest, and overall mental health, as well as more depressive symptoms than did control subjects; although, the clinical significance of these statistical differences appears to be limited.

Authors conclude that at 5 years after diagnosis, cases reported levels of physical, emotional, and mental health functioning similar with those reported in a general healthy female population.

**General comments**

This study represents a smaller, subsequent study arising from an original study which evaluated family history and exogenous/endogenous hormone factors and breast cancer in situ risk.

Applicability of results is likely to be affected due to possible differences in psychological/QOL traits between the Italian and British populations.

## Prospective comparative study

Hayman, Kabeto, Schipper, Bennett, Vicini & Pierce . Assessing the benefit of radiation therapy after breast-conserving surgery for ductal carcinoma-in-situ. J Clin Oncol 23[22], 5171-5177. 2005.

### Design

Design: Prospective comparative study (therapy), evidence level: 3  
Country: USA, setting: Secondary care

### Inclusion criteria

120 patients treated for DCIS who had undergone lumpectomy plus RT and who were free of disease, with an interval of >1 month between RT and assessment.

210 non patients, identified from an appointment list for routine health maintenance visits.

### Exclusion criteria

Patients whose radiation oncologists requested no contact be made;  
Patients who refused participation.

### Population

-

### Interventions

Aim: to measure the utilities of patients and nonpatients for relevant health states following treatment for DCIS with lumpectomy, compared to lumpectomy plus RT.

Participants were given an in-depth overview of issues attending DCIS, its treatment and necessary actions in different scenarios of recurrence e.g. the need for axillary surgery in cases of invasive recurrence.

Participants were then asked to rank 8 scenarios in order of most desirable to least desirable (see outcomes).

### Outcomes

Differences within groups and between groups in the ranking of 8 scenarios according to desirability:

- A: BCS + RT without recurrence
- B: BCS + RT then noninvasive recurrence, salvaged by mastectomy
- C: BCS + RT then invasive recurrence salvaged by mastectomy
- D: BCS alone without recurrence
- E: BCS alone then noninvasive recurrence salvaged with BCS + RT
- F: BCS alone then noninvasive recurrence salvaged with mastectomy
- G: BCS alone then invasive recurrence salvaged with BCS + RT

H: BCS alone then then invasive recurrence salvaged by mastectomy

In addition, logistic regression was performed to examine whether participants' utilities for scenarios or differences in utility between any two scenarios were affected by any of the following variables:

Age, race, marital status, number of dependents, education, and income for all participants; months since completion of RT, toxicity, treatment with tamoxifen, satisfaction with local outcome, fear of recurrence, and satisfaction with treatment decision for patient participants; and 5-year and lifetime risks of breast cancer for nonpatient participants.

### **Follow up**

Mean 39 months (range 3-175 months)

### **Results**

#### 1. Within-group comparisons

The results of pairwise comparisons between health states within the patient and nonpatient groups were surprisingly similar. For the health states after treatment with RT, both groups had the strongest preference for being without recurrence, followed first by a DCIS recurrence and then by an invasive recurrence (ie,  $A > B > C$ ).

For the health states after treatment with lumpectomy alone, patient and nonpatient participants alike were indifferent to a DCIS recurrence but not to an invasive recurrence (ie,  $D=E=F>G$  and  $H$ ). Both groups had similar utilities for the nonrecurrent health states, whether they had or had not received initial treatment with RT (ie,  $A=D$ ). Patients and nonpatients also had similar utilities for a DCIS recurrence requiring mastectomy whether or not they had received upfront RT (ie,  $B= F$ ).

In contrast, patients and nonpatients not only had different utilities for an invasive recurrence requiring mastectomy after initial treatment with RT compared with no RT (ie,  $C$  vs.  $H$ ), but the direction of the difference was also reversed. Patient participants preferred having received RT (ie,  $C>H$ ), whereas nonpatient participants preferred not to have had received RT (ie,  $C < H$ ).

The only other relevant difference between the two groups was that patient participants preferred to preserve their breast after an invasive recurrence after initial treatment with BCS alone (ie,  $G > H$ ), whereas nonpatient participants were indifferent (ie,  $G = H$ ). Neither group expressed a preference for breast preservation when confronted with a DCIS recurrence after initial treatment with BCS alone (ie,  $E = F$ ).

#### 2. Between-group comparisons

Overall, there were few differences that were statistically significant when comparing patient and nonpatient participants' utilities directly. Patients had higher utilities than nonpatients for being without recurrence after BCS and RT ( $A$ ) and lower utilities for having an invasive recurrence salvaged by mastectomy after BCS alone ( $H$ ).

Differences in utilities for being without recurrence after BCS alone ( $D$ ) and for having had an invasive recurrence salvaged by mastectomy after BCS and RT ( $C$ ) were

reportedly of borderline significance ( $P = .09$  and  $P = .06$ , respectively).

### 3. Factors associated with participants' utilities

Although several of the clinical and sociodemographic factors examined were statistically associated with patient and nonpatient participants' utilities, none of the factors explained more than 5% of the variability in the utilities themselves or in the differences between health states.

Authors conclude that women, after breast conserving therapy for DCIS, fear mostly invasive recurrence, over recurrence, noninvasive recurrence and mastectomy.

#### **General comments**

The absolute reduction in risk of recurrence arising from RT following treatment with BCS presented to participants was 5% for noninvasive recurrence and 9% for invasive recurrence based on the NSABP B-17 RCT.

Results are reported using utilities, which are described as: "global measures of quality of life that represent the strength of one's preference for a particular state of health and are measured on a scale ranging from 0 to 1, where 0 is equivalent to death and 1 is equivalent to optimal health".

The reported differences in relative preference of different scenarios (e.g.  $A > B$ ) reflect statistically significant differences in mean utility scores.

At baseline assessment, nonpatients, compared with patient participants, were younger (mean age, 50 v 61 years, respectively;  $p < .001$ ), more likely not to be white (16% v 7%, respectively;  $p < .03$ ), less likely to have dependents at home (mean, 0.65 v 1.1 dependent, respectively;  $p < .001$ ), and better educated (71% v 50% college graduates, respectively;  $p < .001$ ).

Re: the finding: *Patient participants preferred having received RT (ie,  $C > H$ ), whereas nonpatient participants preferred not to have had received RT (ie,  $C < H$ ); this may be affected by a bias since the patients in this study all underwent breast conserving surgery plus RT and were hence possibly more likely to view it favourably.*

Overall the study may be confounded since the patients were treated; whereas non-patients had to rely on imagination.

## Retrospective case series

Baxter, Virnig, Durham & Tuttle . Radiation after lumpectomy for DCIS to reduce the risk of invasive breast cancer: A population-based study. J Clin Oncol (Meeting Abstracts) 23[16\_suppl], 516. 2005.

### Design

Design: Retrospective case series (therapy), evidence level: 3  
Country: USA, setting: Secondary care

### Inclusion criteria

9960 women with DCIS of age 18-75 years treated with lumpectomy plus RT in the period 1987-1996, with details held on the SEER database.

### Exclusion criteria

Patients with no information regarding treatment with RT.

Patients developing ipsilateral invasive recurrence within 3 months of treatment; as misdiagnosis assumed.

Patients followed for < 3 months (74).

### Population

number of patients = 9960, median age = 56 years.

### Interventions

Aim: to derive a population-based estimate of the effectiveness of RT after lumpectomy for DCIS using the SEER database.

Two patient groups were defined for analysis:  
Lumpectomy alone treatment group (n=5008);  
Lumpectomy + RT treatment group (n=4952).

### Outcomes

Occurrence of:  
Any invasive breast cancer;  
Ipsilateral breast cancer;  
Contralateral breast cancer;  
Death.

The risk of subsequent breast cancer was modelled using a proportional hazards model to evaluate the effect of RT over time and adjusting for potential confounders (age, race, comedo status and geographic location). Tumour grade and size were poorly characterised and were not included in the model.

### Follow up

Mean: 8 years

## Results

Invasive breast cancer developed in 809 patients (8.1%); 428 (4.3%) cases of invasive breast cancer were in the ipsilateral breast and 379 (3.8%) in the contralateral breast (laterality was unknown in 2 cancers; 45 cases were excluded due to occurrence within 3 months of diagnosis).

### All incident invasive disease

Over the follow-up period the actuarial rate of invasive (ipsilateral plus contralateral) breast cancer was statistically significantly higher in the lumpectomy alone group compared to the lumpectomy plus RT group ( $p < 0.0001$ ; see below for cumulative rates at 8 years).

### Invasive ipsilateral disease

Over the follow-up period the actuarial rate of invasive ipsilateral breast cancer was statistically significantly higher in the lumpectomy alone group compared to the lumpectomy plus RT group ( $p < 0.0001$ ; see below for cumulative rates at 8 years).

### Contralateral invasive disease

Over the follow-up period there was no statistically significant difference between the two groups in terms of contralateral invasive breast cancer-free survival ( $p = 0.8$ ; see below for cumulative rates at 8 years).

## Cumulative rates of invasive breast events at 8 years from diagnosis:

	Overall	Ipsilateral	Contralateral
<b>Lumpectomy alone:</b>	9.7%	6.0%	3.8%
<b>Lumpectomy plus RT</b>	6.3%	2.7%	3.7%

### Proportional hazards model:

Lumpectomy alone was strongly associated with development of ipsilateral breast cancer over time after adjusting for potential confounders: HR (Lumpectomy + RT:Lumpectomy alone) 0.43 [95% CI 0.35-0.53];  $p < 0.0001$ .

RT after lumpectomy was not associated with development of contralateral invasive cancer: HR (Lumpectomy + RT:Lumpectomy alone) 1.01 [95% CI not reported];  $p = 0.91$ .

African American race was associated with development of ipsilateral breast cancer over time after adjusting for potential confounders:

	African American	Others
<b>Cumulative risk:</b>	7.9%	4.1%

HR (African American:other races) 1.7 [95% CI not reported];  $p = 0.0004$ .

However African American race was not associated with development of contralateral breast

cancer over time:

	<b>African American</b>	<b>Others</b>
<b>Cumulative risk:</b>	3.8 %	3.8%

HR (African American:other races) 1.13 [95% CI not reported]; p=0.51.

### **General comments**

Women in the lumpectomy plus RT group were, on average 2 years younger than those in the lumpectomy group.

Study potentially has high applicability to patients treated outside of RCTs; the authors comment that the rate of ipsilateral invasive breast cancer is lower than in published trials; possibly due to limitations of SEER data e.g. errors in transcribing codes or migration of patients from SEER registry areas.

Study does not report any data for non-invasive breast events subsequent to treatment e.g. DCIS.

Study does not analyse survival by the two treatment-defined patient groups.

Tumour grade and size are omitted from the proportional hazards model due to poor data quality; a possible drawback.

The age variable was associated with development of ipsilateral breast cancer over time after adjusting for potential confounders: HR (for an increment of one 5-year age group) 0.93 [95% CI not reported]; p=0.003 but not with development of contralateral breast cancer over time: HR (for an increment of one 5-year age group) 1.06 [95% CI not reported]; p=0.02. NB from these data it is not possible to determine the direction of effect i.e. older age or younger age.

Data extracted from ASCO meeting abstract and presentation audio/slides; available online at:

[http://www.asco.org/portal/site/ASCO/menuitem.34d60f5624ba07fd506fe310ee37a01d/?vgnextoid=76f8201eb61a7010VgnVCM100000ed730ad1RCRD&vmview=abst\\_detail\\_view&confID=34&index=y&abstractID=30402](http://www.asco.org/portal/site/ASCO/menuitem.34d60f5624ba07fd506fe310ee37a01d/?vgnextoid=76f8201eb61a7010VgnVCM100000ed730ad1RCRD&vmview=abst_detail_view&confID=34&index=y&abstractID=30402); last accessed: 4.04.07

Mills, Schultz & Solin . Preservation of cosmesis with low complication risk after conservative surgery and radiotherapy for ductal carcinoma in situ of the breast. Int J Radiat.Oncol Biol.Phys. 39[3], 637-641. 1997.

## **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: USA, setting: Secondary care

## **Inclusion criteria**

90 women treated with breast conserving surgery plus RT for DCIS between 1978 and 1991 at a single centre, who were free of disease with a minimum follow-up extent of 3 years.

28 cases (31%) were detected by palpation and 62 (69%) by routine mammography

## **Exclusion criteria**

No cosmetic evaluation (12 patients)  
Local recurrence before 3 years (4 patients)  
Adjuvant tamoxifen (1 patient)  
Second unrelated malignancy (1 patient)  
Dead of intercurrent disease (1 patient)

## **Population**

-

## **Interventions**

Aim: to report on cosmetic results in patients treated with breast conserving surgery plus RT for DCIS.

All patients underwent complete gross excision. 44 patients (49%) underwent re-excision and 24 patients (27%) underwent axillary dissection.

All patients in addition received RT as follows:

50-50.4 Gy in 1.8-2.0 fractions over 5-5.5 weeks (84 patients);

46 Gy (4 patients)

48 Gy (1 patient)

42 Gy (1 patient)

Most patients received a boost to the lumpectomy site: 10-16 Gy (71 patients) or by Iridium implant (2 patients).

## **Outcomes**

1. Physician-assessed cosmetic result at 1, 3 and 5 years follow-up, based on:

- a) Size oedema, retraction, elevation
- b) induration, fibrosis
- c) telangiectasias and pigmentary changes to the skin

- d) volume loss secondary to surgery
- e) symmetry with the untreated breast.

Result was classed as excellent, good, fair or poor accordingly.

2. Complications, including: arm oedema (mild or moderate based on circumference), cellulitis, axillary vein thrombosis, rib fracture, symptomatic pneumonitis.

**Follow up**

Median 6 years (range 3-14 years).

**Results**

1. Physician-assessed cosmetic result

Proportion of patients with cosmetic result: good/excellent (where n = number evaluable):

- 1 year: 99% (n=90)
- 3 years: 98% (n=90)
- 5 years: 97% (n=64)

At 5 years follow-up the cosmetic result of 64 evaluable patients was as follows:

- Excellent: 46 (72%)
- Good: 16 (25%)
- Fair: 2 (3%)
- Poor: 0

There was a trend of reduction in the proportion of patients with excellent cosmetic result over time.

**Percentage of cases with excellent cosmetic result by volume of excision:**

	1 year	3 years	5 years
>70 cm <sup>3</sup> :	72	65	43
<=70cm <sup>3</sup> :	96	81	76
<b>p value</b>	0.014	0.076	0.036

2. Complications

14 complications were observed in 9 patients, and which were statistically significantly associated with axillary dissection (p<0.0001).

Only two patients developed complications who did not receive axillary surgery; 1 case of breast cellulitis and 1 case of arm cellulitis.

**General comments**

The exclusion criteria apply to subgroups in whom the outcome is relevant e.g. those treated by tamoxifen, or who experienced recurrence.

The volume of tissue excised was available for 57 patients (63%)

Although 27% of the series underwent axillary dissection (no longer favoured at the institution for DCIS), there was no statistically significant difference in cosmetic outcome by subgroup for axillary surgery at 3 or 5 years follow-up.

Study size is small, and probably does not permit a fuller analysis of outcomes, due to low power.

Omlin, Amichetti, Azria, Cole, Fournieret, Poortmans, Naehrig, Miller, Krengli, Gutierrez, Morgan, Goldberg, Scandolaro, Gastelblum, Ozsahin, Dohr, Christie, Oppitz, Abacioglu & Gruber . Boost radiotherapy in young women with ductal carcinoma in situ: a multicentre, retrospective study of the Rare Cancer Network.[see comment]. Lancet Oncology 7[8], 652-656. 2006.

## **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: Multinational, setting: Secondary care

## **Inclusion criteria**

373 patients treated during the period 1978-2004 in 18 institutions in Australia, Belgium, France, UK, Israel, Italy, Netherlands, Spain, Switzerland, Turkey and USA. All patients met the following criteria:

Pure DCIS (stage Tis, N0);  
Age  $\leq$ 45 years at diagnosis;  
Primary treatment with local excision

## **Exclusion criteria**

See inclusion criteria.

## **Population**

number of patients = 373, age range 23 to 45 years, median age = 41 years.

## **Interventions**

Aim: to examine the effectiveness of boost RT in younger patients treated with local excision for DCIS. Three groups were retrospectively defined for analysis:

1. No RT group (n=57): underwent wide local excision alone;
2. RT group (n= 166): underwent wide local excision plus whole breast RT with median dose 50 Gy (range 40-60 Gy);
3. RT + boost group (n=150): underwent wide local excision plus whole breast RT plus a boost. The boost was of 10 Gy for 98 patients,  $<$ 10 Gy for 11 patients and  $>$ 10 Gy for 41 patients; delivered as either orthovoltage photons (41 patients), electrons (101 patients) or implants (9 patients).

Overall 26 patients (7%) received tamoxifen in addition:

No RT:  $2/57 = 3.5\%$   
RT:  $17/166 = 10\%$   
RT + Boost:  $7/150 = 5\%$

## **Outcomes**

Local recurrence (invasive or in situ breast cancer in the ipsilateral breast);

Contralateral recurrence (invasive or in situ breast cancer in the contralateral breast);

Regional recurrence (invasive breast cancer in the node bearing tissues);

Distant recurrence (invasive breast cancer in any body site excluding those listed above).

A proportional hazards model was used to examine the effect of RT (with and without boost) with adjustment for age; method of detection; tumour size; necrosis; tumour grade; margin status and ER status.

### **Follow up**

Median 72 months (range 1-281 months).

### **Results**

At a median follow-up of 72 months 55 (15%) patients had local recurrence; 8 (2%) had regional recurrence, 23 (6%) had contralateral recurrence and 9 (2%) had distant recurrence.

#### Overall survival

There was no statistically significant difference in 10-year overall survival between the three groups (p=0.96, log-rank test); 10-year overall survival was 97% overall [95% CI 95%-100%].

#### Local recurrence-free survival

Over the entire follow-up period, local recurrence-free survival was statistically significantly different between the three analysis groups (p<0.0001, log-rank test); e.g. 10-year local recurrence-free survival:

No RT group: 46% [95% CI 24%-67%]

RT group: 72% [95% CI 61%-83%]

RT + Boost group: 86% [95% CI 78%-93%]

#### Proportional hazards model

The following variables were statistically significantly associated with risk of local relapse: RT treatment group, age and margin status.

#### Hazard ratio for local relapse-free survival:

##### 1. RT treatment group:

No RT group: 1.00

RT group: 0.33 [95% CI 0.16-0.71]

RT + Boost group: 0.15 [95% CI 0.06-0.36]; p<0.0001

##### 2. Age:

<= 39 years: 1.00

40-45 years: 0.46 [95% CI 0.25-0.83]; p=0.010

##### 3. Margin status:

Clear: 1.00

Positive: 3.53 [95% CI 1.48-8.43]

Unknown: 1.23 [95% CI 0.54-2.34]; p=0.02

The following variables were not statistically significantly associated with risk of local relapse:

method of detection, tumour size, necrosis, tumour grade and ER status.

**General comments**

Paper recommended for selection by GDG.

There is a wide definition of RT boost in this study (see 'interventions').

Compared to the RCTs and larger analyses identified for this question, this is a small, retrospective study undertaken in a younger group of patients with DCIS.

Smith, Haffty, Buchholz, Smith, Galusha, Bekelman & Gross . Effectiveness of radiation therapy in older women with ductal carcinoma in situ. J Natl Cancer Inst 98[18], 1302-1310. 2006.

## **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: US, setting: Secondary care

## **Inclusion criteria**

3409 patients with DCIS of age 66 years or more with details held on the US Surveillance, Epidemiology and End Results (SEER) database; treated with breast conserving surgery between January 1992 and December 1999.

## **Exclusion criteria**

Non ductal histology (558);  
Biopsy or mastectomy as primary treatment (3183);  
History of prior malignancy (160);  
Second primary within 9 months (147);  
Inadequate Medicare records (1877);  
Unknown laterality at diagnosis (8);  
Patients who developed a contralateral breast cancer (159); leaving 3409 patients for analysis.

## **Population**

number of patients = 3409, median age = 74 years.

## **Interventions**

Aim: to examine whether RT performed in older patients (of age 66 years or more) after breast conserving surgery (BCS) is associated with a reduction in the risk of a second breast cancer event.

Two treatment groups were defined retrospectively:

BCS + RT (n=1676);

BCS alone (n=1733).

In addition patients were classified into subgroups according to pre-specified criteria assumed to predict risk of breast events:

High risk group (n=1570): defined by any of age 66-69 years, tumour size >2.5cm, comedo histology, high grade.

Low risk group (n=539): defined by the absence of all of these criteria.

Unclassified (n=1300); due to missing data.

## Outcomes

Second breast cancer event, defined as either:

1. Subsequent ipsilateral in-situ or invasive breast tumour reported by SEER, and/or;
2. Subsequent mastectomy reported by Medicare claims data.

Analysis was by the Kaplan-Meier method and the relationship between RT and risk of subsequent event was examined using a Cox proportional hazards model, adjusting for the following co-variates:

Age, race, urban-rural status, median income, marital status, comorbidity, tumour size, histology and grade.

NB age and comorbidity were included due to clinical relevance; all other variables were chosen due to their statistical significance in univariate analysis.

## Follow up

Median 5 years

## Results

Unadjusted risk of breast events:

5-year risk of second breast cancer event:

BCS alone: 10.7%

BCS + RT: 3.6%

Difference: 7.1% [95% CI 5.2%-9.0%],  $p < 0.001$

Adjusted effect of RT:

RT was associated with a reduced risk of the following breast cancer events:

Event	HR	95% CI	p value
Ipsilateral, in-situ	0.23	0.12-0.45	<0.001
Ipsilateral, invasive	0.27	0.16-0.45	<0.001
Mastectomy	0.42	0.29-0.60	<0.001
Any event	0.32	0.24-0.44	<0.001

Effect of other factors on any breast cancer event (statistically significant results):

Factor	HR	95% CI	p value
Advanced age	0.97	0.95-1.00	<0.05
Large tumour size	1.14	1.02-1.26	<0.05
Comedo histology	1.40	1.00-1.97	<0.05

High grade	2.38	1.24- 4.56	<0.05

There was no significant interaction between RT and these factors i.e. the benefit of RT was similar for patients at low risk for an event to that for those at high risk for an event.

Effect of RT in reducing risk of any breast event, by risk group (ARR = absolute risk reduction, expressed in number of events per 100 persons):

Group	ARR	95% CI	p value (log-rank test)
Low risk	7.3 3	6-11	<0.001
High risk	9.8 6	5-13.2	<0.001
Unclassified	5	1 2.2-8.1	<0.001

### General comments

'Mastectomy' as a surrogate outcome for breast cancer recurrence does not appear to have laterality defined, but since patients with subsequent contralateral breast cancers were excluded, it is reasonable to accept mastectomy as an ipsilateral procedure.

Margin status was not reported; neither was use of tamoxifen.

Receipt of RT correlated with the following baseline characteristics: younger age, absence of comorbidity, comedo histology and high grade.

Rakovitch, E., Pignol, J., Hanna, W., Narod, S., Spayne, J., Nofech-Mozes, S., Chariter, C., Paszat, L. (2007) Significance of Multifocality in Ductal Carcinoma In Situ: Outcomes of Women treated with Breast Conserving Therapy *Journal of Clinical Oncology* 25;35:5591-5596

**Design:** Retrospective case series    **Evidence Level:** 3

**Country:** Canada

**Aim:** To evaluate the risk of local recurrence risk among women with multifocal DCIS who were treated with breast conserving surgery and to determine whether multifocality is an independent risk factor for local recurrence.

**Inclusion criteria:** All patients with DCIS diagnosis who were referred to a single regional centre between 1982 and 2000.

**Exclusion criteria:** Cases treated with mastectomy

**Population** N=615

**Interventions:** 310 treated with breast conserving surgery only  
305 treated with breast conserving surgery and radiotherapy

**Outcomes:** Local Recurrence

**Results:**

Among women treated with breast conserving surgery only, 21% developed local recurrence as compared with 9% of women treated with breast conserving surgery and radiotherapy.

The 5 year actuarial local recurrence free survival rates were 85% for women treated with breast conserving surgery alone and 93% for those treated with BCS plus radiotherapy.

		<b>5 year actuarial</b>	<b>10 year actuarial</b>
<b>Local recurrence free survival rates</b>	BCS Alone	85%	72%
	BCS + RT	93%	82%
<b>Invasive local recurrence free survival rates</b>	BCS Alone	95%	85%
	BCS + RT	99%	92%

Median time to local recurrence was 4.2 years (Range; 0.3-16.7 years) following BCS Alone and 3.0 years (Range; 0.6-8.7) following BCS + RT.

On univariate analysis, administration of radiation (HR: 0.48 (95% CI; 0.30-0.75), P=0.002), presence of comedonecrosis (HR: 1.7 (95% CI; 1.02-2.85), P=0.04) and resection margins of 4mm or smaller (HR: 1.89 (1.20-2.98), P=0.006), were significantly associated with the development of local recurrence. Administration of radiation and positive or close resection margins (≤4mm) were associated with the development of an invasive recurrence.

On multivariate analysis multifocality (HR: 1.8 (95% CI; 1.2-2.8), P=0.01), radiotherapy (HR

0.46 (95% CI; 0.29-0.74), P=0.001), margin width 4mm or smaller (HR: 1.7 (95% CI; 1.0-2.9), P=0.04) and high nuclear grade (HR: 1.6 (95% CI; 1.0-2.7), P=0.04) were predictors of local recurrence.

For women treated with breast conserving surgery alone, the 5 year actuarial local recurrence free survival rates were 82% for women with multifocal disease and 87% for those with unifocal disease. At ten years the recurrence-free survival rate was significantly lower; 59% for women with multifocal disease compared to 80% for women with unifocal disease (p=0.02). There was no significant impact of multifocality among women that received radiation therapy.

**General comments**

There is currently no agreement on the precise definition of multifocality and in most RCT's and cohort studies of DCIS it is not routinely evaluated.

**Authors Comment:** The results of the study indicate that multifocality an independent risk factor for the development of local recurrence following breast conserving surgery for DCIS. However BCS is still an option for women with multifocal DCIS with low recurrence rates achieved through complete excision with negative resection margins followed by adjuvant radiotherapy.

Schouten van der Velden, A., van Vught, Roel, van Dijck, J., Leer, J., Wobbes, T. (2007) Local Recurrences After Different Treatment Strategies for Ductal Carcinoma In Situ of the Breast: A Population Based Study in the East Netherlands. *Int. J. Radiation Oncology Biol. Phys.* 69;3:703-710

**Design:** Retrospective Case Series      **Evidence Level:** 3

**Country:** Netherlands

**Aim:** To assess the risk of local recurrences following different treatment strategies for DCIS and to determine whether RT decreased the risk of local recurrences.

**Inclusion criteria:** All patients recorded in the Cancer Registry with breast tumours classified as *in situ* between January 1989 and December 2003.

**Exclusion criteria:** Patients with a history of or a simultaneous invasive breast cancer and other malignancies (apart from nonmelanoma skin cancer and *in situ* cervical carcinoma).

**Population:** 888 of which 90 had inaccessible medical records thus leaving a study population of 798 patients.

**Interventions:**

237 patients treated with BCS only

153 patients treated with BCS followed by RT

408 patients treated with mastectomy

9 patients treated with either adjuvant chemotherapy or hormonal therapy

**Outcomes:** Local recurrence, defined as non-invasive and invasive carcinoma anywhere within the treated breast.

**Results:**

19 patients died of non-breast cancer related causes and 113 patients developed a breast cancer related failure in either the treated or contra-lateral breast during the follow-up period. 83 patients developed recurrent disease (39 invasive carcinomas) within the treated breast, which were considered as true recurrences.

The median time from surgery to recurrent disease was 38 months and the 5-year local recurrence survival was 90% for all patients.

The 5 year recurrence free survival by treatment type was as follows (p<0.01):

	5-Year Recurrence Free Survival
BCS	75% (61 recurrences in 237 patients)
BCS + RT	91% (11 recurrences in 153 patients)
Mastectomy	98.7% (11 recurrences in 408 patients)

Patients with close or involved margins had a lower recurrence free survival rate than patients with surgical margins free of tumour (p<0.01).

On multivariate analysis, presence of comedo necrosis and treatment strategy were significant predictors of recurrent disease (p<0.01).

Margin status was a non-significant predictor for recurrent disease, though excluding patients treated with mastectomy resulted in significance at multivariate analysis (HR, 2.0; 95% CI; 1.1-4.0).

**General comments**

Treatment by mastectomy is a viable option for DCIS resulting in excellent cure rates and should be considered in line with patient preferences and/or tumor characteristics.

The low numbers of patients receiving BCS + RT can be explained by the fact that this treatment procedure for DCIS was only recommended in the regional guideline after 1999 and the number of patients receiving BCS + RT has increased significantly since then (7% pre 1999 and 62% post 1999).

**Authors Comment:** Our data support the beneficial effect of radiotherapy in the prevention of local recurrences.

## Prospective cross sectional study

Amichetti, Caffo, Arcicasa, Roncadin, Lora, Rigon, Zini, Armaroli, Coghetto, Zorat, Neri & Teodorani . Quality of life in patients with ductal carcinoma in situ of the breast treated with conservative surgery and postoperative irradiation. Breast Cancer Research & Treatment 54[2], 109-115. 1999.

### Design

Design: Prospective cross sectional study (harm), evidence level: 3  
Country: Italy, setting: Community

### Inclusion criteria

106 women treated in six Italian institutions of DCIS with breast conserving surgery plus RT between 1980 and 1990, all of whom were free of disease at the time of the survey.  
75% were married;  
19% lived alone;  
70% were either retired or were 'homemakers'  
11% were on prescribed psychotherapeutic medication for non-severe conditions.

### Exclusion criteria

None reported.

### Population

number of patients = 83, age range 32 to 94 years, median age = 54 years.

### Interventions

Aim: to measure quality of life (QOL) in patients treated with breast conserving surgery plus RT for DCIS.

A questionnaire was administered, consisting of 34 items grouped into five fields of post-treatment adjustment:

Physical well being;  
Sexual adaptation;  
Aesthetic outcome;  
Emotional/psychological well being;  
Relational behaviour.

### General items

In addition further questions explored the adequacy of information given at the time of treatment and the effects of treatment on social and overall life.

### Outcomes

The relationship between items and the following possibly relevant variables: Age, marital status, employment, follow-up, degree of information, use of psychotherapeutic drugs; assessed by ANOVA or Wilcoxon tests.

### Follow up

Median 54.5 months

## Results

### Physical well being

Patients reported that they were in good physical condition:

71% felt energetic;

76% felt physically well;

10% felt ill;

19% felt tired.

Poor physical condition correlated with the use of psychotherapeutic drugs and a low level of information given at the time of treatment.

### Sexual adaption

93% of respondents completed these items, 73% of whom were sexually active. Limitations in sexual activity items were reported by between 6% and 8% of respondents. No external factor statistically significantly predicted sexual adjustment but patients with a poor perception of their body image or thought they were less attractive after treatment had a lower rate of sexual resumption.

### Aesthetic outcome

16% perceived a worsened body image;

14% experienced discomfort at the surgical scar;

18% felt less attractive than before their treatment;

41% viewed the treated breast as similar to the untreated breast;

50% reported a good/excellent cosmetic outcome.

There was a close correlation between aesthetic outcomes and sexual outcomes.

### Emotional/psychological well being

46% felt tense;

48% nervous;

29% lonely;

59% anxious;

41% depressed.

There was no correlation between responses and any assessed variables.

### Relational behaviour

14% reported a lower frequency of meeting relatives;

16% reported a lower frequency of meeting friends.

There were no differences in subgroups stratified by the assessed variables.

### General items

8% of patients declared that treatment had a bad effect on their social life;

18% reported that their current life was affected by treatment.

75% reported that the information provided at the time of treatment was sufficient.

Authors conclude that this study reveals a good QOL in patients treated for DCIS with breast conserving surgery plus RT, with a preserved favourable body image and little negative

impact on sexual activity.

**General comments**

Of 106 patients sent a questionnaire, 83 (78%) responded. There were no statistically significant difference in demographic characteristics between those who responded and those who did not.

The questionnaire was assessed for reliability and content/construct validity, with satisfactory results.

### **6.3 Which groups of patients should receive chest wall radiotherapy after mastectomy?**

#### **Short Summary**

A large volume of high quality evidence was available examining both post-mastectomy and breast conserving surgery (BCS) with adjuvant radiotherapy. Several meta-analyses of RCTs were available including a recent analysis from the EBCTCG (Clarke *et al.* 2005; two additional meta-analyses were reviewed that included some of the same studies as the EBCTCG, as well as additional RCTs (Gebski *et al.* 2006; Killander *et al.* 2007, Kyndi *et al.* 2008; Whelan *et al.* 2000). Some analyses were conducted in specified subgroups of the Danish Breast Cancer Cooperative Group (Nielsen *et al.* 2006; Overgaard *et al.* 2007), and another used all trials from the EBCTCG (Van de Steene *et al.* 2000). Evidence from other studies included Bartelink *et al.* 2000; Bellon *et al.* 2006; Fisher *et al.* 2002; Gustavsson *et al.* 1999; Hojris *et al.* 2000; Hojris *et al.* 1999; Recht *et al.* 2001; Smith *et al.* 2006; Truong *et al.* 2004.

There was general consistency that radiotherapy reduced locoregional recurrence. The effects of radiotherapy on overall survival were of benefit for women of all ages with positive lymph nodes, but of less benefit for women with negative lymph nodes.

#### Loco-regional recurrence

Clarke *et al.* (2005) reported that radiotherapy after mastectomy with axillary clearance significantly reduced locoregional recurrence. The absolute reduction in local recurrence was greater in lymph node-positive than lymph node-negative disease (17% versus 4%). Whelan *et al.* (2000b) included some of the trials from the EBCTCG and found a large reduction in locoregional recurrence and for any recurrence after post-mastectomy radiotherapy. A 25 year follow-up of an RCT (Fisher *et al.* 2002) reported no significant differences between the three groups of women with negative lymph nodes or between the two groups of women with positive nodes for disease-free survival, relapse-free survival, distant-disease-free survival, or overall survival. A subgroup analysis of the DBCG 82 b and c trials was performed to evaluate the loco-regional recurrence rate in relation to number of positive lymph nodes (1-3 or 4 or more) (Overgaard *et al.* 2007). The risk of loco-regional recurrence was most pronounced in patients with 4+ positive nodes. Another subgroup analysis of the DBCG 82 b and c trials by Nielsen *et al.* (2006) found the frequency of locoregional recurrence was 30% among patients randomised to no radiotherapy and 5% for patients randomised to radiotherapy.

#### Mortality

The EBCTCG (Clarke *et al.* 2005) reported that in trials of radiotherapy after mastectomy with axillary clearance there was a reduction in 15 year all cause mortality of 4.2% with radiotherapy for node negative disease and in node-positive disease, the reduction in 15-year all-cause mortality in the radiotherapy group was 4.4%. In a meta-analysis by Gebski *et al.* (2006) studies were categorised according to how the radiotherapy dose was delivered. Category 1 studies were defined as delivering optimal radiation therapy doses in the range of 40-60 Gy in 2-Gy fractions or as a biologically equivalent dose to the chest wall, axillary lymph nodes, and the supraclavicular fossa with or without the internal mammary lymph nodes. At a follow-up of 5 years category 1 studies gave a statistically significant 13% relative survival advantage associated with radiation therapy, compared with no radiation therapy. This equates to an absolute 2.9% increase in survival. At a follow-up of 10 years; category 1

studies gave a statistically significant 22% increase in relative survival associated with radiation therapy, compared with no radiation therapy. This corresponds to an absolute 6.4% increase in survival. In trials of high-risk patients (patients with lymph node positive disease) a separate analysis found that an absolute 5.2% increase in survival (52 per 1000) at 10-year follow-up was associated with adjuvant radiation therapy compared with no radiation therapy. In the analysis by Whelan *et al.* (2000) radiation was shown to significantly reduce mortality. The Danish Breast Cancer Cooperative Group (DBCCG) (2006) reported that with 18 years follow-up the probability of loco-regional recurrences (with or without distant metastases) or loco-regional recurrences alone was significantly lower in the post-mastectomy radiotherapy group than the no radiotherapy group. It also showed that overall fewer patients have distant metastases. Killander *et al.* (2007) reported that post-mastectomy radiotherapy significantly reduced loco-regional recurrences, but overall survival was not improved. At 20 years, a lower mortality was recorded for non-irradiated patients treated with tamoxifen. A survival benefit was found for node 1-3 and node 4+ patients in the analysis of high risk patients by Overgaard *et al.* (2007) from the DBCCG trials only. A further analysis comparing locoregional recurrence and survival in patients with 1-3 positive lymph nodes and 4+ positive lymph nodes showed that the values were almost identical irrespective of the number of positive lymph nodes. Another analysis of the same trials by Nielsen *et al.* (2006) assessed the independent prognostic factors for survival after locoregional recurrence from multivariate analysis. Significant factors reducing survival were a large tumour size (larger than 21mm), number of involved lymph nodes, extra-capsular invasion, and site of local recurrence. The meta-analysis of the EBCTCG reported no significant reduction in 15 year breast cancer mortality with radiotherapy. Kyndi *et al.* (2008) reported that there were significantly smaller improvements in locoregional recurrence control after post-mastectomy radiotherapy were found for ER-negative and PgR-negative tumours compared with the ER-positive and PgR-positive tumours and for the triple-negative, and the ER-negative and PgR-negative/human epidermal growth factor receptor 2 (HER2) positive subtypes compared with the ER-positive PgR-positive /HER2-negative subtype.

## PICO

Patients	Interventions	Comparisons	Outcomes
Patients treated for invasive breast cancer with mastectomy (excluding patients with DCIS)	RT to the chest wall following mastectomy	Mastectomy alone	Disease-free survival Overall survival Rates of local recurrence Morbidity Lymphoedema

## Evidence Summary

A large volume of high quality evidence was available which included both postmastectomy and BCS with adjuvant radiotherapy. Several meta-analyses of RCTs were available including a recent analysis from the EBCTCG (Clarke *et al.* 2005). Two additional meta-analyses were reviewed that included some of the same studies as the EBCTCG, as well as additional RCTs (Gebiski *et al.* 2006, Whelan *et al.* 2000). Some analyses were conducted in specified subgroups of the Danish Breast Cancer Cooperative Group (Nielsen *et al.* *et al.* 2006, Overgaard *et al.* 2007), and another used all trials from the EBCTCG (Van de Steene *et al.* 2000). Data on morbidity was only available from the DBC Cooperative Group trials and the

South Sweden breast cancer trial. One retrospective cohort from the SEER database was assessed since data were available for elderly breast cancer patients (Smith *et al.* 2006). A number of guidelines were found and two recent ones were included originating in Canada and the USA.

## **Local Recurrence**

### **Level 1++**

A large systematic review of individual patient data conducted by the EBCTCG ( Clarke *et al.* 2005) reported that RT after postmastectomy with axillary clearance significantly reduced locoregional recurrence. The absolute reduction in local recurrence was greater in node positive than node negative disease (17% vs.4%). The 5 year local recurrence risks of women with 1-3 positive nodes were again greater in the no RT than the RT group. Larger rates were seen in women with N4+ disease but the magnitude of absolute 5 year reduction was similar to those with 1-3 positive nodes. At 15 years the reductions in local recurrence between RT and no RT arms were similar in magnitude to 5 year rates however the rates of recurrence were larger. Local recurrence rates increased with increasing node involvement, however recurrence risk was lower in the RT arm of node positive participants.

The absolute effects of post-mastectomy radiotherapy on the risk of local recurrence were approximately independent of age (local recurrence reductions of 17%, 18%, and 18% for women aged <50, 50–59, and 60–69 years respectively; there were few older women in these trials). For women with node-positive disease in trials of RT after mastectomy and axillary clearance, RT produced similar proportional reductions in local recurrence risk, irrespective of age, tumour grade, tumour size, ER status, or amount of node involvement. Within each subgroup the absolute benefit produced by RT was determined largely by the magnitude of local recurrence risk in un-irradiated women.

A second systematic review of RCTs by Whelan *et al.* (2000) which included some of the trials from the EBCTCG found a large reduction in locoregional recurrence (OR 0.25) and for any recurrence after postmastectomy RT.

A 25 year follow-up of an RCT (Fisher *et al.* 2002) included in the EBCTCG analysis reported no significant differences between the three groups of women with negative nodes or between the two groups of women with positive nodes for disease-free survival, relapse-free survival, distant-disease-free survival, or overall survival. The comparisons made were between women who had radical mastectomy, total mastectomy and total mastectomy + RT.

### **Level 1+**

A subgroup analysis of the DBCG 82 b and c trials was performed to evaluate the loco-regional recurrence rate in relation to number of positive nodes (1-3 or 4 or more) (Overgaard *et al.* 2007). The risk of loco-regional recurrence was most pronounced in patients with 4+ positive nodes.

Another subgroup analysis of the DBCG 82 b and c trials by Nielsen *et al.* (2006) found the frequency of locoregional recurrence was 30% among patients randomized to no RT and 5% for patients randomized to RT. For patients in the no RT group a multivariate analysis found that independent risk factors for locoregional recurrence in node positive patients were:

Primary tumour size larger than 50mm (RR=1.64, 95%CI 1.16–2.29)

Malignancy grade III (RR=1.96, 95%CI 1.45–2.65)

Invasion of the fascia (RR=1.38, 95%CI 1.05–1.81)  
Less than 8 removed nodes (RR=1.64, 95%CI 1.33–2.04)  
4+ positive nodes (RR=1.96, 95% CI 1.56–2.45).

## Overall mortality

### 1++

The EBCTCG (Clarke *et al.* 2005) reported that in trials of RT after postmastectomy with axillary clearance there was a 15 year loss of 4.2% with RT for node negative disease in all cause mortality. In node-positive disease, the reduction in 15-year all-cause mortality in the RT group was 4.4%. At 20 years, the reduction in breast cancer mortality remained unchanged at 5.4% (66.4% vs. 61.0%), while that for all cause mortality, although still significant, was 3.5% (72.3% vs. 68.8%), indicating a continuing excess of non-breast-cancer mortality long after treatment with the older radiotherapy regimens.

In a meta-analysis by Gebiski *et al.* (2006) studies were categorized according to how the RT dose was delivered. Category 1 studies were defined as delivering optimal radiation therapy doses in the range of 40 – 60 Gy in 2-Gy fractions or as a BED to the chest wall, axillary lymph nodes, and the supraclavicular fossa with or without the internal mammary lymph nodes. At a follow-up of 5 years category 1 studies gave a statistically significant 13% relative survival advantage associated with radiation therapy (OR of death from any cause = 0.87, 95% CI 0.79 to 0.96;  $p = 0.006$ ), compared with no radiation therapy, this equates to an absolute 2.9% increase in survival. At a follow-up of 10 years category 1 studies gave a statistically significant 22% increase in relative survival associated with radiation therapy (OR = 0.78, 95% CI = 0.70 to 0.85;  $p < 0.001$ ), compared with no radiation therapy. This corresponds to an absolute 6.4% increase in survival. In trials of high-risk patients (i.e., patients with lymph node positive disease) a separate analysis found that an absolute 5.2% increase in survival (52 per 1000) at 10-year follow-up was associated with adjuvant radiation therapy (OR = 0.80, 95% CI = 0.64 to 1.0) compared with no radiation therapy.

In the analysis by Whelan *et al.* (2000) radiation was shown to reduce mortality with an odds ratio of 0.83 (95% CI, 0.74 to 0.94;  $p = 0.004$ ). On multivariate analysis the timing of radiation therapy was statistically significant ( $p=0.03$ ), with treatment given before 6 months after surgery being more effective (OR 0.78 (95%CI 0.69-0.89). Radiation technique was also found to be statistically significant ( $p=0.05$ ) favouring megavoltage rather than orthovoltage (OR 0.78 (95%CI 0.69-0.89).

### 1+

A survival benefit was found for node 1-3 and node 4+ patients in the analysis of high risk patients by Overgaard *et al.* (2007) from the DBC Cooperative Group trials only. A further analysis comparing LRR and survival in patients with 1-3 positive nodes and 4+ positive nodes found that the values were almost identical irrespective of number of positive nodes. For every ten patients irradiated approximately two LRR and one death could be avoided suggesting that overall postmastectomy radiotherapy is beneficial in high-risk patients and unrelated to the number of positive lymph nodes.

Another analysis of the same trials by Nielsen *et al.* (2006) assessed the independent prognostic factors for survival after LRR from multivariate analysis. Significant factors reducing survival were a large tumour size (larger than 21mm), number of involved nodes, extra-capsular invasion, and site of local recurrence.

## Breast cancer mortality

1++

The meta-analysis of the EBCTCG reported no significant reduction in 15 year breast cancer mortality with RT. (3.6% increase in comparison with no RT,  $p=0.01$ ) in women with node negative disease.

In node positive disease the 15-year breast cancer mortality with and without post-mastectomy radiotherapy was 54.7% versus 60.1%, an absolute reduction of 5.4% (SE 1.3,  $2p=0.0002$ ).

Outcome	Study	RT	No RT	
Local recurrence Node negative Node positive	EBCTCG	5 yr risk reduction 2.3% 5.8%	5 yr risk reduction 6.3% 22.8%	Absolute 5 yr gain 4% 17%

Overall survival at 25 years Node positive	Fisher 2002	Hazard Ratio RM vs. TM+RT: 1.06 (95% CI 0.89 to 1.27, $p=0.49$ )		
Breast cancer mortality (15 yr) Node negative Node positive	EBCTCG			Absolute difference +3.6% with RT (NS) -5.4% with RT (2 $p=0.0002$ )

Another analysis of EBCTCG trials by Van de Steene (2000) found that on univariate analysis begin year of trial, number of patients in the trial, fraction dose, and crude survival in the trial to be statistically significant for overall survival.

The univariate analysis reported a significant survival benefit in the radiotherapy arm for:

- Recent trials (2P < 0.05), the more recent the trial the larger the survival benefit (21.1% gain for trials started after 1980);
- Large trials produce a larger survival benefit (2P < 0.03);
- Trials that used standard fractionation of 1.8-2.5 Gy/fraction (2P < 0.02);
- Trials with a favourable crude survival (2P < 0.03).

Surgical adjuvant radiotherapy significantly improves overall survival of breast cancer patients provided that current techniques are used and treatment is given with standard fractionation.

### Postmastectomy radiation and survival in older women with breast cancer

#### 2+

The analysis of data from women aged > 70 years from the SEER database (Smith *et al.* 2006) found that adjuvant PMRT was associated with a survival benefit for high risk (T3/4 and/or N2/3) breast cancer (Hazard Ratio, 0.85; 95% CI, 0.75 to 0.97; P = 0.02). Five-year adjusted survival was 50% for patients not treated with PMRT or chemotherapy, 56% for

patients treated with PMRT only, 57% for patients treated with chemotherapy only, and 59% for patients treated with both PMRT and chemotherapy. PMRT was not associated with survival in the elderly for low- and intermediate-risk patients.

### **Morbidity**

Three RCTs examined the effects of RT on non-cancer morbidity. Two RCTs used data from the DBC Cooperative Group (Hojris *et al.* 1999, 2000), the other used data from the Swedish trials (Gustavssen 1999).

### **Lymphedema (1++)**

Lymphedema was measured in 14% of the irradiated patients versus 3% of the non-irradiated patients (NS). Slightly decreased shoulder morbidity was measured in 52% of the irradiated women versus 15% of the non-irradiated patients, but moderate or more severe impairment was seen in only 5% of irradiated patients and in none of the non-irradiated patients ( $p = 0.004$ ). Seventeen percent of irradiated patients and 2% of non-irradiated patients found that impairment of shoulder movement caused symptoms ( $p = 0.001$ ) (Hojris *et al.* 2000).

### **Ischaemic Heart Disease (1++)**

More women in the no-radiotherapy group than in the radiotherapy group died of breast cancer (799 [52.5%] vs 674 [44.2%]). Similar proportions of each group died from ischaemic heart disease (13 [0.9%] vs 12 [0.8%]). The relative hazard of morbidity from ischaemic heart disease for patients in the radiotherapy compared with the no-radiotherapy group was 0.86 (95% CI 0.6-1.3), and that for death from ischaemic heart disease was 0.84 (0.4-1.8). The hazard rate of morbidity from ischaemic heart disease in the radiotherapy group compared with the no-radiotherapy group did not increase with time from treatment. Postmastectomy radiotherapy with this regimen did not increase the actuarial risk of ischaemic heart disease after 12 years (Hojris *et al.* 1999).

### **Late Cardiac Effects (1++)**

No cardiac deaths were found among the original 275 patients randomized to adjuvant radiotherapy. In the 90 patients examined, abnormal findings were recorded for ECG (14 patients), exercise test (5 patients), myocardial scintigraphy (6 patients), thickening of valve cusps (14 patients), and mild valvular regurgitation (20 patients). All patients had normal systolic function. Diastolic dysfunction was observed in 6 patients (abnormal relaxation in 4 patients and restrictive filling abnormality in 2 patients). Although no significant differences were found between the 3 study groups, there was a tendency to more abnormal findings after radiotherapy.

### **Guidelines**

There was a general consensus for RT in women with large tumours and more than 4 positive nodes. The role of RT for women with 1-3 positive nodes was less clear. However the guidelines predate the recent EBCTGC and DBC analyses.

### **UPDATE EVIDENCE:**

*Danish Breast Cancer Cooperative Group Nielsen HM, Overgaard M, Grau C, Jensen AR, Overgaard J (2006). Study of failure pattern among high-risk breast cancer patients with or without postmastectomy radiotherapy in addition to adjuvant systemic therapy: long-term results from the Danish Breast Cancer Cooperative Group DBCG 82 b and c randomized studies. J Clin Oncol May 20;24(15):2268-75.*

**Aim:** The aim of this follow up analysis was to evaluate the overall failure pattern among high-risk breast cancer patients who were randomly assigned to RT or no RT in addition to systemic therapy (as part of the Danish Breast Cancer Cooperative Group (DBCG) 82 b and c trials).

## **Results**

### **LRR:**

- The probability of any first BC event (LRR, simLRR-DM, DM, or CBC) was significantly reduced among patients in the RT group: RR=0.68 95% CI 0.63-0.75, P< 0.001).
- The median time to any first BC event was 3.9 after no RT and 7.9 years after RT, (P<0.001).
- The 18-year probability of LRR (with or without DM) or LRR alone was significantly lower in the RT group than the no RT group.
- The frequency of all sites of LRR was lower with RT than without RT.
- Overall, 22% of the patients with LRR in the no-RT group appeared with simultaneous DM, whereas 48% of the patients with LRR in the RT group also had DM at the time of diagnosis of LRR.

### **DM:**

- The 18-year probability of DM subsequent to LRR = 35% after no RT and 6% after RT (P<0.001). The 18-year probability of any DM = 64% after no RT and 53% after RT (P<0.001)
- The median time to DM = 6.5 years in the no-RT group and 12.3 years in the RT group (P=0.04).
- In the no-RT group: DM after LRR and DM as first site of failure were equally common
- In the RT group, DM occurred most often as the first site of failure.
- To assess if the risk of DM was time dependent in the two groups, the hazard rates for 2-year time interval were calculated:
- The DM hazard rates were at all times increased among patients in the no-RT group compared with patients in the RT group.
- In both groups, the DM hazard rate decreased with time after mastectomy (authors note that even 18 years after mastectomy, a small risk of DM was present in both groups).

*Kyndi M, Sorensen FB, Knudsen H, Overgaard M, Nielsen HM, Overgaard J, et al. Estrogen receptor, progesterone receptor, HER-2, and response to postmastectomy radiotherapy in high-risk breast cancer: the Danish Breast Cancer Cooperative Group. J Clin Oncol 2008 Mar 20;26(9):1419-26.*

**Aim:** To examine the effect of oestrogen receptor (ER), progesterone receptor (PgR), human epidermal growth factor receptor 2 (HER-2), and constructed subtypes patients who received or did not receive post-mastectomy radiotherapy (PMRT).

## **Results**

- As reported in the DBCG82 series, overall mortality was significantly reduced (HR=0.84; 95% CI, 0.72 to 0.97), DM (HR=0.80; 95% CI, 0.68 to 0.94) and LRR (HR=0.17; 95% CI, 0.10 to 0.26) probabilities after PMRT were found within the subgroup of 1,000 patients.
- A significantly improved overall survival after PMRT was reported in patients with good prognostic markers such as hormonal receptor-positive and HER2- patients (including the two Rec+ subtypes).

- No significant overall survival improvement after PMRT was reported in patients with an a priori poor prognosis, that is the hormonal receptor–negative and HER2+ patients, and in particular the Rec–/HER-2+ subtype.
- When comparing hazard ratios and 95% CIs, there were significantly smaller improvements in locoregional recurrence control after PMRT were found for ER– and PgR– tumours compared with the ER+ and PgR+ tumors (P=0.003 and 0.04, respectively), and for the triple-negative (P=0.02), and the Rec–/HER-2+ subtypes (P=0.003) compared with the Rec+/HER2– subtype.

*Killander F, Anderson H, Rydén S, Möller T, Aspegren K, Ceberg J, et al. Radiotherapy and tamoxifen after mastectomy in postmenopausal women -- 20 year follow-up of the South Sweden Breast Cancer Group randomised trial SSBCG II:I. European journal of cancer (Oxford, England : 1990) 2007;43(14):2100-8.*

**Aim:** To evaluate long-term effects of radiotherapy and tamoxifen after mastectomy on recurrence and survival in stage II breast cancer.

**LRR:**

- The cumulative incidence of loco-regional recurrences as first event at 20 years of follow-up was significantly reduced, with 71%, with radiotherapy ( $p < 0.001$ ), and 18.5% (95% CI 13.8–23.8%) in the tamoxifen group compared to 5.3% in the RT + tamoxifen group and 6.7% (95% CI 3.8–10.4%) in patients randomised to RT with and without tamoxifen.
- In N0 patients: 7% loco-regional recurrences were diagnosed after 20 years in the Tamoxifen group, versus 6% in the RT + Tam group.
- In the N1–3 subgroup: the incidence was 25.9% (95% CI 17.5– 35.1%) in the Tamoxifen group, and 2.6% (95% CI 0.5–8.3%) in the RT + Tamoxifen group.

**Cumulative incidence of systemic disease**

- At 20 years the cumulative incidence of systemic disease = 50% in the RT group, 40% in the RT + Tamoxifen group and 45% in the tamoxifen group ( $p = 0.33$  comparing RT + Tam versus Tam, and  $p = 0.047$  comparing RT vs RT + Tam)
- Considering only receptor positive patients the numbers were 54% (RT only) , 40% (tamoxifen) and 41% (RT plus tamoxifen), ( $p = 0.047$  comparing RT versus RT + Tamoxifen).
- In patients with more than three lymph nodes, there was a significant difference between RT and RT + Tamoxifen (88% versus 67%,  $p = 0.02$ ).
- There were no significant differences reported for node negative patients.

**Survival:**

- Overall mortality at 20 years = 71% with RT, 68% with RT + tamoxifen group and 62% in tamoxifen group.
- The difference between RT + Tamoxifen versus Tamoxifen was not significant ( $p = 0.14$ ).
- The difference between was not significantly different between RT and RT + Tamoxifen ( $p = 0.50$ ).
- WRT hormone receptor positive patients the mortality rates at 20 years were 74% in the RT arm, 67% in the combination arm, and 54% in the Tamoxifen group.

- No statistically significant difference was reported when comparing RT to RT + Tamoxifen ( $p = 0.28$ ) but the comparison of RT + Tamoxifen versus Tamoxifen was significant in favour of patients not receiving radiotherapy ( $p = 0.047$ )
- In the N1–3 group, mortality at 20 years was 74%, 65% and 64% (but there was no significant difference).

## Evidence Tables

### Systematic review of RCTs

Clarke M, Collins R, Darby S, Davies C, Elphinstone P, Evans E, Godwin J, Gray R, Hicks C, James S, MacKinnon E, McGale P, McHugh T, Peto R, Taylor C, Wang Y, Early Breast Cancer Trialists' Collaborative Group (2005) Effects of radiotherapy and of differences in the extent of surgery for early breast cancer on local recurrence and 15-year survival: an overview of the randomised trials.[see comment]. [Review] [33 refs]. *Lancet* **366**, 2087-2106.

Design: Systematic review of individual patient data

Level 1++

Country: Multinational

Aim: To update previous meta-analyses of individual patient data from randomised trials of the effects of radiotherapy and extent of surgery on local disease control and cause-specific mortality in early breast cancer. To quantify the relationship between local control and long term mortality.

#### Inclusion criteria

Randomised trials of mastectomy alone or with axillary clearance (AC) or axillary sampling (AS), then radiotherapy (RT) versus no RT. (Other studies involving breast conserving surgery were also included in the overview).

#### Exclusion criteria

Trials considered to be confounded, e g., no difference in treatment groups in the use of systemic therapy.

#### Population

Comparison

Trials

Women

Mastectomy + AC then RT versus no RT

25

9933

Mastectomy + AS then RT versus no RT

4

647

Mastectomy alone, then RT versus no RT

7

5597

#### Interventions

Update of individual patient data from randomised trials by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) from results up to the year 2000. The randomised trials compare local treatments of various types of surgery or radiotherapy (RT) or both. The intervention categories relevant to this topic were mastectomy alone or with axillary clearance or sampling, then RT or no RT.

#### Outcomes

Breast cancer recurrence (ipsilateral locoregional, contralateral or distant). Includes residual breast tissue, scar area, chest wall, ipsilateral regional lymph nodes. 5 year risk.

Cause-specific mortality

Breast cancer mortality- 15 year risk

Overall mortality

Incidence of second primary cancers before breast cancer recurrence.

#### Follow up –

This is an ongoing systematic overview of randomised trials with an update every 5 years. The current publication (2005) used a pooled analysis of individual patient data from the included studies rather than the primary studies themselves.

#### Results

A number of analyses were conducted after stratification by trial, time since randomization and nodal status (positive or negative). The main outcomes of local recurrence, breast cancer mortality and overall mortality were also stratified by age at randomization (<40, 40-49, 50-59, 60-69, > 70 years).

#### Local recurrence

Results of a meta-analysis of 36 trials in 3 subgroups (by type of surgery) were provided as a Forest plot in the paper.

RT was compared with no RT by node status. Data are shown in the following table:

	Events by year 5		5 year risk (actuarial %)		Absolute reduction in 5 year risk (%) for addition of RT Reduction (SE)
	Mast +RT	Mast only	Mast +RT	Mast only	
Mastectomy + AC (25 trials)					
Node negative	13/662	41/691	2.3	6.3	4.0% (1.1)
Node Positive	214/4170	778/4170	5.8	22.8	17.1% (0.9)
Mastectomy + AS (4 trials)					
Node negative	13/225	52/224	6.1	24.5	18.5% (3.5)
Node Positive	11/95	43/103	13.8	50.1	36.3% (7.5)
Mastectomy only (7 trials)					
Node negative	70/1427	307/1477	5.6	23.3	17.6% (1.4)
Node Positive	88/837	243/836	11.6	33.5	21.9% (2.3)

AC = Axillary Clearance  
AS = Axillary Sampling

There were reductions in the risk of local recurrence in the radiotherapy arms compared to no radiotherapy after all three types of surgery at 5 years. The absolute reductions were greatest amongst node positive women. The lowest absolute reduction occurred in the subgroup of women who were node negative after mastectomy with axillary clearance followed by RT.

#### *Node negative disease*

5 year risk of local recurrence after mastectomy with AC was 6.3% without RT and 2.3% with RT ( $2p=0.0002$ ). This corresponds to an absolute 5 year gain of 4% (SE 1.1).

#### *Node positive disease*

5 year risk of local recurrence after mastectomy with AC was 22.8% without RT and 5.8% with RT corresponding to an absolute 5 year gain of 17% (SE 0.9).

#### **Breast cancer mortality**

Breast cancer mortality data for women after mastectomy with axillary clearance (AC) were reported by subgroup.

#### *Node negative disease (n=1428)*

There was no significant reduction in 15 year breast cancer mortality with RT. A small increase in mortality (3.6%, SE 2.6) with RT was reported, however the number of events was small.

Breast cancer mortality (%) at 15 years:

31.3% after mastectomy + AC + RT

25.7% after mastectomy + AC excluding data beyond 15 years logrank  $2p=0.18$

#### *Node positive disease (n=8505)*

In node positive disease the 15-year breast cancer mortality rate with post-mastectomy radiotherapy was 54.7%, and 60.1% without RT. The absolute gain of 5.4% with post-mastectomy RT was significant (SE 1.3, logrank  $2p=0.0002$ ).

The authors comment that although 8505 women had mastectomy with AC in node positive disease, inclusion of the 2500 women with AS would not have substantially altered breast cancer mortality or local recurrence rates.

In a further analysis the authors suggest that the avoidance of a local recurrence (during the first 5 years) may reduce mortality (after the first 5 years) from trials of post-mastectomy RT and post BCS RT.

#### **Subgroup analyses**

Treatment comparisons were analysed by subgroups of age and tumour characteristics (grade, size, ER status, node involvement). For women with node-positive disease in trials of RT after mastectomy with axillary clearance, RT produced similar absolute reduction rates in local recurrence risk, irrespective of age, tumour grade, tumour size, ER status, or amount of node involvement. Within each subgroup the absolute benefit produced by RT was determined largely by the magnitude of local recurrence risk in unirradiated women.

Effects of age and tumour characteristics on 5 year risks of local recurrence in trials of RT after mastectomy and AC in women with node-positive disease are shown in the table below which is taken from the paper.

*5 year local recurrence risk (%) after mastectomy with AC in women with node positive disease*

Subgroup	5 year risk of local recurrence (%) in RCTs of RT after mastectomy + AC (node positive)	
	RT vs. control	Absolute reduction (SE)
<b>Age (years)</b>		
<50	6 vs 23	17 (1)
50-59	6 vs 24	18 (2)
60-69	5 vs 23	18 (2)
≥ 70	-	-
<b>Tumour grade</b>		
Well differentiated	4 vs 22	18 (3)
Moderately differentiated	4 vs 30	26 (2)
Poorly differentiated	6 vs 40	34 (4)
<b>Tumour size (T category)</b>		
1-20mm (T1)	5 vs 22	17 (2)
21-50mm (T2)	6 vs 30	24 (2)
> 50mm (T3 or T4)	8 vs 36	28 (4)
<b>ER status</b>		
ER poor	8 vs 28	20 (2)
ER positive	6 vs 24	18 (2)
<b>N of involved nodes</b>		
1-3	4 vs 16	12 (2)
>4	12 vs 26	14 (2)
<b>All women</b>	6 vs 23	17 (1)

*Age*

There was no trend in 5 year risk of local recurrence (in the chest wall or lymph nodes) with age among women with mastectomy, axillary clearance and node-positive disease with or without RT. Consequently the absolute effects of post-mastectomy radiotherapy on the risk of local recurrence were also independent of age:

Age	5-year risk reduction
< 50 years	17%
50-59	18%
60-69	18%

*Tumour characteristics*

Women with large tumours or with direct extension to the skin or chest wall (T2/T3/T4 tumours), or poorly differentiated tumours had a higher 5 year risk of local recurrence when RT was omitted. ER status did not appear to affect this risk.

The number of involved nodes (1–3 or ≥4) was unavailable for more than half the women who were node positive and had mastectomy with axillary clearance. The data that was available is reported below:

5-year local recurrence risks	RT	no RT	Risk reduction
Node 1-3	4%	16%	12% (SE 2)
Node ≥ 4	12%	26%	14% (SE 2)

*Local recurrence and node status*

The 15-year isolated local recurrence rates for women with 1 to 3 or with 4 or more involved nodes were very different and are reported below (from webtables published in the original paper):

MAST+AC ± RT (15 year outcome) for women with 1-3 involved lymph nodes (pN1-3) (Life table curves 1890 women) and for women with 4 or more involved lymph nodes (pN4+) (Life table curves 1868 women):

15-year local recurrence risks	RT	no RT	5 year gain
Node 1-3	5.8%	19.5%	11.6% (SE 1.5)
Node ≥ 4	15.4%	35.2%	14.8% (SE 2.3)

*Overall mortality, breast cancer mortality and node status*

At 15 years the reduction in all-cause mortality (4.4%) in trials of radiotherapy after mastectomy with axillary clearance in node-positive disease was lower than the reduction in 15-year breast cancer mortality (5.4%). When the data is was extended to 20 years, the reduction in breast cancer mortality remained unchanged, and that for all cause mortality was lower than at 15 years. The authors suggest that this indicates an excess of non-breast-cancer mortality long after treatment with the older radiotherapy regimens. The data is reported below:

All node positive (n=8505)	RT	no RT	Gain
15 year all-cause mortality	59.8%	64.2%	4.4% (SE 1.2, 2p 0.0009)
15 year breast cancer mortality	54.7%	60.1%	5.4% (SE 1.3, 2p 0.0002)
20 year all-cause mortality	68.8%	72.3%	3.5%
20 year breast cancer mortality	61.0%	66.4%	5.4%

The 15 year outcomes of the subgroup of women with 1-3 involved nodes are reported below:

Node 1-3 positive (n=1890)	RT	no RT	Gain
15 year all-cause mortality	51.1%	52.7%	1.6% (SE 2.6, 2p >0.1; NS)
15 year breast cancer mortality	43.3%	47.7%	4.4% (SE 2.6, 2p >0.1; NS)

The 15 year outcomes of the subgroup of women with 4 or more involved nodes are reported below:

Node 4+ positive (n=1868)	RT	no RT	Gain
15 year all-cause mortality	70.8%	72.4%	1.7% (SE 2.5, 2p >0.1; NS)
15 year breast cancer mortality	68.0%	70.3%	2.3% (SE 2.3, 2p >0.1; NS)

*Node negative disease*

A further analysis of all women with node negative nodes (n=1428) was also conducted, and results are reported below:

All node negative (n=1428)	RT	no RT	Gain
15 year isolated local recurrence	3.1%	8.1%	4.0% (SE 1.1)
15 year all-cause mortality	42.4%	38.2%	4.2% (SE 2.7, 2p 0.0002)
When data beyond 15 year excluded			2p=0.12
15 year breast cancer mortality	31.3%	27.7%	3.6% (SE 2.6, 2p 0.01)
When data beyond 15 year excluded			2p=0.18

A 5 year gain of 4% (SE 1.1%) was achieved with RT in local recurrence rates in women with node negative disease. Conversely there was a 15 year loss with RT for node negative disease in breast cancer mortality (3.6% SE 2.6) and all cause mortality (4.2% SE 2.7). Both these findings were statistically significant, however, when data beyond 15 years was excluded the findings were not significant.

**Author conclusions** (from the paper)

In trials of radiotherapy after mastectomy and axillary clearance, the 5-year risk of local recurrence in controls depended on the number of involved nodes, (risks 6%, 16%, and 26% respectively for 0, 1–3, and ≥4 involved nodes). Among women with mastectomy, axillary clearance, and node-negative disease the absolute reduction in 5-year local recurrence risk after radiotherapy was 4% (2% vs. 6%) If one death from the original breast cancer is avoided for every four local recurrences avoided, then the expected reduction in 15-year breast cancer mortality after radiotherapy would be

1% (less the adverse effects of any increase in contralateral disease). However, sample size was small in this subgroup and the effect of radiotherapy on breast cancer mortality was unfavourable.

Among all women with mastectomy, axillary clearance, and node-positive disease, the absolute effects of radiotherapy on 5-year local recurrence risk were substantial (6% vs. 23%), particularly if the tumour was poorly differentiated or large, and breast cancer mortality was correspondingly reduced. In these post-mastectomy trials age had little influence on local recurrence (mainly in the nodes or chest wall).

In early breast cancer, local treatments that substantially improve local control have little effect on breast cancer mortality during the first few years, but have definite, although moderate, effects by 15 years, and avoidance of local recurrence in a conserved breast and elsewhere are of comparable relevance to 15-year breast cancer mortality. These trials of radiotherapy and of the extent of surgery show that, in the hypothetical absence of other causes of death, about one breast cancer death over the next 15 years would be avoided for every four local recurrences avoided. Although the management of early breast cancer continues to change, it is reasonable to assume that this approximate four-to-one relationship will continue to apply and will still be of relevance to future treatment choices.

**General comments -**

Updated 2018

Gebski, V., Lagleva, M., Keech, A., Simes, J., & Langlands, A. O. 2006, "Survival effects of postmastectomy adjuvant radiation therapy using biologically equivalent doses: a clinical perspective.[see comment][erratum appears in J Natl Cancer Inst. 2006 Jun 21;98(12):876]", *Journal of the National Cancer Institute*, vol. 98, no. 1, pp. 26-38

Design: Meta-analysis of RCTs that had been previously included in earlier published meta-analyses and systematic reviews. Trials were identified up to 2002.

Country: Australia

Level 1++

Aim: The association between post-mastectomy radiation therapy for early breast cancer and overall survival was assessed in a meta-analysis of 36 randomized trials containing 38 comparisons that were unconfounded (addition of radiation therapy was the sole discriminant between treatments being compared). The specific issues of radiation dosage and target volume coverage were of interest. Studies using optimal BED (Biological Equivalent Dose) and appropriate target volumes were assessed for any observed benefit of radiation therapy.

#### **Inclusion criteria**

- 1) Studies were of operable breast cancer that was initially treated by mastectomy. (Stage I and stage II disease and selected cases of stage III disease were considered operable).
- 2) Studies were randomized controlled clinical trials that compared adjuvant radiation therapy with no such therapy. This treatment was the sole discriminating factor between the two arms of the trial. Other treatments, including extent of surgery, endocrine therapy, and chemotherapy, if given, had to be common to each arm.

Three studies that reported the use of randomization but may have used date of birth as the allocation method were included in the primary analysis but were excluded from a sensitivity analysis.

#### **Exclusion criteria**

##### **Population**

Thirty-eight unconfounded randomized comparisons from 36 trials were identified, with data available from a total cohort of 13 199 patients. Thirty-three of these comparisons were included in the EBCTCG analysis. Because of access to individual patient data for some studies, the EBCTCG was able to provide comparisons in addition to or different from those in published reports, so a direct comparison between this meta-analysis and the EBCTCG was not always possible.

##### **Interventions**

Radiotherapy treatment for each trial was classified into three major categories:

###### Category 1

Optimal radiation therapy: studies that delivered optimal radiation therapy defined as doses in the range of 40 – 60 Gy in 2-Gy fractions (where 50 Gy = 5000 rads) or as a BED to the chest wall, axillary lymph nodes, and the supraclavicular fossa with or without the internal mammary lymph nodes.

###### Category 2

Inadequate or excessive radiation therapy: studies that delivered inadequate or excessive radiation therapy defined as either doses of less than 40 Gy in 2-Gy fractions (or, for other fractionation schedules, the calculated BED being less than 40 Gy) or if greater than 60 Gy in 2-Gy fractions (or for other fractionation schedules the calculated BED being more than 60 Gy). (The authors state that the BED was calculated by use of  $\alpha/\beta$ , a ratio that reflects the weight of the dose per fraction in the schedule to the total dose delivered, equal to 10, standardized to 2-Gy fractions).

###### Category 3

Incomplete tissue coverage: studies in which radiation therapy provided incomplete tissue coverage by restricting the target volume to areas of less than the area of the chest wall and regional lymph nodes. Techniques for which the target volume was restricted were considered to be inappropriate because an area at risk of recurrence received no radiation therapy.

Category 2 studies provided treatment that delivered an inadequate or excess dose irrespective of

target volume. Those studies in category 3 provided treatment that delivered an inappropriate target volume irrespective of dose. Studies that met category 2 and 3 criteria were included in category 2.

### **Outcomes**

The primary outcomes were 5-year and 10-year overall survival rates calculated by intention-to-treat analysis.

### **Follow up**

### **Results**

38/40 RCTs compared postoperative radiation therapy with no RT and were not confounded.

Category 1: 25 RCTs used optimal RT with appropriate target volume.

Category 2: 7 RCTs used inadequate or excessive doses of RT.

Category 3: 6 RCTs used inappropriate target volumes.

26 studies with follow-up data at 5 years included a total of 13 199 patients  
19 studies with follow-up data at 10 years included a total of 8921 patients  
Thirteen studies compared megavoltage, one compared orthovoltage, two compared both orthovoltage and megavoltage, and one compared radiation energy not stated.

For eight of the 38 comparisons, no systemic chemotherapy was given and for the comparisons in the primary analysis, no systemic chemotherapy was given in four of the early studies — the Stockholm study (1993) the Edinburgh study (1994), NSABP-04 (1980, 1985), and the Wessex study (1978); the rest of the studies included chemotherapy and/or hormone therapy.

Pooled weighted estimates were calculated for survival at 5 and 10 years.

### **5 year follow-up**

A meta-analysis of the association between post-mastectomy RT and mortality at 5 years of follow-up was conducted and included 38 comparisons from 36 unconfounded trials.

At a follow-up of 5 years category 1 studies gave a statistically significant 13% relative survival advantage associated with radiation therapy (OR of death from any cause = 0.87, 95% CI = 0.79 to 0.96;  $P = 0.006$ ), compared with no radiation therapy.

This translates into an absolute 2.9% increase in survival (or 29 lives per 1000 patients treated) and a number needed to treat of 34 (i.e., on average, for every 34 patients treated, one life would be saved over 5 years).

### **10 year follow-up**

A meta-analysis of the association between post-mastectomy RT and mortality at 10 years of follow-up was conducted and included 19 comparisons from 18 unconfounded trials.

After follow-up of 10 years studies in category 1 gave a statistically significant 22% increase in relative survival associated with radiation therapy (OR = 0.78, 95% CI = 0.70 to 0.85;  $P < 0.001$ ), compared with no radiation therapy. This corresponds to an absolute 6.4% increase in survival (64 per 1000) and number needed to treat of 16.

### **Node positive disease**

In trials of high-risk patients (i.e., patients with lymph node positive disease) a separate analysis found that an absolute 5.2% increase in survival (52 per 1000) at 10-year follow-up was associated with adjuvant radiation therapy (OR = 0.80, 95% CI = 0.64 to 1.0;  $P = 0.05$ , with no evidence of heterogeneity), compared with no radiation therapy.

There was no statistically significant association between radiation therapy and survival after 5 or 10 years for category 2 (inadequate or excessive dose) or 3 (inappropriate target volume) studies.

(5 year category 2: OR 0.92 (95% CI 0.81-1.04); category 3: OR 1.03 (95% CI 0.73-1.44).

(10 year category 2: OR 0.91 (95% CI 0.75-1.11); category 3: OR 0.97 (95% CI 0.61-1.55).

## Application of classification system to EBCTCG trials (from data in year 2000)

### *Overall survival*

In the 23 studies from the EBCTCG report that were classified as category 1, overall survival improved significantly. An absolute survival benefit associated with radiation therapy was reported of 3.9% (39 per 1000), and a relative benefit of 13% (OR of death = 0.87, 95% CI = 0.80 to 0.94,  $P < 0.001$ ). The association was stronger than for category 2 studies (OR = 0.97, 95% CI = 0.87 to 1.09) and category 3 studies (OR = 1.26, 95% CI = 1.03 to 1.53) showed substantial harm. Heterogeneity was statistically significant over the three classification groups ( $P$  heterogeneity = 0.006).

Data from nine category 1, four category 2 and one category 3 trials of the EBCTCG were used for a meta-analysis of the association between radiotherapy and isolated local recurrence, breast cancer mortality and non-breast cancer mortality.

Local recurrence rates varied by category, radiation therapy was associated with an 80% reduction in local recurrence in category 1 studies, a 70% reduction in category 2, and a 64% reduction in category 3 studies. Heterogeneity was statistically significant between these categories ( $P$  heterogeneity  $< 0.001$ ). However, heterogeneity was not statistically significant between the studies of radiation therapy associated with non-breast cancer mortality, although some was detected for breast cancer mortality ( $P$  heterogeneity = 0.07).

An analysis of the 9 category 1 studies found a 20% reduction in breast cancer deaths associated with radiation therapy (OR = 0.8, 95% CI = 0.73 to 0.88), and a 15% increase in non-breast cancer deaths associated with radiation therapy (OR = 1.15, 95% CI = 0.97 to 1.36).

### **Author conclusions**

By restricting meta-analyses to trials that used the optimal radiation therapy dose delivered to appropriate target volumes the authors found that radiation therapy was associated with improved overall survival. Over all such trials with available data and among those eligible trials included in the EBCTCG overview (23 of 26 have common comparisons), improved 5-year survival and 10-year survival was associated with optimal radiation therapy.

Evidence from randomized trials of other outcomes (isolated local recurrence and cause-specific deaths) appeared to consistently support the findings. Among EBCTCG trials with available data, trials that used optimal radiation therapy found a statistically significant association of radiation therapy with a lower risk of local recurrence than trials using another radiation therapy regimen. Furthermore, studies that used optimal radiation therapy might show a larger reduction of breast cancer mortality and a smaller reduction of non-breast cancer mortality (because of less radiation to inappropriate target volumes). Among EBCTCG trials that reported cause-specific mortality, the results were consistent with this expectation but not definitive, possibly because of the small number of trials with available data.

The results of both the primary analysis and reanalysis of the EBCTCG indicate that the balance between breast cancer and non-breast cancer deaths should favour radiation therapy for women with a high risk of death from breast cancer, particularly when the proportion of non-breast cancer deaths is low (i.e., there is a low risk of non-breast cancer deaths among all women at high risk of breast cancer death).

### **General comments –**

#### Definitions:

EBCTCG: the statistics for breast cancer mortality are derived by logrank subtraction (i.e. subtraction of the logrank statistics for mortality from causes other than breast cancer from the logrank statistics for any death). The EBCTCG report breast cancer deaths and any death. It is not clear how the analysis by Gebiski et al has measured non-breast cancer mortality or breast cancer mortality.

#### Limitations:

The authors state that survival data at 5 and 10 years follow-up was missing in several trials which

may have contributed to a biased estimate of effect favouring postoperative RT. Also the analyses of survival at 5 and 10 years follow-up ignore the late effects after 10 years.

An Editorial by Prosnitz and Marks (2006) points out further limitations of this analysis which are reported below:

(Journal of the National Cancer Institute (2006); 98 (1): 3-4. Post-mastectomy Radiotherapy: Quality Counts!

Additional limitations of this analysis are as follows:

1) The inclusion of many studies in which adjuvant systemic therapy was not used. In a disease with a high frequency of systemic relapse, local-regional therapy is most likely to improve survival when effective systemic therapy is used.

2) The inclusion of patients with various risks of relapse (i.e., high, medium, and low). Potential absolute survival benefits of radiation therapy will be less in the low-risk group.

3) Ten-year analysis may not fully reflect the impact of radiation therapy-related mortality, which is primarily cardiac mortality and usually occurs more than 10 years after treatment. Radiation therapy-induced cardiac damage is largely a technical issue; the heart can, for the most part, be avoided with modern treatment planning. Recent studies have suggested no increase in cardiac deaths after post-mastectomy radiation therapy, but further follow-up is desirable. One can account for length of follow-up by performing meta-analyses subdivided by year of onset of the trial.

#### Comparison of results for EBCTG 2005 and Gebski 2006

Outcome	Clarke 2005	Follow-up	RT	No RT	Absolute difference for RT arm	Gebski 2006	Relative difference for RT arm

Whelan, T. J., Julian, J., Wright, J., Jadad, A. R., & Levine, M. L. 2000, "Does locoregional radiation therapy improve survival in breast cancer? A meta-analysis", *Journal of Clinical Oncology*, vol. 18, no. 6, pp. 1220-1229.

Design: Systematic review of RCTs (1966-1999) Level 1++

Country: Canada

Aim: To review all trials of locoregional radiation therapy in women treated with systemic therapy to determine if the mortality effects observed in recently published studies were consistent with those in other trials and to assess the generalizability of these findings to current practice. Specific objectives were to conduct a systematic review of randomized trials that examined the effectiveness and toxicity of locoregional radiation therapy in patients with breast cancer treated by definitive surgery and adjuvant systemic therapy, to perform a meta-analysis of the results of these trials, and to consider possible factors (patient- and treatment-related) that could influence the treatment effect.

#### **Inclusion criteria**

Published in a peer-reviewed journal in any language;

All patients were treated by definitive surgery, either radical/modified radical mastectomy or lumpectomy plus axillary dissection;

Patients in both treatment arms received the same systemic therapy;

Allocation of locoregional radiation treatment was randomized;

Radiation therapy was delivered to the regional lymph nodes and chest wall or breast;

Median follow-up of 5 years or more.

#### **Exclusion criteria**

None reported

#### **Population**

##### *Patient characteristics*

Trials were heterogeneous regarding patient characteristics.

Most trials included both pre- and postmenopausal women.

Two trials included only pre-menopausal patients, one trial included only postmenopausal patients.

Most trials limited eligibility to patients with positive nodes. One trial limited patients with more than four positive nodes, and two trials limited patients with stage III disease.

Several trials included patients with node-negative breast cancer and stage III disease.

One trial included patients with node-negative breast cancer with primary tumours 2 to 5 cm.

#### **Interventions**

In the majority of trials, patients were treated with modified radical mastectomies. No trials treated patients with lumpectomies and axillary dissections. The extent of axillary dissection was reported in 12 trials.

A majority of trials delivered radiation to the chest wall, supraclavicular, axilla, and internal mammary nodal areas.

Field arrangements or techniques varied between and within trials. The chest wall was irradiated with two tangential fields or with a single direct electron or photon field.

Radiation was delivered primarily with megavoltage linear accelerators. The radiation dose ranged from 35 to 60 Gy in 12 to 30 fractions and was delivered over 2.5 to 7 weeks. The most common fractionation schedule was 50 Gy in 25 fractions over a 5-week period.

Compliance with radiation therapy where reported ranged from 68% - 100% (median, 96%).

All trials included patients treated with systemic therapy. Chemotherapy was used in 19 trials; combined chemo-endocrine therapy in three trials; tamoxifen alone in two trials; and immunotherapy with chemotherapy in two trials.

#### **Outcomes**

Toxicity

Any recurrence, locoregional recurrence

## Mortality

### Follow up

Median follow-up ranged from 7.5 to 14.5 years.

### Results

Eighteen randomized trials met the inclusion criteria with a total of 6367 patients

#### Toxicity

Eight trials provided data on toxicity.

Acute toxicity was reported infrequently and included: severe skin toxicity, 2.7% and 5% (2 trials); myelosuppression attributed to radiation therapy, 2% and 32% (2 trials); and radiation pneumonitis, 1%, 15%, and 23% (3 trials). Radiation oesophagitis occurred in 17% of patients in one trial. This study had particularly high rates of acute and long-term toxicity and was the only trial in which radiation was given concurrently with chemotherapy.

Late toxicity:

- No cases of brachial plexus neuropathy were reported.
- Arm oedema was reported in three trials. The incidence ranged from 0% to 25% (median, 3%) in non-irradiated patients and from 10% to 54% (median, 12%) in irradiated patients.
- Cardiac toxicity, primarily congestive heart failure, was reported in six trials. In trials using CMF, no cardiac complications were reported in patients treated with chemotherapy alone (2 trials). One case of pericarditis was reported in a patient treated with CMF and radiation therapy (1 trial). In patients treated with anthracycline-containing chemotherapy (4 trials), the incidence of congestive heart failure in non-irradiated patients ranged from 0% to 19.2% (median, 2.6%), whilst in irradiated patients cardiac failure ranged from 1.9% to 23.6% (median, 3.2%).
- In two studies, no increase in 12-year cumulative morbidity or mortality from ischemic heart disease was observed in irradiated patients.
- The incidence of secondary cancers was reported in two trials; no increase was noted in irradiated patients. One case of acute myelogenous leukaemia was reported in a patient treated with CMF and radiotherapy.

#### Recurrence

Data on recurrence were available from 13 trials.

Radiation therapy significantly reduced the risk of any recurrence [odds ratio 0.69 (95% CI 0.58-0.83;  $p = 0.00004$ )].

This was mainly due to a reduction in locoregional recurrence [odds ratio 0.25 (95% CI, 0.19-0.34;  $p=0<0.000001$ )].

#### Mortality

Mortality data were available for all trials.

Radiation therapy significantly reduced mortality [odds ratio 0.83 (95% CI 0.74-0.94;  $p = 0.004$ )]. Heterogeneity was not significant ( $p = 0.26$ ).

A positive treatment effect was seen in 6/9 trials of more than 200 patients.

Two of three trials had negative treatment effects, compliance with radiation therapy was poor in these studies.

A further statistical analysis using univariate and multivariate tests found that timing of RT ( $\geq 6$  months vs.  $< 6$  months) was statistically significant, with RT given early reducing mortality:

$< 6$ months	12 studies OR 0.78 (95%CI 0.69-0.89)	
$\geq 6$ months	3 studies OR 1.14 (95%CI 0.80-1.62)	$p=0.05$

All other univariate comparisons were not statistically significant for effect on mortality:

Early vs advanced disease  
Axillary dissection: less extensive vs. extensive  
Anthracycline use  
Radiation technique: megavoltage vs. orthovoltage  
Extent of radiation: all sites vs. not all sites  
Radiation dose:  $\geq 45\text{Gy}$  vs.  $< 45\text{Gy}$   
Locoregional recurrence:  $> 24\%$  vs.  $\leq 24\%$   
Methodological quality:  $\geq 2$  vs.  $< 2$

When multivariate analysis was conducted timing of radiation remained statistically significant ( $p=0.03$ ). Radiation technique megavoltage vs. orthovoltage was also found to be statistically significant:

Megavoltage	13 studies OR 0.78 (95%CI 0.69-0.89)	
Orthovoltage	5 studies OR 0.94 (95%CI 0.74-1.19)	$p=0.05$

#### **Author Conclusions**

Locoregional radiation after surgery in patients treated with systemic therapy reduced mortality. Several questions remain on how these results should be translated into current-day clinical practice.

#### **General comments -**

Updated 2018

Overgaard M, Nielsen HM, Overgaard J, Overgaard M, Nielsen HM, Overgaard J. Is the benefit of postmastectomy irradiation limited to patients with four or more positive nodes, as recommended in international consensus reports? A subgroup analysis of the DBCG 82 b&c randomized trials. *Radiotherapy & Oncology* 2007 Mar;82(3):247-53.

Design: Subgroup analysis of DBCG 82 b and c RCTs (1982-1990) Level 1+  
Country: Denmark

Aim: A subgroup analysis of the DBCG 82 b and c trials was performed to evaluate the loco-regional recurrence rate and survival in relation to number of positive nodes (1-3 or 4 or more), and whether this is a relevant descriptor of the indication for postmastectomy radiotherapy in high risk patients receiving systemic therapy.

#### **Inclusion criteria**

The DBCG 82 b and c trials enrolled 3083 pre- and postmenopausal high-risk women who were randomized to postoperative RT in addition to adjuvant systemic therapy. The present analysis was limited to 1152 node positive patients with 8 or more nodes removed. All patients were aged < 70 years.

#### **Exclusion criteria**

Patients with distant metastases occurring within one month of the LRR were not included in this analysis.

#### **Population**

3083 patients included;  
1708 pre- and menopausal (DBCG 82b);  
1375 patients postmenopausal and < 70 years of age (DBCG 82c);  
Only high-risk patients were included, defined as patients with positive nodes and/or a T3 or T4 tumour and/or skin or deep fascia invasion.

#### **Interventions**

All patients were treated with total mastectomy and partial axillary dissection to remove level 1 and some level 2 axillary nodes, and all macroscopically enlarged lymph nodes.

After surgery, adjuvant systemic therapy was administered, and patients were randomized to postoperative radiotherapy or no radiotherapy.

Systemic therapy in premenopausal and menopausal patients as 8–9 cycles of CMF. Postmenopausal patients received Tamoxifen 30 mg daily for 48 weeks.

Radiotherapy was given as a dose of 48–50 Gy in 22–25 fractions over 5 weeks to the chest wall, and regional lymph nodes (internal mammary nodes, peri-clavicular nodes, axilla).

The applied radiotherapy avoided irradiation of the heart, and no excess cardiac morbidity and death was recorded.

#### **Outcomes**

Definitions:

A loco-regional recurrence (LRR) was defined as any reappearance of cancer in the ipsilateral chest wall and/or axillary and/or supra/infraclavicular nodes without any prior or simultaneous distant failure.

Outcomes:

Overall survival

Loco-regional recurrence after mastectomy without simultaneous distant metastases.

#### **Follow up**

The evaluation date for recurrences and survival was November 15, 2004, which resulted in a median follow-up time after mastectomy of 18 years (range 15–22).

#### **Results**

Patient and tumour characteristics of the 1152 patient cohort did not differ substantially from the original cohort of 3083 patients, although p values were not reported. The group of patients with 1-3 positive nodes did not appear to differ from the group with 4+ positive nodes (again p values were not reported).

At 15 years:

179 (16%) patients had a LRR

762 (66%) patients had died

*Loco-regional recurrence*

The distribution of LRR between treatment groups is shown below:

LRR	Patients	15 year actuarial value for LRR	
RT group	23/563 (4%)	6%	
No RT	156/589 (26%)	37%	p<0.001

Relative risk (RR) of 0.12 (95% CI 0.07–0.19)

*Survival*

A similar effect was seen when evaluating the outcome for survival:

	Patients	15 year actuarial survival values	
RT group	343/563 (61%) deaths	39%	
No RT group	419/589 (71%) deaths	29%	p=0.015

RR of 0.63 (95% CI 0.49–0.81)

The results were also analysed by node status for patients with 1-3 positive lymph nodes and 4+ positive lymph nodes.

*Loco-regional recurrence*

The distribution of LRR between treatment groups and node status is shown below:

**Node 1-3**

LRR	Patients (1-3 +ve nodes)	15 year actuarial values for LRR	
RT group	8/276 (3%)	4%	
No RT	63/276(23%)	27%	p<0.001

Relative risk (RR) of 0.10 (95% CI 0.05–0.22)

**Node 4+**

LRR	Patients (4+ +ve nodes)	15 year actuarial values for LRR	
RT group	15/287 (5%)	10%	
No RT	93/313(30%)	51%	p<0.001

Relative risk (RR) of 0.17 (95% CI 0.10–0.28)

*Survival*

**Node 1-3**

	Patients (1-3 +ve nodes)	15 year actuarial survival values	
RT group	118/276 (43%) deaths	57%	
No RT group	143/276 (52%) deaths	48%	p=0.03

RR of 0.69 (95% CI 0.50–0.97)

**Node 4+**

	Patients (4+ +ve nodes)	15 year actuarial survival values	
RT group	225/287 (78%) deaths	21%	
No RT group	276/313 (88%) deaths	12%	p=0.03

RR of 0.49 (95% CI 0.31–0.76)

Other analyses were conducted by tumour size:

15 year LRR failure	RT	No RT
Tumours ≤ 20mm	4%	29%
Large tumours	7%	43%

15 year survival:	RT	No RT
-------------------	----	-------

Tumours ≤ 20mm	50%	36%
Large tumours	33%	25%

The 15-year survival benefit was most marked in patients with smaller tumours (≤20 mm), whilst the reduction in the 15-year loco-regional failure rate was most pronounced in patients with large tumours.

The absolute and relative risk reduction and number of patients needed to treat were similar in both subgroups (N1-3 and N4+). For every 10 patients irradiated approximately two LRR and one death could be avoided. The authors suggest that overall this indicates that postmastectomy radiotherapy is beneficial in the described cohort of high-risk patients and is unrelated to the number of positive lymph nodes

A summary of outcomes is shown below:

Outcome 15 year actuarial values	RT	No RT	p value
LRR	6%	37%	< 0.001
	RR = 0.12 (95% CI 0.07–0.19)		
Survival	39%	29%	0.015
	RR = 0.63 (95% CI 0.49–0.81)		
	<b>1-3 positive nodes</b>	<b>4+ positive nodes</b>	
<b>LRR</b>			
Relative risk reduction	87%	82%	
Absolute risk reduction	20%	24%	
NNT	5	4	
<b>Deaths</b>			
Relative risk reduction	17%	11%	
Absolute risk reduction	9%	10%	
NNT	11	10	

#### Author conclusions

The survival benefit after postmastectomy RT was substantial and similar in patients with 1-3 and 4+ positive lymph nodes. Furthermore, it was not strictly associated with the risk of loco-regional recurrence, which was most pronounced in patients with 4+ positive nodes. The indication for RT seems therefore to be at least equally beneficial in patients with 1-3 positive nodes, and future consensus should be modified accordingly.

#### General comments –

In the discussion the authors state that there is accumulating information from other subgroup analyses to support these results. The 20-year results of the British Columbia study have shown that the impact of radiation therapy for all survival outcomes in the subgroup with 1–3 nodes involved was similar to the subgroup with 4+ nodes involved and had a similar magnitude of risk reduction. The 2005 EBCTCG overview also showed a similar magnitude of benefit of radiotherapy to node 1-3 and 4+ patients, however, most of the patients in this EBCTG subgroup were from the DBCG 82 trials.

RT was also applied to the regional lymph nodes as well as the chest wall.

Nielsen, H. M., Overgaard, M., Grau, C., Jensen, A. R., & Overgaard, J. 2006, "Loco-regional recurrence after mastectomy in high-risk breast cancer--risk and prognosis. An analysis of patients from the DBCG 82 b&c randomization trials", *Radiotherapy & Oncology*, vol. 79, no. 2, pp. 147-155

Design: 2 RCTs (1982-1990)

Level 1+

Country: Denmark

Aim: The aim of the study was to identify risk factors for loco-regional recurrence (LRR), to evaluate the treatment of LRR and to examine the prognosis after LRR

**Inclusion criteria**

The DBCG 82 b and c trials enrolled 3083 pre- and postmenopausal high-risk women (<70 years) who were randomized to postoperative RT in addition to adjuvant systemic therapy.

**Exclusion criteria**

If a distant metastasis occurred within 1 month of the locoregional recurrence (LRR) the patient was not included in this analysis.

**Population**

Of 3083 patients included, 1708 were pre- and menopausal (DBCG 82b), and 1375 patients were postmenopausal and below 70 years of age (DBCG 82c). Only high-risk patients were included, defined as patients who were node positive and/or a T3 or T4 tumour and/or skin or deep fascia invasion.

**Interventions**

Patients were randomized to  $\pm$ RT in addition to systemic therapy after total mastectomy and partial axillary dissection. Adjuvant systemic therapy was CMF. Post-menopausal patients had tamoxifen 30 mg daily for 1 year. Of the 1538 patients randomized to RT, 1341 patients (87%) had megavoltage RT to the chest wall and regional lymph nodes including the axillary, supra/infraclavicular and ipsilateral internal mammary nodes with the prescribed dose of 48–50 Gy in 22–25 fractions, four or five fractions per week; 120 patients (8%) had orthovoltage RT (36 Gy/20 fx, 5 fx/week) and 77 patients (5%) never began or completed RT.

**Outcomes**

Locoregional recurrence (LRR)

Subsequent LRR (LRR2)

Overall survival at 10 years

**Follow up**

Recurrences and survival were assessed in November 15, 2004, resulting in a median follow-up time after mastectomy of 18 years (range 15–22). The median follow-up time after LRR was 3.2 years. The follow-up time for survivors was 12.7 years, and 2.6 years for patients who died.

**Results**

Definitions:

A LRR was defined as (1) any reappearance of cancer in the ipsilateral chest wall or skin or soft tissue overlaying the ipsilateral chest wall, axilla or supra/infraclavicular region; or 2) cancer spread to the ipsilateral axillary nodes or 3) ipsilateral supra/infraclavicular nodes.

The endpoints for evaluating prognosis after LRR, were overall survival, second LRR (LRR2) and distant metastases.

The median time from mastectomy to LRR was 23 months among patients randomized to no RT and 32 months among patients randomized to RT. None of the 456 patients initially randomized to no RT received post-mastectomy RT.

Risk factors for developing LRR were only evaluated for the 1545 patients randomized to no RT, since LRR among patients randomized to RT were infrequent.

*Locoregional recurrence*

A total of 535/3083 patients had a LRR as first site of failure (chest wall: N=259 (48%), axilla: N=153, supra/infraclavicular: N=44, multiple LRR: N=79).

Frequency of LRR was:

30% (456/1545) in the no RT arm  
 5% (79/1538) in the RT arm.

Of the 535 patients with a LRR, 82% (441/535) had died at the time of analysis.

Of the 79 patients with LRR randomized to RT, 15% (12/79) never began or completed RT, 71% (56/79) had megavoltage RT and 14% (11/79) had orthovoltage RT.

*Risk factors for locoregional recurrence (18 year probability)*

1545 patients were randomized to no RT, the probabilities of LRR, chest wall alone and axillary failure alone were analysed for this group.

- In a univariate analysis risk factors for developing a LRR were: increasing tumour size, ductal carcinoma, increasing malignancy grade, invasion of the fascia, few removed nodes, many positive nodes and extracapsular invasion.
- Patients with 4+ positive axillary nodes had a high probability of LRR, with 59% having a LRR within 18-years of follow-up.
- A multivariate analysis stratified by ductal versus non-ductal carcinoma and excluding N0 disease found independent risk factors for LRR:
- Primary tumour size larger than 50mm (RR=1.64, 95%CI 1.16–2.29)
- Malignancy grade III (RR=1.96, 95%CI 1.45–2.65)
- Invasion of the fascia (RR=1.38, 95%CI 1.05–1.81)
- Less than 8 removed nodes (RR=1.64 95%CI 1.33–2.04)
- 4+ positive nodes (RR=1.96, 95% CI 1.56–2.45).

*Risk factors for locoregional recurrence in the chest wall (18 year probability)*

A univariate analysis of risk factors for chest wall failures within 18 years of follow-up were:

- Increasing tumour size (p<0.001)
- Ductal carcinoma (p=0.04)
- Invasion of the fascia (p=0.003)
- Many positive nodes and approximately 30% of patients with tumour size of 50 mm or larger (p<0.001)
- Invasion of the fascia (p=0.003) and
- Four or more positive nodes (p<0.001)

*Risk factors for locoregional recurrence in the axilla (18 year probability)*

On univariate analysis:

- Increasing malignancy grade (p=0.05)
- Few removed nodes (<8) (p=0.001)
- Many positive nodes (p<0.001)
- Extracapsular invasion (p=0.001)

*Prognosis after LRR*

A univariate analysis of prognostic factors that were statistically significant for survival, a second locoregional recurrence and distant metastases were: many positive nodes, extracapsular invasion and a short interval to LRR.

A univariate analysis of prognostic factors for survival and distant metastases were: site of the LRR at the supra/infraclavicular region and at multiple sites, and the following original primary tumour variables: large tumour size, high malignancy grade and invasion of the fascia.

The significant independent prognostic factors for overall survival after LRR from multivariate analysis are shown in the table from the paper below (n=482):

Variable	P value	RR (95% CI)
Tumour size:	0.006	
<21mm		1.00
21-50 mm		1.33 (1.03-2.14)
> 50 mm		1.66 (1.19-2.32)
Positive nodes	0.04	
1-3		1.00
4+		1.27 (1.01-1.61)

Extracapsular invasion	0.05	
No		1.00
Yes		1.25 (1.01-1.57)
Site of LRR	<0.001	
Chest wall		1.00
Axilla		0.92 (0.72-1.17)
Supra/infra		1.48 (1.02-2.14)
Multiple LRR		1.70 (1.25-2.27)
Interval to first LRR	<0.001	
> 2 years		1.00
≤2 years		1.97 (1.59-2.44)

A poor survival after LRR was seen among patients (N=482) with primary tumour characteristics of a large tumour size, many (4+) positive nodes and extracapsular invasion. Localization of the LRR at the supraclavicular region or at multiple loco-regional sites and a short interval, less than 2 years from mastectomy to LRR, were also independent poor prognostic factors.

#### Author conclusions

Twenty-seven percent of LRR patients had no distant metastases 5 years after failure. Initial randomization group did not alter the prognosis after LRR. Primary tumour characteristics, localization of the LRR and time interval from mastectomy to LRR were important for outcome after LRR, whilst postmastectomy RT did not alter this prognosis. There is a need for further examination of the optimal treatment modalities of patients with LRR. Combined treatment of the LRR with surgery and RT improved persistent loco-regional control compared with surgery or RT alone.

#### General comments –

RT was applied to the regional lymph nodes as well as the chest wall in some patients.

Updated 2019

Van de Steene, J., Soete, G., & Storme, G. 2000, "Adjuvant radiotherapy for breast cancer significantly improves overall survival: The missing link", *Radiotherapy & Oncology*, vol. 55, no. 3, pp. 263-272.

Design: Analysis of EBCTCG RCTs

Level 1+

Country: Belgium

Aim: To explore the trials analyzed by the EBCTCG to discover essential mutual differences between the trials, based on hypotheses (pointing to determinants for the effect of adjuvant radiotherapy) in the literature.

#### Inclusion criteria

Randomized clinical trials comparing radical mastectomy or breast conserving surgery with (in the study group) and without (in the control group) adjuvant radiotherapy.

#### Exclusion criteria

#### Population

The 36 trials of the EBCTCG (Early breast cancer trialists', collaborative group, 1995).  
Total number of patients treated 17 273.

#### Interventions

Each of the studies was characterized by a number of objective features which may influence a treatment effect. Most of these were biological or technical factors related to either the patient population, the trial or the radiotherapy. The influence of these factors on overall survival was investigated.

#### Outcomes

Overall survival

Crude survival (% of deaths in the trial) was a surrogate for global prognosis of patients in the trial. If the trial included low stage patients than the crude survival was high and vice versa.

#### Follow up

#### Results

In a univariate analysis, the start year of the trial, number of patients in each trial, fraction dose, and crude survival in the trial had a statistically significant effect on overall survival. Relevant data for these four factors are summarized below from the paper:

Variable	N of patients	Odds Ratio (95% CI)	Odds reduction (%)	P value
<i>Trial start date</i>				
> 1970	12567	0.935 (0.88-1.00)	6.5	0.048
> 1980	4936	0.882 (0.77-1.02)	11.8	0.080
<i>N of patients in trial</i>				
> 600	11354	0.932 (0.88-0.99)	6.8	0.028
< 150	933	1.304 (1.07-1.59)	-30.4	0.008
<i>Fractionation (Gy/fraction)</i>				
All known	12960	0.933 (0.88-0.99)	6.7	0.034
≥ 1.8 ≤ 2.0	7915	0.896 (0.82-0.98)	10.4	0.016
Other	5054	0.973 (0.89-1.07)	2.7	0.557
≥ 1.8 ≤ 2.5	9060	0.894 (0.83-0.97)	10.6	0.006
Other	3909	1.005 (0.90-1.12)	-0.5	0.931
<i>Crude survival</i>				
≥ 80%	3337	0.799 (0.66-0.97)	20.0	0.025
≤ 35%	398	1.272 (1.01-1.61)	-27.2	0.044

Factors that were not significant to overall survival were adjuvant systemic therapy (hormonal or chemotherapy or both), beam energy (ortho- or megavoltage), radiotherapy dose intensity (≥ 12.6 Gy/w) and extension of radiotherapy target volume.

On univariate analysis a significant survival benefit for the radiotherapy arm was found for:

- Recent trials (2P < 0.05), the more recent the trial the larger the survival benefit (21.1% gain for trials started after 1980);

- Large trials produced a larger survival benefit ( $2P < 0.03$ );
- Trials that used standard fractionation of 1.8-2.5 Gy/fraction ( $2P < 0.02$ );
- Trials with a favourable crude survival ( $2P < 0.03$ ).

Significant parameter-effect relationships were found for these factors. In recent and large trials the odds reduction was 12.4% ( $2P = 0.004$ ).

**Author conclusions:**

Surgical adjuvant radiotherapy significantly improves overall survival of breast cancer patients provided that current techniques are used and treatment is given with standard fractionation. For the best subgroups we observed an odds of death reduction of more than 20%. The results of this study stress the importance of reducing cardiovascular and other late toxicity in adjuvant radiotherapy for breast cancer.

**General comments –**

All EBCTG studies were used for the analysis and included patients who were treated with mastectomy or BCS.

Updated 2018

## Randomized controlled trials

Fisher, B., Jeong, J. H., Anderson, S., Bryant, J., Fisher, E. R., & Wolmark, N. 2002, "Twenty-five-year follow-up of a randomized trial comparing radical mastectomy, total mastectomy, and total mastectomy followed by irradiation.[see comment]", *New England Journal of Medicine*, vol. 347, no. 8, pp. 567-575.

Design: RCT (1971-1974)

Level 1++

Country: USA, setting:

Aim: To determine whether patients with either clinically negative or clinically positive axillary nodes who received local or regional treatments other than radical mastectomy would have outcomes similar to those achieved with radical mastectomy.

### Inclusion criteria

Women with primary operable breast cancer

### Exclusion criteria

**Population** number of patients = 1765

1079 women with clinically negative axillary nodes underwent radical mastectomy (RM) (n=362), total mastectomy without axillary dissection but with postoperative irradiation (n=352), or total mastectomy (TM) plus axillary dissection (n=365) only if they developed positive nodes.

A total of 586 women with clinically positive axillary nodes either underwent radical mastectomy (n=292) or total mastectomy without axillary dissection but with postoperative regional irradiation (n=294).

70% of women in each group were 50 years or more at time of entry. On pathological examination, the mean (SD) diameter of the largest tumour was 3.3 +/- 2.0 cm in women with negative nodes and 3.7 +/- 2.0 cm in women with positive nodes.

### Interventions

Radiotherapy was delivered with supervoltage equipment.

Node negative received 50 Gy in 25 fractions;

Node positive received an additional boost of 10 to 20 Gy. A dose of 45 Gy in 25 fractions was delivered to both the internal mammary nodes and the supraclavicular nodes.

The chest wall was treated with 50 Gy in 25 treatments using tangential fields.

No patients received adjuvant systemic therapy.

### Outcomes

Disease free survival (DFS)

Relapse free survival

Distant disease free survival

Overall survival

### Follow up

87% were followed for at least 25 years. Data collected up to March 2001.

### Results

Definitions used:

Local recurrences: tumour recurrences in the chest wall, the surgical scar, or both.

Regional recurrences: recurrences in supraclavicular, subclavicular, or internal mammary nodes or in the ipsilateral axilla of patients treated with either radical mastectomy or total mastectomy and regional irradiation.

Women with negative nodes who had total mastectomy alone and who subsequently had ipsilateral positive nodes that required axillary dissection were not considered to have had a recurrence unless the nodes could not be removed, this occurred in one patient.

DFS: events considered were the first local, regional, or distant recurrence of tumour; contralateral breast cancer or a second primary tumour not in the breast; and death of a woman who had no evidence of cancer.

Relapse free survival: the first local, regional, or distant recurrence or an event in the contralateral breast that was judged to be a recurrence.

Distant-disease-free survival: distant recurrences that occurred either as the first recurrence or after a local or regional recurrence, contralateral breast cancers, and other second primary cancers.

Overall survival: all deaths.

### Disease-free Survival and Relapse-free Survival

No significant difference in disease-free survival was observed between the three groups of women with negative nodes with or without radiotherapy ( $P=0.65$ ) (Table below). Similarly for women with positive nodes, there was no significant difference in disease-free survival between mastectomy alone vs. mastectomy + RT.

No significant difference in relapse-free survival was observed between the three groups of women with negative nodes ( $P=0.46$ ) (Table below). Similarly for women with positive nodes, there was no significant difference in relapse-free survival between mastectomy alone vs. mastectomy + RT.

Outcome	Radical mastectomy (RM)	Total mastectomy and irradiation (TM+RT)	Total mastectomy (TM)	P value
<b>DFS (25 yrs) Negative nodes</b>	19% (SE2%)	13% (SE2%)	19% (SE2%)	$p=0.65$
Hazard Ratios*	RM vs. TM+RT: 1.06 (95% CI 0.90 to 1.25, $p=0.49$ ) TM vs. RM: 1.07 (95% CI 0.91 to 1.27, $p=0.39$ ) TM+RT vs. TM: 1.02 (95% CI 0.87 to 1.21, $p=0.78$ )			
<b>DFS (25 yrs) Positive nodes</b>	11% (SE2%)	10% (SE2%)		
Hazard Ratio	RM vs. TM+RT: 1.12 (95% CI 0.94 to 1.33, $p=0.20$ )			
<b>RFS (25 yrs) Negative nodes</b>	53% (SE3%)	52% (SE4%)	50% (SE3%)	$p=0.46$
Hazard Ratios	RM vs. TM+RT: 0.96 (95% CI 0.76 to 1.21, $p=0.74$ ) TM vs. RM: 1.14 (95% CI 0.91 to 1.42, $p=0.27$ ) TM+RT vs. TM: 1.18 (95% CI 0.94 to 1.48, $p=0.15$ )			
<b>RFS (25 yrs) Positive nodes</b>	36% (SE3%)	33% (SE3%)		
Hazard Ratio	RM vs. TM+RT: 1.09 (95% CI 0.89 to 1.35, $p=0.40$ )			

\* not clear from paper which is the reference set  
SE standard error

### Time to first event

20% of women with negative nodes and 13% of women with positive nodes were alive and event-free after 25 years of follow-up (See Table below). Most first events were distant recurrences of tumour and non-breast cancer deaths, irrespective of node status. The frequency of events between groups with negative or positive nodes were similar. (No statistical data were provided for these comparisons).

Event	Negative nodes			Positive nodes		All Women (N=1665)
	RM (n=362)	TM (n=365)	TM + RT (n=352)	RM (n=292)	TM + RT (n=294)	
	N (%)	N (%)	N (%)	N (%)	N (%)	N (%)
Event	281 (78)	287 (79)	292 (83)	254 (87)	258 (88)	1372 (82)
Any recurrence*	135 (37)	156 (43)	131 (37)	165 (57)	168 (57)	755 (45)
Local	19 (5)	26 (7)	5 (1)	23 (8)	8 (3)	81 (5)
Regional	15 (4)	23 (6)	15 (4)	22 (8)	33 (11)	108 (6)
Distant	101 (28)	107 (29)	111 (32)	120 (41)	127 (43)	566 (34)
Contralateral breast cancer	19 (5)	27 (7)	32 (9)	13 (4)	15 (5)	105 (6)
Deaths (no evidence of disease)	104 (29)	86 (24)	101 (29)	64 (22)	58 (20)	413 (25)
Alive (event free)	81 (22)	78 (21)	60 (17)	38 (13)	36 (12)	293 (18)

\* except contralateral breast

### Node negative

There was a statistically significant difference between the 3 groups of women with negative nodes for the cumulative incidence of local or regional recurrence ( $p=0.002$  for 3 way comparison). The rate was lowest in the total mastectomy with RT group, indicating a significant benefit of RT in reducing local recurrence. In contrast there were no statistically significant differences between the 3 groups in the cumulative incidence of distant recurrence as a first event ( $p=0.61$ ).

#### Node positive

There were no significant differences in women with positive nodes between the RM and TM + irradiation groups for cumulative incidence of local or regional recurrence ( $P=0.67$ ). Similarly there were no significant differences between the RM and TM + irradiation groups for the incidence of regional recurrence or the incidence of distant recurrence ( $P=0.44$ ). However there was a significant reduction in the incidence of local recurrence after radiation therapy.

#### Distant-Disease-free Survival and Overall Survival

There were no significant differences in distant-disease-free survival between the 3 treatment groups with negative nodes at 25 years ( $p = 0.63$  for three-way comparison). For women with positive nodes, there was no significant difference in distant-disease-free survival between the radical mastectomy and total mastectomy plus radiation therapy groups (See table below).

There was no significant difference in overall survival between the 3 treatment groups with negative nodes at 25 years ( $p=0.68$  for three-way comparison). In women with positive nodes there was also no significant difference in overall survival between the radical mastectomy and total mastectomy plus radiation therapy groups (See table below).

Outcome	Radical mastectomy (RM)	Total mastectomy and irradiation (TM+RT)	Total mastectomy (TM)	P value
<b>Distant-DFS (25 yrs) NO</b>	46% (SE3%)	38% (SE3%)	43% (SE3%)	$p=0.63$
Hazard Ratios	RM vs. TM+RT: 1.08 (95% CI 0.88 to 1.34, $p=0.44$ ) TM vs. RM: 1.10 (95% CI 0.89 to 1.35, $p=0.39$ ) TM+RT vs. TM: 1.02 (95% CI 0.83 to 1.25, $p=0.85$ )			
<b>Distant-DFS (25 yrs) Positive nodes</b>	32% (SE3%)	29% (SE3%)		
Hazard Ratio	RM vs. TM+RT: 1.07 (95% CI 0.87 to 1.32, $p=0.51$ )			
<b>Overall Survival (25 yrs) NO</b>	25% (SE3%)	19% (SE2%)	26% (SE3%)	$p=0.68$
Hazard Ratios	RM vs. TM+RT: 1.08 (95% CI 0.91 to 1.28, $p=0.38$ ) TM vs. RM: 1.03 (95% CI 0.87 to 1.23, $p=0.72$ ) TM+RT vs. TM: 0.96 (95% CI 0.81 to 1.13, $p=0.60$ )			
<b>Overall Survival (25 yrs) Positive nodes</b>	14% (SE2%)	14% (SE2%)		
Hazard Ratio	RM vs. TM+RT: 1.06 (95% CI 0.89 to 1.27, $p=0.49$ )			

#### Positive Axillary Nodes after Total Mastectomy without Radiation Therapy

A total of 68/365 (18.6%) women with negative nodes who underwent total mastectomy with no radiation therapy subsequently developed positive ipsilateral nodes.

The time to recurrence of involved nodes was:

Within 2 years after surgery	51/68 (75%)
> 2 < 5 years after surgery	10/68 (15%)
>5 <10 years after surgery	6/68 (9%)
> 10 < 25 years after surgery	1/68 (1%)

The median time from mastectomy to the identification of positive axillary nodes was 14.8 months (range, 3.0-134.5).

#### Author conclusions

The findings validate earlier results showing no advantage from radical mastectomy. Although

differences of a few percentage points cannot be excluded, the findings fail to show a significant survival advantage from removing occult positive nodes at the time of initial surgery or from radiation therapy.

**General comments –**

This trial was included in the EBCTCG and Gebski (2006) reviews.

In the discussion by the authors an important finding of the study reported was that about 40% of women with clinically negative nodes treated with radical mastectomy had pathological confirmation of tumour-positive axillary lymph nodes. Since the women were randomized to treatment groups, an estimate of about 40% of those undergoing total mastectomy alone having positive nodes that were not removed at the time of initial surgery is also assumed. About half of these women subsequently received a diagnosis of positive axillary nodes as a first event. Some investigators suggest that the frequency of delayed occurrence of positive axillary nodes is underestimated because patients with nodes that became positive after a distant recurrence should also have been included in the analysis. They suggest that axillary dissection in all women with clinically negative ancillary nodes is justified. This may achieve local control of disease; however, the data from this trial indicate that leaving positive nodes unremoved did not significantly increase the rate of distant recurrence or breast-cancer-related mortality.

Another point was made about there being no survival advantage for the RT plus total mastectomy group with negative nodes at 25 years follow-up. These findings agree with two other studies at 10 year follow-up (Cancer Research Campaign. Br Med J 1976;1:1035-8; Cancer Research Campaign Working Party Lancet 1980;2:55-60), but differ from 3 studies reporting a 10% decrease in overall survival (Overgaard 1997, 1999; Ragaz 1997). They suggest that the use of systemic therapies in conjunction with postoperative RT may have relevance to these variations.

Updated 2018

Hojris, I., Andersen, J., Overgaard, M., & Overgaard, J. 2000, "Late treatment-related morbidity in breast cancer patients randomized to postmastectomy radiotherapy and systemic treatment versus systemic treatment alone", *Acta Oncologica*, vol. 39, no. 3, pp. 355-372.

Design: RCT (subgroup analysis) (1982-1990) 1++

Country: Denmark, setting: Single institution.

Aim: The aim of the study was to evaluate late treatment-related morbidity in the DBCG 82b and c trials by assessing the morbidity in survivors living in the county of Aarhus.

#### **Inclusion criteria**

Mastectomy and axillary dissection, no evidence of metastatic disease, no previous history of cancer, no bilateral breast cancer, age less than 70 years, high risk (defined as node positive and/or tumour size > 5cm and/or invasion to skin or fascia).

#### **Exclusion criteria**

Patients without previously treated local recurrence

**Population** number of patients = 84 of 118 eligible patients.

Median age at mastectomy = 50 years (range 35–69 years)

#### **Interventions**

The primary surgical treatment included total mastectomy and axillary node dissection involving level I and partly level II (Waat-Boolsen et al 1988). The pectoral fascia was stripped and neither the major, nor the minor pectoral muscles were removed. All patients were treated on a linear accelerator in one institution. The target volume included the chest wall and regional lymph nodes, i.e. supraclavicular, infraclavicular, axillary and ipsilateral internal mammary nodes in the four upper intercostal spaces. The median dose was 50 Gy in 25 fractions, 5 fractions per week, with a dose variation of less than 10%. The lung and heart cauda to the first rib was protected by individually shaped blocks, and the chest wall covering this part was treated through two anterior shaped electron fields. Chest wall thickness- the distance from the skin surface to the pleural surface- was measured with ultrasound, and the electron energy was chosen to include the clinical target volume within the 85% isodose curve.

Adjuvant systemic therapy was also administered (CMF, tamoxifen or CMF + tamoxifen).

Systemic treatment plus radiotherapy (RT-group) n= 42

Systemic treatment alone (no RT-group) n=42

Significantly more patients in the no RT-group received adjuvant tamoxifen than in the RT-group, otherwise the two groups were comparable.

#### **Outcomes**

Patients were assessed by a structured interview and physical examination by a single observer (1995-1996).

LENT SOMA tables (Late Effects Normal Tissues; Subjective, Objective, Management, Analytic)

Grade 0 = no toxicity

Grade 5 = death or loss of organ

Other definitions:

Occasional = monthly; intermittent = weekly; persistent = daily; refractory = constant

Lymphoedema was assessed by measuring the differences in circumference of the ipsilateral arm and contralateral arm using standard anatomical criteria (15 cm above and 10 cm below the olecranon) as well as the difference in arm volume.

#### **Follow up**

81% of invited participants took part in the follow-up study (95/118 eligible patients). Patients were followed for a median of 9 years (range 6–13 years).

#### **Results**

##### *Lymphoedema*

Objective assessment: 14% of irradiated patients versus 3% of the non-irradiated patients had lymphoedema (not significant).

Subjective assessment: 17% of irradiated women noticed a periodic swelling of the ipsilateral arm, and 26% felt a constant swelling in the arms. This was significantly more than in the non-irradiated group

( $p=0.02$ ).

*Lymphoedema –pain/discomfort* (subjective)

A few patients described more than minimal pain/discomfort related to lymphoedema (NS).

*Lymphoedema – function* (subjective)

17% of irradiated and 9% of non-irradiated patients felt that swelling in the arms had an impact on their lives in addition to interfering with athletic recreation (grade>1) (NS).

*Mobility of shoulder*

Subjective assessment: 38% of RT-group and 5% of the no RT-group noticed some degree of shoulder movement impairment ( $p<0.01$ ).

Objective assessment: 52% of irradiated patients and 15% of non-irradiated patients had some degree of impaired shoulder movements, mainly slightly decreased ( $p<0.01$ ).

*Shoulder function* (subjective)

16% of irradiated patients and 2% of the non-irradiated patients found that impairment of shoulder functions interfered with work and/or daily activities (grade >1) ( $p=0.02$ ).

*Shoulder pain* (subjective)

Occasional or intermittent pain from the shoulder was frequent in both treatment groups, whilst daily pain (grade 3) was more pronounced in the irradiated patients (NS).

Univariate and multivariate analyses were performed of possible factors contributing to lymphedema and impaired shoulder movements. Factors included in the analyses were radiotherapy treatment, chemotherapy treatment, endocrine treatment, number of nodes removed (0-3, 4-6, 7-9, >9), number of positive nodes removed (0-10), tumour size (6-60), age (44-82), obesity (BMI >30) and smoking.

Factors that were significant in increasing the risk of lymphoedema on multivariate analysis were:

Number of axillary lymph nodes removed OR 4.5 (95% CI 1.2-16;  $p=0.02$ )

Age of patient OR 1.1 (95% CI 1.0-1.2;  $p=0.01$ )

Radiotherapy was the only factor shown to reduce shoulder movements OR 7.0 (95% CI 2.2-22;  $p=0.0008$ ).

*Paresthesia*

Subjective assessment: paresthesia of the arm was more common in irradiated than non-irradiated patients, the frequency was more than occasional (>grade 1) in 7% of irradiated and was absent in the non-irradiated patients ( $p<0.01$ ).

Objective examination: paresthesia/hypesthesia occurred 21% of irradiated patients and 7% of non-irradiated patients (NS).

*Decreased arm strength* (subjective)

28% of the RT-group and 19% of the no RT group noticed a weakness in the arm, usually mild (NS).

*Decreased arm strength* (objective)

14% of irradiated patients and 2% of the non-irradiated patients had slightly decreased strength in the ipsilateral arm (NS).

*Other morbidities*

Chest x-rays showed apical lung fibrosis in 60% of irradiated patients, but this was not reflected in pulmonary symptoms (dyspnea or coughing). There were no differences between irradiated and non-irradiated patients in cardiac morbidity by assessment of angina pectoris.

Hojris, I., Overgaard, M., Christensen, J. J., & Overgaard, J. 1999, "Morbidity and mortality of ischaemic heart disease in high-risk breast-cancer patients after adjuvant postmastectomy systemic treatment with or without radiotherapy: Analysis of DBCG 82b and 82c randomised trials", *Lancet*, vol. 354, no. 9188, pp. 1425-1430.

Design: RCT (subgroup analysis) (1982-1990)

Level 1++

Country: Denmark, setting: Single institution.

Aim: To assess morbidity and mortality from ischaemic heart disease in patients treated with postmastectomy radiotherapy.

**Inclusion criteria**

Mastectomy and axillary dissection, no evidence of metastatic disease, no previous history of cancer, no bilateral breast cancer, age less than 70 years, high risk (defined as node positive and/or tumour size > 5cm and/or invasion to skin or fascia).

**Exclusion criteria**

Registered ischaemic heart disease.

**Population** number of patients = 3083 randomized from the DBCG trials.

1538 in RT group, 1545 no RT group.

**Interventions**

Radiotherapy was delivered to the chest wall, including the surgical scar and regional lymph nodes (ie, supraclavicular, infraclavicular, axillary, and ipsilateral internal mammary nodes). An anterior photon field was used to treat the periclavicular region and the axilla. The lung and heart caudal to the first rib were protected by

individually shaped blocks, and the chest wall covering this part was treated through two anterior shaped electron fields.

Chest-wall thickness (the distance from the skin surface to the visceral pleura) was measured by ultrasonography. The target depth for the ipsilateral internal mammary nodes in the four upper intercostal spaces was defined as chest-wall thickness plus 0.5 cm, and the target depth for the scar region was defined as chest-wall thickness minus 1 cm. The electron energy was chosen to include the clinical target volume in the 85% isodose. Most were treated using a linear accelerator.

**Outcomes**

Ischaemic heart disease, including acute myocardial infarction (ICD8 codes 410–14 or ICD10 codes I20–I25) and acute myocardial infarction alone (ICD8 code 410 or ICD10 codes I21 and I22).

Diagnostic, therapeutic, and follow-up data were obtained from the DBCG and National Patient Registers. Data were validated blind to intervention group.

**Follow up**

Follow-up was from the date of mastectomy until the first occurrence of ischaemic heart disease as well as the first occurrence of acute myocardial infarction.

The median follow-up for patients alive at time of assessment was 117 months (range 81–171), and median time to death was 45 months (1–170).

**Results**

1393/3046 women were alive at the time of analysis.

Cumulative survival at 12 years was significantly better for women in the radiotherapy group than the no-radiotherapy group (46 vs. 36%,  $p < 0.0001$ ). At the end of follow-up, more women in the no-radiotherapy group than in the radiotherapy group died of breast cancer. Similar proportions of each group died of ischaemic heart disease (IHD) (see table below from the paper).

	RT (n=1525)	No RT (n=1521)
Alive	766 (50.2%)	627 (41.2%)
<b>Cause of death</b>		
Breast cancer	674 (44.2%)	799 (52.2%)
Other cancers	36 (2.4%)	37 (2.4%)
IHD	12 (0.8%)	13 (0.9%)
Unknown	5 (0.3%)	4 (0.3%)
Other causes	32 (2.1%)	41 (2.7%)

An analysis of the cumulative incidence of morbidity and mortality from IHD found that it increased over time with no significant differences between the RT and no RT arms. Morbidity and mortality of ischaemic heart disease and acute myocardial infarction also did not differ significantly between treatment groups. This also applied to tumour laterality (left or right breast) and menopausal status (pre / perimenopausal or postmenopausal).

A further analysis to assess the risk of IHD with time after treatment found no increase in hazard rate

of morbidity from ischaemic heart disease with increasing time by radiotherapy status.

**Author conclusions**

Morbidity and mortality from ischaemic heart disease were not significantly altered by use of adjuvant radiotherapy after mastectomy. The actuarial risk of ischaemic heart disease did not increase after 12 years.

**General comments -**

Updated 2018

Gustavsson A, Bendahl P-O, Cwikiel M, Eskilsson J, Lofvander Thapper K, Pahlm O. No serious late cardiac effects after adjuvant radiotherapy following mastectomy in premenopausal women with early breast cancer. *Int J Radiat Oncol Biol Phys* 1999 Mar;43(4):745-54.

Design: RCT (subgroup analysis) (1978-1983) Level 1++

Country: Sweden, setting: RT given at 2 centres

Aim: To assess, with sensitive, noninvasive techniques, the prevalence and degree of late cardiac effects, namely coronary artery disease, decreased left and/or right ventricular function, and morphological and/or functional abnormalities in the cardiac valves, in women younger than 65 years of age with Stage II breast cancer 10–17 years after standardized, adjuvant radiotherapy following mastectomy.

#### Inclusion criteria

Patients treated during the period 1978–83, 65 years or younger at examination, and with no relapse or new malignancy.

#### Exclusion criteria

One patient with bilateral breast cancer and RT

**Population** number of patients = 153/275 (56%) eligible, 91 enrolled.

The patients were evenly distributed between the three original therapy groups.

Number	Age (median yrs)	RT	No RT
34	59 (50-64yrs)	Left side	
33	57 (45-64yrs)	Right side	
23	57 (45-63yrs)		Cyclophosphamide

#### Interventions

Following modified radical mastectomy and axillary clearance, premenopausal women were randomized into three groups: (a) postoperative radiotherapy; (b) postoperative radiotherapy plus cyclophosphamide, 130 mg/m<sup>2</sup> orally, days 1–14, 28-day cycle length, 12 cycles; and (c) cyclophosphamide alone.

Radiotherapy technique:

The target volume was divided into four areas: lymph nodes of the supra- and infraclavicular fossae, the axilla, the ipsilateral internal mammary lymph nodes, and the chest wall.

Ventral photon beams were used for the supra- and infraclavicular fossae and the axilla. Ventral electron beams were used for the internal mammary nodes and an adjacent orthovoltage field covered the chest wall. A specified target dose of 38-48 Gy was administered in daily fractions of 1.9-2.4 Gy, 5 days/week.

At follow-up patients were interviewed about cardiovascular and hypothyroid symptoms, risk factors (smoking, hypertension, and diabetes mellitus), and the occurrence of heart disease in the family. All patients had a physical examination, TSH (thyroid stimulating hormone) and blood lipid levels (cholesterol and triglycerides) were analyzed.

#### Outcomes

Myocardial scintigraphy

Exercise test

ECG

Echocardiography

#### Follow up

10-17 years after radiotherapy

#### Results

95/275 women had died, however none died from cardiac disease.

Causes of death were:

Disseminated breast cancer in 88 patients

Another malignancy in 5 patients

Subarachnoid haemorrhage in one case

Cerebral haemorrhage in 1 case

10 patients died of metastatic disease and on autopsy 4 had cardiovascular abnormalities: 1 coronary artery sclerosis (right-sided radiotherapy); 1 (without irradiation) had slight aortic valve sclerosis and moderate sclerosis of the coronary arteries; one (left-sided radiotherapy) with slight hypertrophy of the left ventricle; and one (without irradiation) dilation of the right ventricle, possibly due to massive pulmonary metastases. None of the patients still alive with recurrent disease had any cardiac symptoms.

#### *Myocardial scintigraphy*

Reversible defects were not found in any patient.

Abnormal findings were present in 6 patients, with reduced uptake at rest indicating infarction or fibrosis, (four with left-sided and two with right-sided radiotherapy). The defects in four patients with left-sided radiotherapy had an apical, septal, anterior-septal or inferior-septal location, and in two patients with right-sided radiation the location of the defects was inferior or septal-inferior.

#### *Exercise capacity*

The average exercise capacity for all groups was slightly above 100% of the value expected (chemotherapy 106%; radiotherapy 104%; radiotherapy left 105%; and radiotherapy right 102%).

#### *Resting ECG*

Eighteen patients had abnormal or borderline abnormal resting ECGs. Patients given radiotherapy had significantly ( $p = 0.03$ ) more resting ECG changes than those treated with chemotherapy only (26% vs. 4%). No significant differences were found between patients treated with right-sided or left-sided irradiation. The authors considered that the ECG signs of left ventricular hypertrophy (in three patients without hypertension) or a short P-R interval could not possibly be related to the radiotherapy given.

#### *Echocardiography*

Pericardial effusion was not found in any patients.

Systolic function was not reduced (<25%) in any patient.

Left ventricular diastolic function (E/A Ratio) was significantly lower in both irradiated groups: left-sided radiotherapy ( $p = 0.024$ ), and right-sided radiotherapy ( $p = 0.017$ ), when compared to patients without irradiation. No difference was found between the two radiotherapy groups ( $p = 1.0$ ).

#### **Author conclusions:**

Women younger than 50 years of age at the time of adjuvant radiotherapy following mastectomy in early breast cancer, had no serious cardiac sequelae 13 years (median) later, despite partly old-fashioned radiation techniques.

#### **General comments -**

## Observational Studies (eg. Prospective Cohort or Retrospective Cohort or Case Series):

Smith, B. D., Haffty, B. G., Hurria, A., Galusha, D. H., & Gross, C. P. 2006, "Postmastectomy radiation and survival in older women with breast cancer", *Journal of Clinical Oncology*, vol. 24, no. 30, pp. 4901-4907.

Design: Retrospective Cohort NRS (1992-1999)

Level 2+

Country: USA, setting: Multi-centre

Aim: To determine whether postmastectomy radiotherapy (PMRT) improves survival for older women with breast cancer.

### Inclusion criteria

Women identified from the SEER database aged over 70 years

### Exclusion criteria

No invasive component, not pathologically confirmed, histology not epithelial in origin, distant metastases, prior malignancy, bilateral disease, not treated with mastectomy, received neoadjuvant chemotherapy.

**Population** number of patients = 11 594 women identified

Median age 77 years (73-81)

Median tumour size 2cm (interquartile range 1.2-3.0cm)

8297 (72%) had ductal histology

9565 (82%) ER +ve

3909 (34%) pathologically involved lymph nodes

1529 (13%) had PMRT

1490 (13%) had chemotherapy

7416 (64%) low risk; 2125 (18%) indeterminate risk; 2053 (18%) high risk

### Interventions

Surgery classified by ICD-9 coding. The most extensive surgical procedure during the first 9 months after diagnosis was considered definitive. Treatment with radiation according to ICD-9 coding.

### Outcomes

Overall survival

### Follow up

Median follow-up of 6.2 years (4.2-8.5)

### Results

Factors associated with increased use of PMRT were:

Young age ( $p < 0.0001$ )

Black race ( $p = 0.008$ )

No co-morbid illness ( $p < 0.0001$ )

Large tumour size ( $p < 0.0001$ )

Clinical stage T4 ( $p < 0.0001$ )

High tumour grade ( $p < 0.0001$ )

Lobular histology ( $p < 0.0001$ )

Multiple involved lymph nodes ( $p < 0.0001$ )

High risk groups were more likely to receive both PMRT (38%, 785/2053) and chemotherapy (32%, 659/2053). Those with lobular histology had increased utilization of PMRT.

### Multivariate analyses

Entire cohort:

PMRT at 6.2 years follow-up was not associated with improved survival overall (HR 1.03 95% CI 0.95-1.13;  $p = 0.49$ )

Chemotherapy was associated with a trend in improved survival (HR 0.92 95% CI 0.84-1.01;  $p = 0.08$ )

Lobular histology was associated with a decreased risk of death (HR 0.80 95% CI 0.72-0.88;  $p < 0.0001$ )

*Overall survival (by risk status)*

Neither PMRT nor chemotherapy were associated with survival in the low and intermediate risk groups, but were significant in the high risk group (only PMRT results are included in the table below).

**ER/PR Positive tumours:**

Improved overall survival was associated with PMRT for patients with ER or PR positive (n=9860) tumours in the high risk group, and with chemotherapy (HR 0.77 95% CI 0.64-0.91;  $p = 0.003$ ). There was no association of survival benefit with PMRT for low or intermediate risk groups with ER or PR positive tumours.

**ER/PR negative tumours:**

There was no association of survival benefit with PMRT for the low or intermediate risk groups with ER or PR negative tumours. A trend towards improved overall survival was associated with PMRT for patients with ER or PR negative (n=1652) tumours in the high risk group (although not statistically significant), and with chemotherapy (HR 0.48 95% CI 0.31-0.75;  $p = 0.001$ ).

Risk group	PMRT HR (95% CI)	P value
Low (T1/2 N0)	1.06 (0.90-1.24)	0.48
Intermediate (T1/2 N1)	1.23 (0.99-1.52)	0.06
High (T3/4 and/or N2/3)	0.85 (0.75-0.97)	0.02
All risk groups	1.03 (0.95-1.13)	0.49
ER/PR status		
High (ER/PR +ve)	0.86 (0.74-0.99)	0.04
Low (ER/PR -ve)	0.97 (0.63-1.48)	0.87
Intermediate (ER/PR -ve)	2.23 (1.19-4.18)	0.01
High (ER/PR -ve)	0.80 (0.55-1.18)	0.26

**Author conclusions**

Adjuvant PMRT was associated with a survival benefit for women aged 70 years or more with a high risk (T3/4 and/or N2/3) breast cancer. However only 38% of high risk women were treated with PMRT in this cohort (1992-1999). Further studies are indicated to determine utilization of PMRT and barriers to receipt of PMRT.

**General comments –**

**Limitations:**

Unreported confounders associated with the delivery of the intervention (PMRT) and outcomes of interest may have influenced the treatment assignment bias.

## Guidelines

Recht, A., Edge, S. B., Solin, L. J., Robinson, D. S., Estabrook, A., Fine, R. E., Fleming, G. F., Formenti, S., Hudis, C., Kirshner, J. J., Krause, D. A., Kuske, R. R., Langer, A. S., Sledge, G. W., Jr., Whelan, T. J., & Pfister, D. G. 2001, "Postmastectomy radiotherapy: Clinical practice guidelines of the American Society of Clinical Oncology", *Journal of Clinical Oncology*, vol. 19, no. 5, pp. 1539-1569

Design: Canadian guideline development process.

Country: USA

### Inclusion criteria

### Exclusion criteria

### Population

### Methods

The ASCO guideline was developed by an expert multi-disciplinary panel who reviewed relevant information from the published literature through to July 2000. Searches were conducted on MEDLINE and other databases. In evaluating the evidence of the role of PMRT the panel followed the process of guideline development established by the Canadian Medical Association. The guidelines were validated by seven external reviewers, the American Society of Clinical Oncology (ASCO) Health Services Research Committee members, and the ASCO Board of Directors.

### Outcomes

Locoregional recurrence  
Freedom from distant failure  
Freedom from any relapse  
Overall survival  
Treatment toxicity

### Follow up -

### Results

Recommendations from the paper are reported below:

The panel found that the weight of the evidence from randomized trials was sufficient to recommend the routine use of PMRT for patients with four or more positive axillary lymph nodes. It is much less certain that the benefits of PMRT are sufficient to justify its use in most patients with T1/2 tumours with one to three positive nodes.

The panel did not find sufficient evidence regarding the impact of other tumour-related, patient-related, or treatment related factors to make recommendations or suggestions for modifying these guidelines.

Since the chest wall is the site at greatest risk of recurrence, we suggest that adequately treating the chest wall is mandatory. The situation is less clear regarding irradiation of the regional lymph nodes. However, because the risk of axillary recurrence after a complete or level I/II dissection is very low, and because the combination of axillary dissection and full axillary irradiation markedly increases the risk of lymphoedema, the panel suggests that axillary radiotherapy *not* be given routinely to patients undergoing complete or level I/II axillary dissection.

There is insufficient evidence to suggest or recommend whether internal mammary nodal irradiation should or should not be used routinely. The conclusions of the panel concerning the impact of radiotherapy on relapse-free and overall survival were therefore predominantly supported by level II evidence rather than level I evidence.

PMRT reduced the risk of LRF after mastectomy in patients receiving systemic therapy by a substantial amount in all trials. The majority of available trials, particularly the larger ones, also showed that PMRT improves relapse-free and overall survival rates to a lesser, but clinically relevant, degree.

### General comments -

Truong, P. T., Olivotto, I. A., Whelan, T. J., & Levine, M. 2004, "Clinical practice guidelines for the care and treatment of breast cancer: 16. Locoregional post-mastectomy radiotherapy", *CMAJ: Canadian Medical Association Journal*, vol. 170, no. 8, pp. 1263-1273.

Design: Review of meta-analyses, consensus statements and treatment guidelines.

Country: Canada

**Inclusion criteria** Searches between 1966 – Nov 2002

**Exclusion criteria**

**Population**

**Methods**

The guideline was based on a review of all meta-analyses, consensus statements and other guidelines published between 1966 and November 2002. Searches of MEDLINE and CANCERLIT for English-language randomized controlled trials published between 1995 and November 2002 were also conducted to supplement the literature previously reviewed by the American Society of Clinical Oncology (ASCO) Health Services Research Committee panel in a published guideline. A nonsystematic review of the literature was continued through to June 2003.

Validation: The authors' original text was submitted for review, revision and approval by the Steering Committee on Clinical Practice Guidelines for the Care and Treatment of Breast Cancer. Subsequently, feedback was provided by 11 oncologists from across Canada. The final document was approved by the steering committee.

**Outcomes**

Locoregional control

DFS

OS

Treatment related toxicity

**Follow up -**

**Results**

**Recommendations (from the paper):**

- Locoregional PMRT is recommended for women with an advanced primary tumour (tumour size 5 cm or greater, or tumour invasion of the skin, pectoral muscle or chest wall).
- Locoregional PMRT is recommended for women with 4 or more positive axillary lymph nodes.
- The role of PMRT in women with 1 to 3 positive axillary lymph nodes is unclear. These women should be offered the opportunity to participate in clinical trials of PMRT.
- Locoregional PMRT is generally not recommended for women who have tumours that are less than 5 cm in diameter and who have negative axillary nodes.
- Other patient, tumour and treatment characteristics, including age, histologic grade, lymphovascular invasion, hormone receptor status, number of axillary nodes removed, axillary extracapsular extension and surgical margin status, may affect locoregional control, but their use in specifying additional indications for PMRT is currently unclear.
- PMRT should encompass the chest wall and the supraclavicular, infraclavicular and axillary apical lymph node areas.
- To reduce the risk of lymphedema, radiation of the entire axilla should not be used routinely after complete axillary dissection of level I and II lymph nodes.
- A definite recommendation regarding the inclusion of the internal mammary lymph nodes in PMRT cannot be made because of limited and inconsistent data.
- The use of modern techniques in radiotherapy planning is recommended to minimize excessive normal tissue exposure, particularly to the cardiac and pulmonary structures.
- Common short-term side effects of PMRT, including fatigue and skin erythema, are generally tolerable and not dose-limiting. Severe long-term side effects, including lymphedema, cardiac and pulmonary toxicities, brachial plexopathy, rib fractures and secondary neoplasms, are relatively rare.
- The optimal sequencing of PMRT and systemic therapy is currently unclear. Regimens containing anthracyclines or taxanes should not be administered concurrently with radiotherapy because of the potential for increased toxicity.

## Reviews

### Bartelink (2000)

Bartelink, H. 2000, "Post-mastectomy radiotherapy: Recommended standards", *Annals of Oncology*, vol. 11, no. SUPPL. 3, pp. 7-11.

In the paper Bartelink suggests that there is a general consensus that a loco-regional recurrence rate of 20% at 10 years or more justifies postoperative radiotherapy. This proportion (or higher) is frequently seen in patients with a microscopically incomplete resection, a T3 N0 tumour with unfavourable histological signs or positive nodes, and for patients with four or more positive lymph node metastases (N4+). The indications for postoperative irradiation of the chest wall and axilla should be considered separately since the recurrence rate for the axilla is much lower than in the chest wall. The most difficult question concerns whether patients with T1–2 and N1 still need post-mastectomy radiotherapy, since the major benefit in survival is seen in this patient group from the Danish trials. The indications for post-mastectomy radiotherapy should be discussed in a multidisciplinary team including the pathologist, surgeon and radiation oncologist. They should consider the surgical technique, such as the adequacy of the axillary dissection, and pathological factors associated with a high local recurrence rate, such as vascular invasion and extra nodal spread, together with the proximity of the tumour to the resection margins. Of importance is that, for patients receiving neo-adjuvant chemotherapy, the indication for post-mastectomy should be based on the pre-treatment tumour extension.

*Indications for postoperative chest wall irradiation (from the paper)*

Incomplete resection (micro- or macroscopic)  
4 or more positive lymph nodes  
T3 tumours with grade 2 or 3 and/or vascular invasion  
T3 N+ tumours  
Diffusely growing tumours in more than one quadrant

### Bellon (2006)

Bellon, J. R., Katz, A., & Taghian, A. "Radiation therapy for breast cancer", *Hematology/Oncology Clinics of North America*, vol. 2006 Apr; 20, no. 2, pp. 239-257.

Bellon et al describe the benefits of post-mastectomy RT following adjuvant systemic therapy on survival for premenopausal women (Overgaard 1997; Ragaz 1997), and post-menopausal women (Overgaard 1999). The findings from these studies are presented in the following table:

Author	Patients	Follow-up (Years)	DFS			OS		
			CT (%)	CT+RT(%)	p	CT (%)	CT+RT(%)	p
Ragaz 1997	Node +ve Premenopausal	20	38	53	0.008	47	37	0.03
Overgaard 1997	High risk Premenopausal	10	34	48	0.001	45	54	0.001
Overgaard 1999	High risk Postmenopausal	10	24	36	0.001	36	45	0.03

CT = chemotherapy  
RT = Radiotherapy

Survival benefit was demonstrated in high risk patients, e g., four or more positive lymph nodes, as well as for women at lower risk with 1-3 positive lymph nodes. Controversy still exists for this latter group.

## Update Evidence

Danish Breast Cancer Cooperative Group, Nielsen HM, Overgaard M, Grau C, Jensen AR, Overgaard J. Study of failure pattern among high-risk breast cancer patients with or without postmastectomy radiotherapy in addition to adjuvant systemic therapy: long-term results from the Danish Breast Cancer Cooperative Group DBCG 82 b and c randomized studies. J Clin Oncol 2006 May 20;24(15):2268-75.

Design: RCT (extended follow-up) Level 1+

Country: Multinational

setting:

Aim: The aim of this follow up analysis was to evaluate the overall failure pattern among high-risk breast cancer patients who were randomly assigned to RT or no RT in addition to systemic therapy (as part of the Danish Breast Cancer Cooperative Group (DBCG) 82 b and c trials).

### Inclusion criteria

- High-risk BC patients who had total mastectomy and partial axillary dissections were included.
- Patients had no evidence of distant metastases (DM), had no history of cancer, had unilateral BC, and were age younger than 70 years. All patients were at high risk of recurrence because of a tumour size larger than 5 cm, and/or positive axillary nodes, and/or invasion of the skin or pectoral fascia.
- The adjuvant systemic therapy to the pre-menopausal patients consisted of CMF

### Exclusion criteria

Not described in this paper

### Population

A long-term follow-up was performed among the 3,083 patients from the Danish Breast Cancer

Cooperative Group 82 b and c trials, except in those already recorded with distant metastases (DM) or contralateral breast cancer.

### Interventions

- Patients were randomly assigned to RT or no RT in addition to systemic therapy
- The RT in the DBCG82 b and c trials was intended to cover the chest wall and regional lymph nodes including the axillary, supra/intra-clavicular, and ipsilateral internal mammary nodes.

### Outcomes

- Locoregional recurrences (LRR)
- Distant metastases (DM)

**LRR alone was defined as an LRR with no sign of subsequent DM within 1 month, whereas patients with LRR followed by DM within the same month were recorded as simultaneous failures (simLRR-DM)**

- Contralateral breast cancer (CBC)
- Disease-free survival (DFS)

- Overall survival (OS)

#### **Follow up –**

- According to DBCG protocol, follow-up information was recorded routinely at regular intervals for up to 10 years or until first recurrence, death, or the occurrence of a new primary cancer, whichever came first.
- Follow-up was continued until DM, CBC, emigration, or death. Nine patients were lost to follow-up because of emigration; otherwise, the follow-up was complete.

Median follow-up = 18 years

#### **Results**

##### **LRR:**

- The probability of any first BC event (LRR, simLRR-DM, DM, or CBC) was significantly reduced among patients in the RT group: RR=0.68 95% CI 0.63-0.75, P< 0.001).
- The median time to any first BC event was 3.9 after no RT and 7.9 years after RT, (P<0.001).
- The 18-year probability of LRR (with or without DM) or LRR alone was significantly lower in the RT group than the no RT group.

The table below lists the site of first LRR alone and first simLRR-DM.

The frequency of all sites of LRR was lower with RT than without RT.

- Chest wall failures were the most common type of LRR, with involvement of this site in 55% in the no-RT group and 70% in the RT group.
- Axillary failures were especially pronounced among patients in the no-RT group, with involvement of this site in 43%.
- In the RT group, the axilla was involved in 24% of the LRRs.
- In the no-RT group, chest wall and axillary failures most commonly occurred without simultaneous DM, whereas supra/infraclavicular failures were associated as often with DM.

Overall, 22% of the patients with LRR in the no-RT group appeared with simultaneous DM, whereas 48% of the patients with LRR in the RT group also had DM at the time of diagnosis of LRR.

##### **DM:**

- The 18-year probability of DM subsequent to LRR = 35% after no RT and 6% after RT (P<0.001). The 18-year probability of any DM = 64% after no RT and 53% after RT (P<0.001)
- The median time to DM = 6.5 years in the no-RT group and 12.3 years in the RT group (P=0.04).

In the no-RT group: DM after LRR and DM as first site of failure were equally common  
In the RT group, DM occurred most often as the first site of failure. See table 2 in paper.

- To assess if the risk of DM was time dependent in the two groups, the hazard rates for 2-

year time interval were calculated:

- The DM hazard rates were at all times increased among patients in the no-RT group compared with patients in the RT group.
- In both groups, the DM hazard rate decreased with time after mastectomy (authors note that even 18 years after mastectomy, a small risk of DM was present in both groups).
- The six most common sites of first DM were bone; lung; pleura; liver; CNS and skin.
- Bone: 18-year probability of bone metastases = 40% after no RT and 32% after RT (P=0.003)
- The 18-year probabilities of lung metastases, CNS metastases and skin metastases outside the ipsilateral chest wall were significantly lower in the RT group.

**Overall Comments:**

In high-risk breast cancer patients who had had total mastectomy and partial axillary dissection, this study showed that post-mastectomy RT reduced loco-regional recurrences as the first site of failure, and overall fewer patients have distant metastases.

Updated 2018

Kyndi M, Sorensen FB, Knudsen H, Overgaard M, Nielsen HM, Overgaard J, et al. Estrogen receptor, progesterone receptor, HER-2, and response to postmastectomy radiotherapy in high-risk breast cancer: the Danish Breast Cancer Cooperative Group. *J Clin Oncol* 2008 Mar 20;26(9):1419-26.

**Design:** RCT – subgroup analysis, evidence level 1+

**Country:** Denmark

**Aim:** To examine the effect of oestrogen receptor (ER), progesterone receptor (PgR), human epidermal growth factor receptor 2 (HER-2), and constructed subtypes patients who received or did not receive post-mastectomy radiotherapy (PMRT).

#### **Inclusion criteria**

High-risk breast cancer patients:

High-risk was defined as either positive lymph nodes and/or tumour size larger than 5 cm and/or invasion of tumour to surrounding skin or pectoral fascia. All women had a total mastectomy and a partial axillary dissection.

#### **Exclusion criteria**

#### **Population**

3,083 high-risk breast cancer patients randomly assigned to PMRT in the Danish Breast Cancer Cooperative Group (DBCG) protocol 82 trials b and c.

The premenopausal women were enrolled in the DBCG82 b protocol and were assigned to either radiotherapy plus CMF or to CMF chemotherapy alone.

The postmenopausal women were enrolled in the DBCG82 c protocol and were assigned either to radiotherapy plus tamoxifen or to tamoxifen alone.

1,000 patients had invasive tissue available for tumour marker identification and analysis but successful identification could be done for all three markers in 996 patients.

For statistical analyses four subgroups were constructed from hormonal receptors (Rec).

- Rec+ was defined as ER+ and/or PgR+
- Rec– as both ER– and PgR–
- The four subgroups were Rec+/HER2–, Rec+/HER2+, Rec–/HER2– (triple negative), and Rec–/HER2+

#### **Interventions**

- Patients were randomly assigned to RT or no RT in addition to systemic therapy

#### **Outcomes**

- LRR, distant metastasis(DM) (including patients presenting with LRR and DM at the same time), and overall survival.
- End points have been described in detail previously – see Nielson 2006
- Hazard ratios (HRs) presented on Kaplan-Meier OS probability plots were for overall

mortality.

**Follow up –**

Within the subgroup of 1,000 patients, median follow-up time was 17 years for the patients alive and still at risk.

**Results**

- As reported in the DBCG82 series, overall mortality was significantly reduced (HR=0.84; 95% CI, 0.72 to 0.97), DM (HR=0.80; 95% CI, 0.68 to 0.94) and LRR (HR=0.17; 95% CI, 0.10 to 0.26) probabilities after PMRT were found within the subgroup of 1,000 patients.
- A significantly improved overall survival after PMRT was reported in patients with good prognostic markers such as hormonal receptor–positive and HER2- patients (including the two Rec+ subtypes).
- No significant overall survival improvement after PMRT was reported in patients with an a priori poor prognosis, that is the hormonal receptor–negative and HER2+ patients, and in particular the Rec–/HER-2+ subtype.
- When comparing hazard ratios and 95% CIs, there were significantly smaller improvements in locoregional recurrence control after PMRT were found for ER– and PgR– tumours compared with the ER+ and PgR+ tumors (P=0.003 and 0.04, respectively), and for the triple-negative (P=0.02), and the Rec–/HER-2+ subtypes (P=0.003) compared with the Rec+/HER2– subtype.

Updated 2018

Killander F, Anderson H, Rydén S, Möller T, Aspegren K, Ceberg J, et al. Radiotherapy and tamoxifen after mastectomy in postmenopausal women -- 20 year follow-up of the South Sweden Breast Cancer Group randomised trial SSBCG II:I. *European journal of cancer* (Oxford, England : 1990) 2007;43(14):2100-8.

**Design:** RCT, evidence level 1-

Country:

setting:

**Aim:** To evaluate long-term effects of radiotherapy and tamoxifen after mastectomy on recurrence and survival in stage II breast cancer.

**Inclusion criteria**

Postmenopausal women who had modified radical mastectomy (MRM) and the presence of stage II invasive mammary adenocarcinoma and age below 71 years

**Exclusion criteria**

**Population**

724 postmenopausal women; 713 patients could be followed up for survival, and 668 were fully evaluable

**Interventions**

A RCT with three treatment alternatives:

1. Radiotherapy 50 Gy/25 fractions to chest wall and regional lymph nodes (RT).
2. Radiotherapy and tamoxifen 30 mg/day for one year (RT + tam)
3. Tamoxifen (tam).

**Outcomes**

time to recurrence, type of recurrence and overall survival.

In the present long-term analysis, we have added time to systemic disease, incidence of other events and side effects.

**Follow up**

Follow-up for survival was 23 years

**Results**

**LRR:**

- The cumulative incidence of loco-regional recurrences as first event at 20 years of follow-up was significantly reduced, with 71%, by radiotherapy ( $p < 0.001$ ), 18.5% (95% CI 13.8–23.8%) in the tamoxifen group compared to 5.3% in the RT + tamoxifen group and 6.7% (95% CI 3.8–10.4%) in patients randomised to RT with and without tamoxifen.
- In N0 patients: 7% loco-regional recurrences were diagnosed after 20 years in the Tamoxifen group, versus 6% in the RT + Tam group.
- In the N1–3 subgroup: the incidence was 25.9% (95% CI 17.5– 35.1%) in the Tamoxifen group, and 2.6% (95% CI 0.5–8.3%) in the RT + Tamoxifen group.
- Authors note that in patients who developed loco-regional recurrences, the majority later developed distant metastases in spite of salvage therapy. Salvage treatment after recurrence was thus successful in 31% of patients non-irradiated after mastectomy but

only in 4% of irradiated patients.

### **Cumulative incidence of systemic disease**

- At 20 years the cumulative incidence of systemic disease = 50% in the RT group, 40% in the RT + Tamoxifen group and 45% in the tamoxifen group ( $p = 0.33$  comparing RT + Tam versus Tam, and  $p = 0.047$  comparing RT vs RT + Tam)
- Considering only receptor positive patients the numbers were 54% (RT only) , 40% (tamoxifen) and 41% (RT plus tamoxifen), ( $p = 0.047$  comparing RT versus RT + Tamoxifen).
- In patients with more than three lymph nodes, there was a significant difference between RT and RT + Tamoxifen (88% versus 67%,  $p = 0.02$ ).
- There were no significant differences reported for node negative patients.

### **Survival:**

- Overall mortality at 20 years = 71% with RT, 68% with RT + tamoxifen group and 62% in tamoxifen group.
- The difference between RT + Tamoxifen versus Tamoxifen was not significant ( $p = 0.14$ ).
- The difference between was not significantly different between RT and RT + Tamoxifen ( $p = 0.50$ ).
- WRT hormone receptor positive patients the mortality rates at 20 years were 74% in the RT arm, 67% in the combination arm, and 54% in the Tamoxifen group.
- No statistically significant difference was reported when comparing RT to RT + Tamoxifen ( $p = 0.28$ ) but the comparison of RT + Tamoxifen versus Tamoxifen was significant in favour of patients not receiving radiotherapy ( $p = 0.047$ )
- In the N1–3 group, mortality at 20 years was 74%, 65% and 64% (but there was no significant difference).

### **Overall Comments:**

This study reported a very clear relative reduction in loco-regional recurrences, 71%, was obtained with radiotherapy which is in common with the majority of adjuvant radiotherapy trials.

Patient numbers in the comparative groups were not balanced and due to long follow up (20 years) there were some losses of data. The authors claim that this should not have affected the findings.

## 6.4 What is the most effective radiotherapy dose fractionation regimen for patients receiving external beam radiotherapy after surgical excision of the breast?

### Short Summary

Two systematic reviews of high quality were identified that compared hypofractionated radiotherapy with no radiotherapy (RT) (EBCTCG 2002, and Gebski *et al* 2006). The strongest evidence was from randomised controlled trials (RCT) (Owen *et al* 2006; START A and B 2008; Whelan *et al* 2002; Yarnold *et al* 2005). An earlier trial by Bates *et al.* (1998) did not use the conventional 50 Gy in 25 fractions radiotherapy dose as comparator. The remaining two trials were small and of lower quality (Goel *et al* 2000, Taher *et al* 2004).

Side effects or cosmesis were assessed in five RCTs (Bates 1988, Goel *et al* 2000, Taher *et al* 2005, Whelan *et al* 2002, Yarnold *et al* 2005) two cohort studies (Olivotto *et al* 1996, Marhin *et al* 2007) and four non-randomised (NRS) studies (Marcenaro *et al* 2004, Mladenovic 2001, Wallace *et al* 1993 and Yamada *et al* 1999). One NRS focussed on women aged 65 years or over (Mladenovic *et al.* 2001). Two guidelines originating in Canada were included (Cancer Care Ontario Practice Guidelines Initiative 2002, Whelan *et al* 2003).

Rates of local recurrence were not significantly different between conventional 50Gy fractions and hypofractionated schedules (Owen *et al* 2006, Whelan *et al* 2002, Dewar *et al* 2007, Bates 1988, Goel *et al* 2000, Mladenovic 2001, START A 2008, Yamada *et al* 1999). Distant relapse was lower in the hypofractionated arm of the START B (2008) trial and this improved the rates of disease free survival and overall survival. Assessments of cosmetic outcomes were less consistent, and depended on the comparisons made. One strong RCT (Whelan *et al* 2002) reported no significant difference between the 50 Gy and 42.5 Gy arms, whilst another (Yarnold *et al* 2005) reported a significantly poorer cosmetic outcome in the 42.9 Gy arm when compared to the 39 Gy arm. The hazard ratio for no change in breast appearance was significantly improved in the 39 Gy arm of the START A trial compared to 50 Gy; whilst there was no difference between the 50 Gy and 41.6 Gy arms in START A or between 50 Gy and 40 Gy in START B.

Global cosmetic outcomes were also less consistent since effects were reported at different times and between different fractionation doses. Breast oedema, fibrosis, lymphedema and telangiectasia were reported in few studies. Only one study reported on quality of life in terms of daily living (Wallace *et al* 1993).

The START trials reported late normal tissue effects on cardiac and lung morbidity, however the follow-up period was too short to allow the assessment of all potential late effects.

The search strategy developed from this PICO table and used to search the literature for this question can be found in Appendix A

### Evidence Summary

The literature search identified papers published between 1973 and 2008. The strongest evidence was from RCTs (Owen *et al* 2006, START A and B 2008, Whelan *et al* 2002, Yarnold *et al* 2005) which were all quality graded as 1++. The articles by Owen and Yarnold refer to the same trial. An earlier trial by Bates (1988) did not use the conventional 50 Gy in 25 fractions radiotherapy dose as comparator. The remaining two trials were small and of lower quality (Goel *et al* 2000, Taher *et al* 2005, 1-).

Two cohort studies one from an RCT analysis (Olivotto *et al* 1996, 2+) and another from a large population database (Marhin *et al* 2001, 2+) assessed side effects or cosmesis. Four non-randomized (NRS) studies were also included (Marcenaro *et al* 2004, Mladenovic 2001, Wallace *et al* 1993 and Yamada *et al* 1999). One NRS focussed on women aged 65 years or over (Mladenovic 2001). Two guidelines originating in Canada were included (Cancer Care Ontario Practice Guidelines Initiative 2002, Whelan *et al* 2003).

The majority of RCTs compared the conventional schedule of 50 Gy in 25 fractions with a hypofractionated schedule. Exceptions were the studies by Bates (1988) and Goel *et al* (2000) that compared hypofractionated schedules only. The cohort study by Olivotto *et al* (1996) was of a hypofractionated schedule only, whilst that by Marhin *et al* (2001) classified the radiation dose into greater or less than 2 Gy fractions. Two of the non-randomized studies compared 50 Gy in 25 fractions with a hypofractionated schedule, and the third compared 51 Gy in 16 fractions with a hypofractionated schedule. Both systematic reviews compared no radiotherapy with radiotherapy and are not directly relevant to the question, but were included for the subgroup analyses of comparisons between fractionation schedules. The patient population included women after BCS or mastectomy for invasive early breast cancer. One study was conducted amongst older women (Mladenovic *et al*. 2001). Where a number of papers were published on the same trial, only the most recent follow-up was included, unless more data were available from the other publications. A Cochrane review (James *et al*. 2008) was published subsequently to this report being prepared; it does not cover any new evidence from what is reported here and it does not include the START trials most recent publications.

The study characteristics for RT schedules and outcomes assessed are shown in the following table:

**Table 5.6.1** Study characteristics and outcomes assessed

<b>Author Year</b>	<b>Quality score</b>	<b>Comparisons</b>	<b>Outcomes</b>
<b>SR</b>			
Gebski 2006	1++	50 Gy in 25 fr vs no RT  Hypofractionated RT doses vs no RT	5 year overall survival
EBCTCG 2000	1++	Subgroup analysis of different doses RT vs no RT	Local recurrence
<b>RCTs</b>			
START A	1++	50 Gy in 25 fr (5 weeks)  41.6 Gy in 13 fr (5 weeks)  39 Gy in 13 fr (5 weeks)	Locoregional relapse  Disease free survival  Overall survival  Normal tissue effects  Cosmesis
START B	1++	50 Gy in 25 fr (5 weeks)  40 Gy in 15 fr (3 weeks)	Locoregional relapse  Disease free survival  Overall survival  Normal tissue effects  Cosmesis
Owen 2006  (same RCT as Yarnold)	1++	50 Gy in 25 fr (5 weeks)  39 Gy in 13 fr (5 weeks)  42.9 Gy in 13 fr (5 weeks)	Recurrence free survival  Local relapse (in ipsilateral breast)  Distant relapse (bone, liver, lung, CNS)

Whelan 2002	1++	50 Gy in 25 fr (35 days) 42.5 Gy in 16 fr (22 days)	Local recurrence (in ipsilateral breast)  Distant recurrence (regional lymph nodes, bone, liver, lung, CNS)  Overall survival  Global cosmetic outcome  Radiation toxicity
Yarnold 2005	1++	50 Gy in 25 fr (5 weeks) 39 Gy in 13 fr (5 weeks) 42.9 Gy in 13 fr (5 weeks)	Cosmesis  Fibrosis  Ipsilateral recurrence

Mladenovic 2001	3	24-26Gy in 4 fr every 2 <sup>nd</sup> day 51Gy in 16 fr every 2 <sup>nd</sup> day	Acute and late reactions  Local relapse  Distant relapse
Wallace 1993	3	50 Gy in 25 Fr (6 weeks) 40 Gy in 15 fr (4 weeks)	QoL  Hospital anxiety and depression scale (HADS)
Yamada 1999	3	50 Gy in 25 Fr (5 weeks) 40 Gy in 16 fr (3 weeks)	Local recurrence in irradiated breast at 5 yr  5 year overall survival
<b>Guidelines</b>			
Cancer Care Ontario 2002	4	Optmal fractionation schedule not established	
Update of Whelan 2003	4	42.5Gy in 16 fr comparable to 50Gy in 25 fr.	

### *Evidence from systematic reviews (1++)*

Gebiski *et al* 2006

This systematic review aimed to assess the benefits of a biological equivalent dose for different RT schedules and target volumes. All RT schedules were compared with no RT. When the studies delivering an optimal dose were compared against each other the hypofractionated trials achieved comparable 5 year overall survival rates to the conventional schedule of 50 Gy in 25 fractions.

Early Breast Cancer Trialists' Collaborative Group (2002)

A subgroup analysis (non-randomized) of the effects of different types of radiotherapy schedules showed that the proportional reduction in isolated local recurrences was slightly greater in trials delivering 2.0 Gy/fraction to the breast or chest wall than those delivering 2.5 or 3.0 Gy/fraction. The comparisons within trials were against no radiotherapy to the breast or chest wall.

Data on outcomes are shown in the following two tables. The first table reports recurrence and survival outcomes. The second table reports cosmesis, late normal tissue effects and quality of life outcomes.

### *Evidence from RCTs (1++, 1+, 1-) and NRS (3)*

#### *Local Recurrence*

Evidence was identified from five RCTs and two NRS. At 10 years the rate of local recurrence in the ipsilateral breast in one strong RCT was lowest in the hypofractionated arm delivering 42.9Gy in 13 fractions, although not significantly different from the other two arms (50Gy and 39Gy), (Owen *et al* 2006). Similarly Whelan *et al* (2002) in another strong RCT reported a small non-significant absolute difference between the 50Gy and 42.5Gy arms for local recurrence in the ipsilateral breast. The START A and B trials support these findings with no significant differences observed between arms for locoregional relapse when compared with the standard fractionation scheme of 50Gy in 25 fractions in both trials (A and B). The remaining lower quality RCTs did not compare hypofractionated schedules with the conventional fraction of 50Gy but reported similar rates of locoregional recurrence (Bates 1988, Goel *et al* 2000). The NRS also reported similar rates of local relapse (Mladenovic 2001, Yamada *et al* 1999).

One abstract (Nielsen *et al* 2004) reported comparable locoregional recurrence rates between 50Gy and hypofractionated schedules.

#### *Distant recurrence*

Two strong studies reported distant recurrences (START A and B, Whelan *et al* 2002). The disease free survival rates were not significantly different between arms in the Canadian trial (Whelan *et al* 2002). The Hazard Ratios for distant recurrence were not significantly different in comparison to the 50 Gy arm in the START A trial, however in START B there was a

significant reduction in distant recurrences in the shorter hypofractionated 40 Gy arm delivered over 3 weeks in comparison to 50 Gy over 5 weeks.

### *Overall survival*

Two strong studies reported overall survival (START A and B, Whelan *et al* 2002). The survival rates were not significantly different between arms in the Canadian trial (Whelan *et al* 2002). The Hazard Ratios for all cause mortality were not significantly different in comparison to the 50 Gy arm in the START A trial, however in START B there was a significant reduction in all cause mortality in the shorter hypofractionated 40 Gy arm in comparison to 50 Gy as a possible consequence of the lower rate of distant recurrences.

**Table 5.6.2** Local and distant recurrence, and overall survival

Author	Dose fractionation	Local recurrence	Distant recurrence	Overall survival
Owen (2006)  RCT 1++	50 Gy in 25 fr (5 weeks)  42.9 Gy in 13 fr (5 weeks)  39 Gy in 13 fr (5 weeks)	In ipsilateral breast  10 yr Kaplan-Meier  12.1% (8.8-15.5)  9.6% (6.7-12.6)  14.8% (11.2-18.3)

### *Cosmetic and radiation effects*

#### *Global cosmetic scores*

These were graded as 0 to 3 (excellent to poor) using EORTC criteria. One of the strongest RCTs found no difference at 5 years between arms [50Gy vs. 42.5Gy] (Whelan *et al* 2002); whilst Yarnold *et al* (2005) reported a significantly poorer cosmetic outcome at 10 years in patients treated with 42.9Gy compared with 39Gy. The weaker RCT (Taher *et al* 2005) reported fewer grade 2-3 (fair-poor) cosmetic outcomes in the 42.5Gy hypofractionated arm than the conventional 50Gy arm, however the sample size was very small. A cohort study (Olivotto *et al* 1996) reported more excellent or good (0-1) cosmetic outcomes than fair or poor outcomes from a hypofractionated schedule of 44Gy in 16 fractions at 5 years. A NRS (Marcenaro *et al* 2004) reported similar proportions of grade 0-1 and grade 2-3 cosmetic outcomes between 50Gy and 45Gy schedules.

#### *Changes in breast appearance (photographic)*

These were assessed at baseline, 2 and 5 years by self-assessment and physician assessment. In START A the 39 Gy arm had a significantly improved hazard ratio for no change in breast appearance compared with the 50 Gy arm. However in START B the difference between 50 Gy and 40 Gy arms was not significant, but favoured the 40 Gy arm.

#### *Skin toxicity*

The strongest RCT (Whelan *et al* 2002) reported high rates (> 80%) of patients with no toxic skin effects in both arms (50Gy vs 42.5Gy). grade 2 and 3 toxicity were reported in two weaker RCTs (Goel *et al* 2000, Taher *et al* 2005). There was a lower frequency of grade 2 events in the latter study in the hypofractionated arm (42.5Gy).

Very little skin erythema was reported in one cohort study at 5 years with a hypofractionated schedule (Olivotto *et al* 1996). One NRS of older women reported a larger occurrence of erythema in the hypofractionated arm (24-26Gy) at 30 months (Mladenovic 2001).

### Subcutaneous toxicity

Subcutaneous toxicity was mainly low grade 0-1 in one strong RCT in both arms (Whelan *et al* 2002).

Moderate to marked breast oedema was significantly lower in the 39Gy arm compared to the 42.9Gy arm in one strong RCT at 10 years (Yarnold *et al* 2005). Rates were low in both arms of one NRS (Marcenaro *et al* 2004) and in one cohort of a hypofractionated schedule at 5 years (Olivotto *et al* 1996).

Moderate to marked fibrosis was significantly lower in the 39Gy arm compared to the 42.9Gy arm in one strong RCT at 10 years (Yarnold *et al* 2005). Mild to moderate fibrosis was reported more frequently in the 45-51Gy arm than the 31-35Gy arm of a weaker RCT (Bates 1988). There was some mild fibrosis (17%) at 5 years in one cohort of a hypofractionated schedule (Olivotto *et al* 1996). Rates of fibrosis were similar between arms of one NRS at 15 months (Marcenaro *et al* 2004); another NRS of older women reported larger rates of fibrosis in the breast and axilla in the hypofractionated arm (Mladenovic 2001).

Rates of telangiectasia at 10 years were not statistically different between the 3 arms of the RCT by (Yarnold *et al* 2005). Mild telangiectasia was reported in 13% of women in the cohort study receiving 44Gy by Olivotto *et al* (1996). Low rates of grade 2-3 were reported in the NRS by Marcenaro *et al* (2004) in both arms.

### Quality of life

Quality of life measured as “not up to par” was similar in 50 Gy and 40 Gy arms of the NRS by Wallace *et al* (1993). A lower proportion reported “positive outlook” in the 50 Gy than the 40 Gy arm (63% vs. 76%) of the same study at 6 months. Anxiety and depression scores were not statistically significantly different between arms.

Outcomes are reported in the following Table:

**Table 5.6.3** Cosmetic and radiation effects, and quality of life

Author	Dose fractionation	Global cosmetic outcome (EORTC)	Skin toxicity	Subcutaneous toxicity	Telangiectasia
Whelan 2002		5 yr absolute difference			
RCT 1++	50 Gy in 25 fr (35 days)	-0.6% 95%CI (-6.5 to 5.5)	Majority grade 0	Majority grade 0-1	
	42.5 Gy in 16 fr (22 days)		82%	60%	
			87%	66%	
			No grade 4 toxicity	No grade 4 toxicity

### *Cardiac mortality*

One population cohort (Marhin *et al* 2001, 2+) reported no statistical difference in the rates of cardiac mortality in women treated with hypofractionated RT (>2Gy) compared to women treated with conventional fraction sizes of ≤2 Gy irrespective of laterality. In women with right-sided breast cancer neither age, nor fraction size influenced cardiac mortality.

### *Other late normal tissue effects*

The START A and B trials reported very low rates (<1%) of adverse events at 5 years for ischaemic heart disease, rib fracture, lung fibrosis, pneumonitis, brachial plexopathy and acute skin reactions.

### **Guidelines**

No recent guidelines were available. The Canadian clinical practice guidelines (2003) suggest a hypofractionated schedule of 42.5Gy in 16 fractions over 22 days is comparable to the usual schedule of 50 Gy in 25 fractions over 35 days. However this recommendation was limited to women with node negative breast cancer.

## Evidence Tables

Gebski, V., Lagleva, M., Keech, A., Simes, J., & Langlands, A. O. 2006, "Survival effects of postmastectomy adjuvant radiation therapy using biologically equivalent doses: a clinical perspective.[see comment][erratum appears in J Natl Cancer Inst. 2006 Jun 21;98(12):876]", *Journal of the National Cancer Institute*, vol. 98, no. 1, pp. 26-38.

Design: Meta-analysis of RCTs that had been previously included in earlier published meta-analyses and systematic reviews. Trials were identified up to 2002.

Country: Australia

Level 1++

Aim: The association between post-mastectomy radiation therapy for early breast cancer and overall survival was assessed in a meta-analysis of 36 randomized trials containing 38 comparisons that were unconfounded (addition of radiation therapy was the sole discriminant between treatments being compared). The specific issues of radiation dosage and target volume coverage were of interest. Studies using optimal BED (Biological Equivalent Dose) and appropriate target volumes were assessed for any observed benefit of radiation therapy.

### Inclusion criteria

- 1) Studies were of operable breast cancer that was initially treated by mastectomy. (Stage I and stage II disease and selected cases of stage III disease were considered operable).
- 2) Studies were randomized controlled clinical trials that compared adjuvant radiation therapy with no radiation therapy. This treatment was the only discriminating factor between the two arms of the trial. Other treatments such as extent of surgery, endocrine therapy, and chemotherapy, if given, had to be common to each arm.

Three studies that reported the use of randomization but may have used date of birth as the allocation method were included in the primary analysis but were excluded from a sensitivity analysis.

### Exclusion criteria

#### Population

Thirty-eight unconfounded randomized comparisons from 36 trials were identified, with data available from a total cohort of 13 199 patients. Thirty-three of these comparisons were included in the EBCTCG analysis. Because of access to individual patient data for some studies, the EBCTCG was able to provide comparisons in addition to or different from those in published reports, so a direct comparison between this meta-analysis and the EBCTCG was not always possible.

#### Interventions

Radiotherapy treatment for each trial was classified into three major categories:

Category 1

Optimal radiation therapy: studies that delivered optimal radiation therapy defined as doses in the range of 40 – 60 Gy in 2-Gy fractions (where 50 Gy = 5000 rads) or as a BED to the chest wall, axillary lymph nodes, and the supraclavicular fossa with or without the internal mammary lymph nodes.

**Category 2**

Inadequate or excessive radiation therapy: studies that delivered inadequate or excessive radiation therapy defined as either doses of less than 40 Gy in 2-Gy fractions (or, for other fractionation schedules, the calculated BED being less than 40 Gy) or of greater than 60 Gy in 2-Gy fractions (or for other fractionation schedules the calculated BED being more than 60 Gy). (The authors state that the BED was calculated by use of  $\alpha/\beta$ , a ratio that reflects the weight of the dose per fraction in the schedule to the total dose delivered, equal to 10, standardized to 2-Gy fractions).

**Category 3**

Incomplete tissue coverage: studies in which radiation therapy provided incomplete tissue coverage by restricting the target volume to areas of less than the area of the chest wall and regional lymph nodes. Techniques for which the target volume was restricted were considered to be inappropriate because an area at risk of recurrence received no radiation therapy.

Category 2 studies provided treatment that delivered an inadequate or excess dose irrespective of target volume. Those studies in category 3 provided treatment that delivered an inappropriate target volume irrespective of dose. Studies that met category 2 and 3 criteria were included in category 2.

**Outcomes**

The primary outcomes were 5-year and 10-year overall survival rates calculated by intention-to-treat analysis.

**Follow up -**

**Results**

38/40 RCTs compared postoperative radiation therapy with no RT and were not confounded.

Category 1: 25 RCTs used optimal RT with appropriate target volume.

Category 2: 7 RCTs used inadequate or excessive doses of RT.

Category 3: 6 RCTs used inappropriate target volumes.

Only the findings from the optimal dose category 1 trials are reported in the table.

The trials delivering the optimal dose vs. no RT (category 1) that used hypofractionated schedules are shown in the table below:

Trial	Year	Comparison	Dose* (Gy)	N of fractions	BED (Gy)	5 year Overall
-------	------	------------	------------	----------------	----------	----------------

						<b>Survival OR (95% CI)</b>
Edinburgh 1	1974	SM vs SM+XRT	43	10	51.2	1.60 (0.90- 2.82)
ECOG EST3181	1982	RM+T+C vs RM+T+C +XRT	46	23	46	0.88 (0.55- 1.39)
BCCA Vancouver	1978	RM +C vs RM+C+XRT	40	16	42	0.73 (0.45- 1.21)
Helsinki	1981	RM +C vs RM+C+XRT	45	15	49	2.46 (0.89- 6.82)
Klefstrom	1976	RM +C vs RM+C+XRT	45-50	15-25	49- 50	0.19 (0.05- 0.76)
Wessex	1973	SM vs SM+XRT	46	20	47.2	0.42 (0.21- 0.86)
Nottingham	1985	SM +C vs SM+C+XRT	45	15	49	0.74 (0.30- 1.83)
Manchester Q	1949	RM vs RM+XRT	35-40	15	35.4- 43	1.13 (0.84- 1.52)
N1-3 DFCI Boston	1974	RM +C vs RM+C+XRT	45	20	46	1.04 (0.37- 2.91)
N4+ DFCI Boston	1974	RM +C vs RM+C+XRT	45	20	46	1.18 (0.58- 2.41)

C= Chemotherapy

RM= Radical Mastectomy

SM= Simple Mastectomy

T= Tamoxifen

XRT= Radiotherapy

\* Dose applied to breast, chest wall, axilla and supraclavicular fossa.

These trials compared the hypofractionated dose vs. no RT rather than the conventional 50Gy in 25 fractions dose that is relevant to this question.

Trials delivering the optimal dose vs. no RT (category 1) that used a 50Gy dose in 25 fractions:

<b>Trial</b>	<b>Year</b>	<b>Comparison</b>	<b>Dose* (Gy)</b>	<b>N of fractions</b>	<b>BED (Gy)</b>	<b>5 year Overall Survival OR (95% CI)</b>
BMFT 03 Germany	1984	RM +C vs RM+C+XRT	50	25	50	0.83 (0.46- 1.51)
SECSG 1 (N4+)	1976	RM +C vs RM+C+XRT	50	25	50	0.82 (0.50- 1.32)

DBCG82b pre	1982	SM +C vs SM+C+XRT	50	25	50	0.73 (0.60- 0.90)
DBCG82c post	1982	SM +T vs SM+T+XRT	50	25	50	0.96 (0.77- 1.19)
NSABC Israel	1980	RM +C vs RM+C+XRT	46-50	24	45.4- 51	1.25 (0.44- 3.52)

**Author conclusions**

Improved overall 5 and 10 year survival was associated with optimal radiation therapy. When compared with no RT hypofractionated trials achieve comparable 5 year overall survival rates to the conventional schedule of 50 Gy in 25 fractions. All confidence intervals overlap with at least one other study.

Early Breast Cancer Trialists' Collaborative Group. Favourable and unfavourable effects on long-term survival of radiotherapy for early breast cancer: an overview of the randomised trials. Early Breast Cancer Trialists' Collaborative Group.[see comment]. Lancet 2000 May 20;355(9217):1757-70.

Design: Meta analysis

Level 1++

Country: UK

Aim: To determine the longer term effects of radiotherapy on breast cancer mortality.

**Inclusion criteria**

RCTs from the EBCTCG database that began before 1990 and were not confounded.

**Exclusion criteria**

**Population** 45 trials identified, 40 available.  
Total of 19582 participants.

**Interventions**

Trials comparing radiotherapy plus other treatments (including breast surgery) versus the same other treatments without radiotherapy.

**Outcomes**

First local recurrence (as defined by each trial)

**Follow up -**

**Results**

Overall trials:  
2756 isolated local recurrences  
9838 deaths

A subgroup analysis (non-randomized) of the effects of different types of radiotherapy schedules showed that the proportional reduction in isolated local recurrences was slightly greater in trials delivering 2.0Gy/fraction to the breast or chest wall than those delivering 2.5 or 3.0Gy/fraction. The comparisons within trials were against no radiotherapy to the breast or chest wall.

Breast dose per fraction (intervention) vs no radiotherapy (control)

<b>Breast dose/fraction</b>	<b>Events/women Allocated radiotherapy</b>	<b>Events/women Adjusted control (no RT)</b>
1.8Gy – 2.2Gy	313/5351 (5.85%)	1142/5394 (21.2%)
2.3Gy – 2.7Gy	125/1168 (10.7%)	339/1164 (29.1%)
2.8Gy – 3.2Gy	43/359 (12.0%)	96/368 (26.1%)
Various/other	205/2539 (8.07%)	575/2572 (22.4%)
Chi2 = 7.6; 2p= 0.006		

The proportional reduction in local recurrence did not appear to be influenced by the total dose of radiation to the breast axilla or internal mammary chain (p=NS).

The protective effects of RT against local recurrence were sufficiently strong to make the subgroup analyses statistically reliable.

## Randomized controlled trials

Dewar JA, Haviland JS, Agrawal RK, Bliss JM, Hopwood P, Magee B, et al. Hypofractionation for early breast cancer: First results of the UK standardization of breast radiotherapy (START) trials. J Clin Oncol (Meeting Abstracts) 2007 Jun 20; 25(18\_suppl):LBA518.

Design: RCT (1999-2002)

Meeting abstract

Country: UK, setting: Multicentre (N=35)

Aim: To test the hypothesis that breast cancer is as sensitive to fraction (Fr) size as late reacting normal tissues, with an  $\alpha/\beta$  value of about 4Gy.

### Inclusion criteria

Women with completely excised invasive breast cancer (T1-3, N0-1, M0).

### Exclusion criteria

### Population

Number of patients = START A 2236

Number of patients = START B 2215

### Interventions

Hypofractionated post-operative RT

START A: 50Gy in 25Fr (5 wks) vs 41.6Gy vs 39Gy, both in 13Fr on alternate days (5 wks).

START B: 50Gy in 25Fr (5 wks) vs 40Gy in 15Fr (3 wks).

Centres chose either the START A or START B fractionation schedules.

Stratification was by centre, surgery and boost.

### Outcomes

Local-regional (LR) relapse

Late normal tissue effects (NTE) were assessed by breast photographs, clinical examination and quality of life (QoL) questionnaires

Estimates of absolute differences in relapse rates were obtained from the rates in the 50Gy control arms and the Hazard Ratio (HR)

**Follow up** START A median 5.1 years

START B median 6 years

### Results

*Locoregional recurrence*

Results for local regional relapses are shown in the following table.

Outcome	START A	START B
LR relapse at 5 years	N=93 4.1% (95% CI 3.2 to 5.0%)	N= 65 2.8% (95% CI 2.1 to 3.5%)
Hazard Ratio for locoregional relapse at 5 years	41.6 vs 50Gy 1.05 (95% CI 0.63 to 1.75)	40 vs 50Gy 0.79 (95% CI 0.48 to 1.29)

	39 vs 50 Gy 1.26 (95% CI 0.77 to 2.08)	
Absolute difference LR rates at 5 years compared with 50Gy	For 41.6Gy: +0.2% (95% CI -1.3 to 2.6%) For 39Gy: +0.9% (95% CI -0.8 to 3.7%)	For 40 Gy: -0.6% (95% CI -1.7 to 0.9%)
$\alpha/\beta$ estimate for tumour control	5.0Gy (95% CI -2.7 to 12.7%)	

No significant differences were observed between arms for LR relapse when compared with the standard fractionation scheme of 50Gy in 25 fractions in both trials (A and B).

#### Late normal tissue effects

Late normal tissue effects are shown in the table below.

Outcome	START A n (%)	START B n (%)
Severe acute reactions	3 (0.1)	16 (0.7)
Brachial plexopathy	1	-
Symptomatic rib fracture	29 (1.3)	34 (1.5)
Symptomatic lung fibrosis	18 (0.8)	31 (1.4)
Ischaemic heart disease	45 (2.0)	46 (2.1)

Side effects appeared to be low in both trials. Statistical differences were not reported.

#### Cosmesis

Outcome	START A	START B
Mild/marked change in photographic breast appearance	Lower in 39Gy vs 50Gy HR 0.69 (95% CI 0.52-0.91)	Lower in 40Gy vs 50Gy HR 0.83 (95% CI 0.66-1.04)
$\alpha/\beta$ estimate for change in breast appearance	3.1Gy (1.6 to 4.6)	
Rates of induration, telangiectasia and breast oedema	Lower in 39Gy vs 50Gy	Lower in 40Gy vs 50Gy

QoL results were reported as consistent with the clinical findings.

**Author conclusions:** The fractionation sensitivity of breast cancer is comparable to that of late reacting normal tissues, confirming the results of a recent pilot trial. These results support the use of hypofractionated RT schedules for early breast cancer.

The START Trialists' Group. The UK Standardisation of Breast Radiotherapy (START) Trial A of radiotherapy hypofractionation for treatment of early breast cancer: a randomised trial.

Design: RCT (1998-2002)

Level 1++

Country: UK, setting: Multi-centre (17)

Aim: To test two dose levels of a 13-fraction radiotherapy schedule against the standard regimen to measure the sensitivity of normal and malignant tissues to fraction size.

**Inclusion criteria** Women with operable invasive breast cancer (pT1-3a pN0-1 M0), requiring radiotherapy after surgery (breast conserving surgery or mastectomy with clear tumour margins  $\geq$  1mm) aged over 18 years.

**Exclusion criteria** Surgical reconstruction

**Population** number of patients = 2236

Mean age 57.2 (SD 10.6) years

BCS 85% (same proportion in all 3 groups)

Mastectomy 15% (same proportion in all 3 groups)

Pathological node positive 28.8% (similar proportions in all 3 groups)

Pathological node negative 69.2% (similar proportions in all 3 groups)

Not known 2%

Tumour size (cm):

< 1 3.3%

1- 47.6%

2- 27%

3- 21.6%

Tumour grade:

1 20.4%

2 49.9%

3 28.1%

Adjuvant therapies were evenly distributed between treatment groups.

14% had regional RT which was planned before randomisation.

60.6% of BCS patients had tumour bed boost.

### Interventions

Randomised to either:

50 Gy in 25 fractions over 5 weeks (control) 5 fractions / week

41.6 Gy in 13 fractions over 5 weeks (intervention) 5 fractions / fortnight

(M,W,F Tu,Thu)

39 Gy in 13 fractions over 5 weeks (intervention) 5 fractions / fortnight (M,W,F

Tu,Thu)

The target volume was the whole breast with a 1cm margin. Where regional RT was indicated the target volume was supraclavicular nodes with or without axillary chain. Treatment was with 6MV x-rays in most patients, otherwise higher energies or cobalt  $\gamma$ -rays were used.

## Outcomes

Local relapse – ipsilateral local tumour relapse in breast or chest wall  
Loco-regional relapse - regional relapse in ipsilateral axilla or supraclavicular fossa within the irradiated target volume

Normal tissue effects in the breast, arm, and shoulder

Disease free survival (DFS) time to any breast cancer related event (loco-regional or distant relapse, contralateral breast cancer, death from breast cancer)

Overall survival (OS)

Change in breast appearance – photographic (none, mild, moderate). Self assessment and physician assessment at baseline, 2 and 5 years.

Quality of life assessments of normal tissue effects.

**Follow up** Patients reviewed every year for tumour relapse and radiation induced normal tissue effects. Median follow-up 5.1 years (IQR 4.4-6.0), maximum follow-up 8 years.

## Results

Quality of life study n=1129

Photographic assessment study n=1306

1881 (84.1%) alive without relapse

36 (1.6%) alive with locoregional relapse (without distant relapse)

52 (2.4%) alive with distant relapse (includes 14 with locoregional relapse)

256 (11.4%) had died

The survival analyses for relapse and mortality are reported in the following table:

	Events/total (%)	Estimated % with event at 5 years (95% CI)	Crude hazard ratio (95% CI)	Wald test p value
<b>Local relapse</b>				
50 Gy	25/749 (3.3)	3.2 (1.9-4.6)	1	
41.6 Gy	28/750 (3.7)	3.2 (1.9-4.5)	1.09 (0.64-1.88)	0.74
39 Gy	31/737 (4.2)	4.6 (3.0-6.2)	1.25 (0.74-2.12)	0.40
<b>Locoregional relapse</b>				
50 Gy	28/749 (3.7)	3.6 (2.2-5.1)	1	
41.6 Gy	30/750 (4.0)	3.5 (2.1-4.3)	1.05 (0.63-1.75)	0.86
39 Gy	35/737 (4.7)	5.2 (3.5-6.9)	1.26 (0.77-2.08)	0.35
<b>Distant relapse</b>				
50 Gy	73/749 (9.7)	9.8 (7.5-12.0)	1	
	69/750 (9.2)		0.92 (0.66-	0.64

41.6 Gy 39 Gy	93/737 (12.6)	9.5 (7.3- 11.7) 11.9 (9.5- 14.4)	1.28) 1.29 (0.95- 1.76)	0.10
<b>Any breast cancer related event</b>				
50 Gy	102/749 (13.6)	13.6 (11.0- 16.2)	1 0.87 (0.65- 1.15)	0.33
41.6 Gy	91/750 (12.1)	12.0 (9.6- 14.5)	1.14 (0.87- 1.49)	0.33
39 Gy	115/737 (15.6)	15.2 (12.5- 17.9)		
<b>All cause mortality</b>				
50 Gy	84/749 (11.2)	11.1 (8.7- 13.4)	1 1.04 (0.77- 1.40)	0.81
41.6 Gy	89/750 (11.9)	11.3 (8.9- 13.7)	1.00 (0.74- 1.36)	0.99
39 Gy	83/737 (11.3)	10.7 (8.3- 13.1)		

The rates for distant relapse, any breast cancer event and all cause mortality were similar between fractionation schedules.

#### *Locoregional relapse (LRR)*

93 (4.2%) patients had locoregional relapse at 5 years.

Absolute differences in LRR compared with 50Gy dose were not significantly different:

41.6Gy absolute difference = 0.2% (95% CI -1.3 to 2.6)

39Gy absolute difference = 0.9% (95% CI -0.8 to 3.7)

Estimates of excess risk in comparison to the 50Gy dose were:

41.6Gy excess risk 2.1% maximum

39Gy excess risk 3.2% maximum

The  $\alpha/\beta$  ratio for LRR was 4.8Gy (95% CI 0-16.3)

Other sites of relapse are reported in the following table:

	<b>Total</b>	<b>50 Gy</b>	<b>41.6 Gy</b>	<b>39 Gy</b>
Contralateral breast cancer	26 (1.2%)	13 (1.7%)	5 (0.7%)	8 (1.1%)
2 <sup>nd</sup> primary cancer	44 (2%)	15 (0.7%)	10 (0.4%)	19 (0.8%)

#### *Change in breast appearance (photographic)*

Data were available for 1055 patients for at least a baseline and one follow-up image. These are summarized in the following table:

<b>Changes in breast appearance (photographic)</b>	
Mild changes at 5 years [n (%)]	302 (28.6%)

Marked changes at 5 years [n (%)]	32 (3%)
Hazard ratio for any change in appearance (mild or marked) Reference 50Gy	41.6 Gy 1.09 (95% CI 0.85-1.40, p=0.62) 39 Gy 0.69 (95% CI 0.52-0.91, p=0.001)
$\alpha/\beta$ ratio	3.1Gy
$\alpha/\beta$ ratio when data from earlier RMH/GOC trial (n=1202) and START A combined	Any change in breast appearance adjusted for age, chemotherapy, tamoxifen, breast size, surgical deficit 3.4 Gy (95% CI 2.3-4.5)

The 39 Gy arm had a significantly improved hazard ratio for no change in breast appearance compared with the 50 Gy arm.

#### *Quality of life*

Patient self assessments for late normal tissue effects were available for 1080 (95.7%) of patients in this study. The most common effects were changes in breast appearance and breast hardness (BCS patients). The rates of marked or moderate effects by 5 years were similar after 50 Gy and 41.6 Gy. The rates of marked or moderate effects were lower after 39 Gy than 50 Gy. There was a significantly lower rate of change in skin appearance after 39 Gy than 50 Gy (p=0.004). The survival analyses of the photographic and patient QoL self-assessments of late normal tissue effects for START A were displayed as a Forest plot. The rates of effects were similar for the comparison of 41.6 Gy with 50 Gy. Effects favoured the 39 Gy group in comparison with 50 Gy.

The incidence of adverse events was low at this stage in the trial and the findings are reported in the following table:

Event	Fractionation schedule			T=2236
	50 Gy n=749	41.6 Gy n=750	39 Gy n=737	
Ischaemic heart disease (confirmed)[left sided]	3 (0.4%) [1]	2 (0.3%) [0]	3 (0.7%) [4]	10 (0.4%) [5]
Symptomatic rib fracture (confirmed)	1 (0.1%)	2 (0.3%)	1 (0.1%)	4 (0.2%)
Symptomatic lung fibrosis (confirmed)	0 (0%)	2 (0.3%)	1 (0.1%)	3 (0.1%)
Pneumonitis	0 (0%)	1 (0.1%)	0 (0%)	1 (0.1%)
Brachial plexopathy	0 (0%)	1 (0.1%)	0 (0%)	1 (0.1%)
Acute skin	2 (0.3%)	0 (0%)	0 (0%)	2 (0.3%)

reaction (moist desquamation)				
-------------------------------	--	--	--	--

**Author conclusions**

The data are consistent with the hypothesis that breast cancer and the dose-limiting normal tissues respond similarly to change in radiotherapy fraction size. 41.6 Gy in 13 fractions was similar to the control regimen of 50 Gy in 25 fractions in terms of local-regional tumour control and late normal tissue effects, a result consistent with the result of START B trial. A lower total dose in a smaller number of fractions could offer similar rates of tumour control and normal tissue damage as the international standard fractionation schedule of 50 Gy in 25 fractions.

**General comments –**

Short term follow-up of 5 years.

No subgroup analyses of the effects of ER status, node status, boost dose, or adjuvant systemic treatments on outcomes, although these were evenly distributed between groups.

The START Trialists' Group. The UK Standardisation of Breast Radiotherapy (START) Trial B of radiotherapy hypofractionation for treatment of early breast cancer: a randomised trial.

Design: RCT (1999-2001)

Level 1++

Country: UK, setting: Multi-centre (23)

Aim: To test the benefits of radiotherapy schedules using fraction sizes larger than 2.0 Gy in terms of local-regional tumour control, normal tissue responses, quality of life, and economic consequences in women prescribed post-operative radiotherapy.

**Inclusion criteria** Women with operable invasive breast cancer (pT1-3a pN0-1 M0), requiring radiotherapy after surgery (breast conserving surgery or mastectomy with clear tumour margins  $\geq$  1mm) aged over 18 years.

**Exclusion criteria** Surgical reconstruction

**Population** number of patients = 2215

Mean age 57.4 (SD 10.0) years

BCS 92% (similar proportions in each group)

Mastectomy 8% (similar proportions in each group)

Pathological node positive 22.8% (similar proportions in each group)

Pathological node negative 73.8% (similar proportions in each group)

Not known 3.8%

Tumour size (cm):

< 1 14.4%

1- 49.4%

2- 26%

3- 9.9%

Tumour grade:

1 27.9%

2 47.4%

3 23.0%

Adjuvant therapies were evenly distributed between treatment groups.

### Interventions

Randomised to either:

50 Gy in 25 fractions over 5 weeks (control) 5 fractions / week

40 Gy in 15 fractions over 3 weeks (intervention) 5 fractions / week

Stratification was by hospital, type of surgery, and intention to give a tumour bed boost or not.

The target volume was the whole breast with a 1cm margin. Where regional RT was indicated the target volume was supraclavicular nodes with or without axillary chain. Treatment was with 6MV x-rays in most patients, otherwise higher energies or cobalt  $\gamma$ -rays were used.

### Outcomes

Local relapse – ipsilateral local tumour relapse in breast or chest wall

Loco-regional relapse - regional relapse in ipsilateral axilla or supraclavicular fossa within the irradiated target volume

Normal tissue effects in the breast, arm, and shoulder  
 Disease free survival (DFS) time to any breast cancer related event (loco-regional or distant relapse, contralateral breast cancer, death from breast cancer)

Overall survival (OS)

Change in breast appearance – photographic (none, mild, moderate). Self assessment and physician assessment at baseline, 2 and 5 years.

Quality of life assessments of normal tissue effects

**Follow up** Median follow-up 6.0 years (IQR 5.0-6.2), maximum follow-up 8 years

**Results**

Quality of life study n=1079

Photographic assessment study n=1094

1872 (84.5%) alive without relapse

34 (1.5%) alive with locoregional relapse (without distant relapse)

45 (2.0%) alive with distant relapse (includes 4 with locoregional relapse)

245 (11.1%) had died

*Relapse and mortality*

The survival analyses for relapse and mortality are reported in the following table:

	Events/total (%)	Estimated % with event at 5 years (95% CI)	Crude hazard ratio (95% CI)	Log-rank test p value
<b>Local relapse</b>				
50 Gy	34/1105 (3.1)	3.3 (2.2-4.4)	1	0.21
40 Gy	25/1110 (2.2)	2.0 (1.1-2.8)	0.72 (0.43-1.21)	
<b>Locoregional relapse</b>				
50 Gy	36/1105 (3.2)	3.3 (2.2-4.5)	1	0.35
40 Gy	29/1110 (2.6)	2.2 (1.3-3.1)	0.79 (0.48-1.29)	
<b>Distant relapse</b>				
50 Gy	122/1105 (11.0)	10.2 (8.4-12.1)	1	0.01
40 Gy	87/1110 (7.8)	7.6 (6.0-9.2)	0.69 (0.53-0.91)	
<b>Any breast cancer related event</b>				
	164/1105	14.1 (12.0-	1	

50 Gy 40 Gy	(14.8) 127/1110 (11.4)	16.2 10.6 (8.7- 12.4)	0.75 (0.60- 0.95)	0.02
<b>All cause mortality</b>			1	
50 Gy 40 Gy	138/1105 (12.5) 107/1110 (9.6)	11.0 (9.1- 12.9) 8.0 (6.4- 9.7)	0.76 (0.59- 0.98)	0.03

*Locoregional relapse (LRR)*

65 (2.9%) patients had locoregional relapse at the time of analysis. There were no significant differences between the 50 Gy and 40 Gy schedules in the rates of local or locoregional relapses.

The absolute difference in LRR between 40 Gy fraction compared with the 50Gy dose was not significantly different at 5 years:

Absolute difference = -0.7% (95% CI -1.7 to 0.9)

Estimated maximum excess risk in comparison to the 50Gy dose was 0.6% for the 15 fraction schedule.

The 5 year rate of distant relapse was significantly lower in the 40 Gy group, this contributed to the higher rates of DFS and OS in this group compared with the 50 Gy group.

Other sites of relapse are reported in the following table:

	<b>Total</b>	<b>50 Gy</b>	<b>40 Gy</b>
Contralateral breast cancer	36 (1.6%)	19 (1.7%)	17 (1.5%)
2 <sup>nd</sup> primary cancer	58 (2.6%)	32 (2.9%)	26 (2.3%)

*Change in breast appearance (photographic)*

Data were available for 923 patients for at least a baseline and one follow-up image. These are summarized in the following table:

<b>Changes in breast appearance (photographic)</b>	
Mild changes at 5 years [n (%)]	284 (30.8%)
Marked changes at 5 years [n (%)]	28 (3%)
Hazard ratio for any change in appearance (mild or marked) Reference 50Gy	40 Gy 0.83 (95% CI 0.66-1.04, p=0.06)

The treatment differences were seen at 2 years and persisted to 5 years but were not significant.

### Quality of life

Patient self assessments for late normal tissue effects were available for 1037 (96.1%) of patients in this study. The most common effects were changes in breast appearance and breast hardness (BCS patients). The rates of marked or moderate effects by 5 years were lower after 40 Gy than 50 Gy. There was a significantly lower rate of change in skin appearance after 40 Gy than 50 Gy ( $p=0.02$ ). The survival analyses of the photographic and patient QoL self-assessments of late normal tissue effects for START B were displayed as a Forest plot. Effects favoured the 40 Gy group in comparison with 50 Gy.

The incidence of adverse events was low at this stage in the trial and the findings are reported in the following table:

Event	Fractionation schedule		T=2215
	50 Gy n=1105	40 Gy n=1110	
Ischaemic heart disease (confirmed)[left sided]	12 (1.1%) [4]	7 (0.6%) [3]	19 (0.9%) [7]
Symptomatic rib fracture (confirmed)	2 (0.2%)	2 (0.2%)	4 (0.2%)
Symptomatic lung fibrosis (confirmed)	1 (0.1%)	3 (0.3%)	4 (0.2%)
Brachial plexopathy (n=161)	0 (0%)	0 (0%)	0 (0%)
Acute skin reaction (moist desquamation)	13 (1.2%)	3 (0.3%)	16 (0.7%)

**Author conclusions** A radiation schedule delivering 40 Gy in 15 fractions seems to offer rates of local-regional tumour relapse and late adverse effects at least as favourable as the standard schedule of 50 Gy in 25 fractions.

### General comments –

In START B more patients had tumours < 1cm (14.4%) than START A (3.3%); fewer patients had tumours of 3cm or more in START B (9.9%) than START A (21.6%).

More patients had grade 1 tumours in START B (27.9%) than START A (20.4%); and fewer had grade 3 tumours in START B (23%) than START A (28.1%).

Nielsen HM, Overgaard J, Grau C, Overgaard M. Loco-regional control rate in relation to radiotherapy technique and fractionation in the Danish DBCG 82b & c studies with 1538 high-risk breast cancer patients randomized to postmastectomy radiotherapy. *Radiother Oncol* 2004;73:S1 p193 (Abstract only).

Design: Analysis of RCTs

Abstract

Country: Denmark

Aim: To describe any differences in the locoregional control rate related to treatment (dose/fractionation) characteristics from a subset of patients.

**Inclusion criteria**

Women with stage II and III breast cancer (high risk)

**Exclusion criteria**

**Population** number of patients = 3083 from DBCG. Subset of 1538 patients.

**Interventions**

Randomized to postmastectomy RT vs no RT.

Three groups:

- 1) megavoltage photon/electron 3 field technique with two different fractionation schedules (n=1221). Fractionation was 50Gy/25 fractions, 5 fractions/week (n=903, group 1a); or 48Gy in 22 fractions, 4 fractions/week (n=318, group 1b).
- 2) megavoltage 3-field tangential photon beam technique (n=97) with fractionation of 50Gy in 25 fractions, 5 fractions/week.
- 3) Orthovoltage treatment using McWhirter technique (n=128), 36 Gy in 20 fractions

44 patients (3%) had an unknown type of RT or were treated with unconventional techniques, dose or fractionation.

48 patients (3%) assigned for RT had no RT.

**Outcomes**

Locoregional recurrence (LRR)

**Follow up** Median 17 years

**Results**

150/1538 (9.7%) patients experienced a LRR

Locations of recurrences were:

Chest wall n=85 (57%)

Axilla n=21 (14%)

Supra/infraclavicular region n=21 (14%)

Multiple sites n=21 (14%)

Unknown n=3 (2%)

Findings by group are reported in the following table:

	<b>Group 1a</b>	<b>Group 1b</b>	<b>Group 2</b>	<b>Group 3</b>
--	-----------------	-----------------	----------------	----------------

	<b>n=903</b>	<b>n=318</b>	<b>n=97</b>	<b>n=128</b>
Type of RT	Megavoltage photon/electron 3 field technique	Megavoltage photon/electron 3 field technique	Megavoltage 3 field tangential photon beam	Orthovoltage McWhirter technique
Dose	50Gy/25fr 5 fr/week	48Gy/22fr 4fr/week	50Gy/25fr 5 fr/week	36Gy/20fr
15 year actuarial LRR	0.11 (0.09-0.14)	0.14 (0.10-0.19)	0.12 (0.06-0.22)	0.21 (0.14-0.31)

It should be noted that the three megavoltage groups had different patient numbers and consequently the two groups with low patient numbers have wider confidence intervals than the largest group (n=903). There is also overlap between the confidence intervals of these three LRR findings. The LRR rates appear similar for the megavoltage groups, no p values were reported.

Megavoltage techniques produced better control than orthovoltage techniques (p=0.02).

A multivariate analysis was also conducted for risk of LRR. Factors analyzed are shown in the following table:

<b>Factor</b>	<b>Odds Ratio (OR)</b>
Tumour size: 21-50mm	1.57 (1.39-4.05)
> 50mm	2.37 (1.39-4.05) ? misprint in abstract
More than 3 positive lymph nodes	3.40 (1.66-7.00)
Invasion of fascia	1.59 (1.05-2.42)
Invasion of skin	1.71 (1.07-2.75)
Group 1a vs other groups	0.66 (0.47-0.93)

**Author conclusions** were that megavoltage gave better local control than orthovoltage, and that patients treated with the megavoltage combined photon/electron 3 field technique using 50Gy/25fr also had better local control from the multivariate analysis.

Owen JR, Ashton A, Bliss JM, Homewood J, Harper C, Hanson J, et al. Effect of radiotherapy fraction size on tumour control in patients with early-stage breast cancer after local tumour excision: long-term results of a randomised trial. *The lancet oncology* 2006;7(6):467-71

Design: RCT (1986-1998)

Level 1++

Country: UK, setting: Two cancer centres

Aim: To determine whether fewer, larger radiotherapy fractions are at least as safe and effective as standard regimens

**Inclusion criteria**

Operable invasive breast cancer (T 1-3, N 0-1, M 0)

Age < 75 years at presentation

Breast conserving surgery.

**Exclusion criteria** Not reported

**Population** number of patients = 1410

**Interventions**

50 Gy radiotherapy given in 25 fractions or

39 Gy given in 13 fractions or

42.9 Gy given in 13 fractions.

All schedules given over 5 weeks

**Outcomes**

Recurrence free survival

Local relapse defined as any malignant disease in the ipsilateral breast.

Distant relapse defined as malignant disease outside the ipsilateral breast and regional lymph nodes.

**Follow up** Median follow-up 9.7 years (IQR 7.8-11.8). Maximum follow-up of 18.4 years.

**Results**

18 patients (1%) lost to follow-up.

Outcomes are reported in the following table.

<b>Outcome</b>	<b>Number of patients</b>
Alive without local relapse	838 (59%)
Alive with local recurrence (no distant relapse or contralateral breast cancer)	46 (3%)
Alive with distant relapse (10 with local relapse and 5 with contralateral breast cancer)	46 (3%)
Alive with second primary cancer in contralateral breast (incl 3 with local relapse)	35 (2%)
Deaths (99 had a local relapse)	445 (32%)

Alive with local relapse	158 (11%)
--------------------------	-----------

106 (67%) of local recurrence events occurred within 5 years of follow-up.

Survival analysis of local relapse data by fractionation schedule is shown in the following table (50Gy fractionation used as reference):

Fraction (Gy)	N local relapse /person years	Crude Hazard Ratio (95% CI)	Kaplan-Meier estimate local recurrence (95% CI)		Smoothed estimate of absolute difference in local recurrence (95% CI)	
			5 yr	10 yr	5 yr	10 yr
50	50/3965	1	7.9% (5.4-10.4)	12.1%(8.8-15.5)	-	-
42.9	42/3840	0.86 (0.57-1.30)	7.1% (4.6-9.5)	9.6%(6.7-12.6)	-1.1%(-3.3-2.3)	-1.6%(-5.0-3.3)
39	66/3890	1.33 (0.92-1.92)	9.1% (6.4-11.7)	14.8%(11.2-18.3)	2.5%(-0.6-6.7)	3.7%(-0.9-9.8)

A further analysis of fractionation data showed a significant absolute difference between 42.9 and 39 Gy groups for the probability of local recurrence.

Outcome	Number of patients
Probability of local recurrence between 42.9 and 39Gy groups	Absolute difference 3.7% (95% CI 0.3 to 8.3) p=0.027 (favours 42.9Gy)
Hazard ratios over first 5 years	0.90 (95%CI 0.55 – 1.46) for 42.9Gy compared with 50Gy at 5 years 1.14 (95%CI 0.72 – 1.79) for 39Gy compared with 50Gy at 5 years
Hazard ratios from 5 years onwards	0.77 (95%CI 0.36 – 1.69) for 42.9Gy compared with 50Gy 1.81 (95%CI 0.96 – 3.41) for 39Gy compared with 50Gy P=0.1 (no significant difference from 5 year values)

The recurrence free survival curves show that the three fractionation schedules diverge only after 5 years of follow-up.

The sensitivity of breast cancer to dose per fraction was estimated to be 4.0 Gy (95% CI 1.0-7.8), which is similar to that estimated for the late adverse effects in healthy tissue from breast radiotherapy.

**Author conclusions:** Breast cancer tissue is probably just as sensitive to fraction size as dose-limiting healthy tissues. If this finding is confirmed,

radiotherapy schedules can be greatly simplified by the delivery of fewer, larger fractions without compromising effectiveness or safety, and possibly improving both.

Whelan T, MacKenzie R, Julian J, Levine M, Shelley W, Grimard L, et al. Randomized trial of breast irradiation schedules after lumpectomy for women with lymph node-negative breast cancer. *Journal of the National Cancer Institute* 2002;94(15):1143-50.

Design: RCT (1993-1996)

Level 1++

Country: Canada, setting: Multi-centre

Aim: To determine whether a 22-day fractionation schedule is as effective as the more traditional 35-day schedule in reducing recurrence.

**Inclusion criteria** Women with invasive breast cancer treated by lumpectomy who had pathologically clear resection margins and negative axillary lymph nodes.

**Exclusion criteria**

Level I and II axillary dissection not performed

Tumours > 5cm or stage T4

Previous breast cancer

Bilateral malignancy of breast, previous or concomitant malignancies

Patients geographically inaccessible for follow-up

Patients unable to commence RT within specified time for last surgical procedure or last chemotherapy dose

**Population** number of patients = 1234

42.5 Gy in 16 fractions n=622

50 Gy in 25 fractions n=612

**Interventions**

Randomization to receive whole breast irradiation of 42.5 Gy in 16 fractions (2.7Gy/fraction) over 22 days (short arm – 3 weeks) or whole breast irradiation of 50 Gy in 25 fractions (2Gy/fraction) over 35 days (long arm- 5 weeks). Stratification was by age (< 50 or > 50 years); tumour size <2cm or > 2cm); adjuvant systemic therapy (tamoxifen, any chemotherapy, no therapy); and centre.

The breast at risk and chest wall were irradiated.

Radiation was delivered by 4-6 mV LINAC or cobalt-60.

**Outcomes**

Local recurrence of invasive breast cancer in the treated breast

Distant recurrence (in regional lymph nodes –ipsilateral, axilla, supraclavicular, imc- bone, liver, lung, CNS).

Local recurrence free survival - interval from randomization to local recurrence as first event

Disease Free Survival – interval from randomization to any recurrence or death

Overall survival

Histological confirmation required for any local recurrence and first recurrence at other sites if possible.

Global cosmetic outcomes (EORTC)

Graded as:

0 no difference or excellent  
 1 = small difference or good  
 2 = moderate difference or fair  
 3 = large difference or poor

Radiation toxicity (RTOG/EORTC late morbidity scale) on skin and subcutaneous tissue:

0 = No toxicity  
 1 = slight  
 2 = moderate  
 3 = marked  
 4 = severe

**Follow up** Median follow-up was 69 months.

**Results**

ITT analysis of all randomized patients

Drop outs:

Did not receive RT – 1 in short arm 3 in long arm

Did not complete RT – 2 in short arm 2 in long arm

**Local recurrence free survival**

Outcome	Short arm	Long arm	Absolute difference % (95% CI)
Breast cancer recurrence as first event	N=21	N=23	
Local recurrence free survival at 5 years	97.2%	96.8%	0.4% (-1.5 to 2.4)
DCIS local recurrences	4	3	

A stratification of 5 year local recurrence rates by age of patient, tumour size, and adjuvant systemic therapy showed no significant differences between arms (from confidence intervals).

**Disease free and overall survival**

There were no statistically significant differences in DFS or OS between arms.

The number of deaths and distribution of breast cancer recurrences are shown in the following table.

Outcome	Short arm	Long arm
Any recurrence or death as first event	N=91	N=79
Local recurrences	21	23
Regional recurrences	8	6
Distant recurrences	48	26
Deaths	14	24
DFS (2 sided log-rank test)	P=0.37	

OS (2 sided log-rank test)

P=0.78

**Cosmetic outcomes**

Assessed at baseline, 3 and 5 years.

Cosmetic outcomes assessed in 1220 patients at baseline, 1013 at 3 years and 735 at 5 years.

<b>Global cosmetic outcomes (EORTC)</b>	<b>Short arm</b>	<b>Long arm</b>
Baseline N=1220 Excellent or good	83.8%	82.6%
3 years N= 1013 Excellent or good	76.8%	77.0%
5 years N= 735 Excellent or good	76.8%	77.4%
5 year absolute difference	-0.6% 95%CI (-6.5 to 5.5)	

**Radiation toxicity**

No grade 4 toxicity was observed and the incidence of grade 2 or 3 toxicity was very low in both treatment arms. Toxicity effects for the skin and subcutaneous tissue are shown in the following table.

<b>Site</b>	<b>Grade</b>	<b>% at 3 years</b>		<b>% at 5 years</b>	
		<b>Short arm (n=515)</b>	<b>Long arm (n=492)</b>	<b>Short arm (n=394)</b>	<b>Long arm (n=358)</b>
Skin	0	90	87	87	82
	1	8	11	10	15
	2/3	2	2	3	3
No skin toxicity				87%	82%
5 year absolute difference				Abs difference 5% (95% CI -0.3 to 10.0)	
Subcutaneous tissue	0	69	63	66	60
	1	27	32	29	33
	2/3	4	5	5	7
No subcutaneous tissue toxicity				66%	60%
5 year absolute difference				Abs difference 6% (95% CI -1.2 to 13.0)	

Radiation pneumonitis: 4 cases (2 in each intervention arm)

Rib fracture: 1 case (long arm)

**Author conclusions:** The more convenient 22-day fractionation schedule appears to be an acceptable alternative to the 35-day schedule.

Yarnold J, Ashton A, Bliss J, Homewood J, Harper C, Hanson J, et al. Fractionation sensitivity and dose response of late adverse effects in the breast after radiotherapy for early breast cancer: long-term results of a randomised trial. *Radiotherapy and oncology : journal of the European Society for Therapeutic Radiology and Oncology* 2005;75(1):9-17.

Design: RCT (1986-1998)

Level 1++

Country: UK, setting: Two Oncology Centres

Aim: To test the effects of radiotherapy fractions >2.0 Gy on late normal tissue responses in the breast after tumour excision and radiotherapy for early breast cancer.

### **Inclusion criteria**

Patients with operable invasive breast cancer (T1-3, N0-1, M0)

Age under 75 years at presentation, had BCS and complete macroscopic resection of invasive carcinoma.

### **Exclusion criteria**

**Population** number of patients = 1410 enrolled

Mean age 54.5 years (range 25-78)

67.3% underwent axillary staging and were node negative.

Randomisation was to 3 alternative schedules and stratified by centre and the presence of microscopic foci close to the nearest margin (<3mm).

### **Interventions**

All patients had level II/III axillary dissection – exceptions were women over 50 years with impalpable axillary lymph nodes at one centre, and some at the other centre had axillary sampling.

Patients with positive axillary pathology were offered RT to the supraclavicular fossa at one centre, whilst at the other centre this was reserved for patients with heavy node level I/II involvement and any level III involvement.

Axillary RT was recommended after axillary sampling if the axillary nodes were positive, and at one centre if no axillary surgery was undertaken.

A sub-randomization to boost versus no boost was performed, and this closed in May 1994, when all patients were offered an elective boost.

Control arm 50Gy in 25 fractions of 2Gy over 5 weeks

(n=470)

39Gy in 13 fractions of 3Gy over 5 weeks (5 x per fortnight)

(n=474)

42.9 Gy in 13 fractions of 3.3Gy over 5 weeks (5 x per fortnight)

(n=466)

$\alpha/\beta$  ratio of 1.8 Gy for 3.0 Gy; 6.0Gy for 3.3Gy.

6 MV X-rays were used in the majority of patients.

Lung corrections were applied at one centre but not the other.

### **Outcomes**

Late change in breast appearance compared to post-surgical appearance (by 3 observers blinded to treatment allocation) from annual photographs:

None/minimal 0

Mild 1

Marked 2

Fibrosis

Ipsilateral tumour recurrence.

**Follow up** Maximum total 15 years, median 8.1 years.

### Results

Pairs of photos available at each time point:

1128 at 1 year

1004 at 2 years

525 at 3 years

472 at 4 years

765 at 5 years

141 at 10 years

420 patients (34.9%) experienced some change in breast appearance.

The risk of developing any radiation effect was lower in the 39Gy /13 fraction compared with the 42.9Gy /13 fraction group. There was also a significant difference between the 50 and 39 Gy arms over this time period ( $p=0.01$  Log rank test), but weaker evidence for a difference between 50 and 42.9Gy ( $P=0.05$  Log rank test).

Changes in breast appearance were relatively small, 76/1202 (6.3%) of patients scored a grade 2 (marked). However a lower risk of marked change was observed in patients treated with 39 Gy compared with 42.9 Gy (see Table ). There was also a difference between the 50 and 42.9 Gy arms of the trial for marked change in appearance ( $P=0.01$  Log rank test), but not between 50 and 39 Gy ( $P=0.18$  Log rank test).

The value of the  $\alpha/\beta$  ratio estimated from the Cox proportional hazards regression model for any change in breast appearance is 3.6 Gy (95% CI 1.8–5.4 Gy), and is 2.9 Gy (95% CI 1.0–4.8 Gy) for marked change in breast appearance. The  $\alpha/\beta$  value for palpable breast induration was 3.1 Gy (95% CI 1.8-4.4). The  $\alpha/\beta$  values were unchanged if photographic data were restricted to events emerging at 3 or more years when earlier, non-permanent, changes in breast appearance due to, e.g. surgical oedema are censored in the analysis.

Survival analyses of changes in breast appearance and clinical assessments of late radiation effects at 10 years by fractionation schedule are shown in the following table.

Endpoint	Fractionation schedule	Events/total (%)	Estimated % with no event at	Log rank test comparing
----------	------------------------	------------------	------------------------------	-------------------------

			<b>10 years (95%CI)</b>	<b>all 3 schedules (p)</b>
<b>Photographic assessment</b>				
Any change in breast appearance	50Gy 42.9Gy 39Gy	140/396 (35.4) 168/397 (42.3) 112/409 (27.4)	46.6 (37.2- 55.9) 42.0 (33.0- 51.0) 43.9 (30.8- 57.0)	<0.001
Marked change in breast appearance	50Gy 42.9Gy 39Gy	22/396 (5.6) 40/397 (10.1) 14/409 (3.4)	90.2 (85.0- 95.5) 84.4 (77.7- 91.1) 93.4 (87.8- 99.0)	<0.001
<b>Clinical assessment</b>				
Cosmesis (fair/poor)	50Gy 42.9Gy 39Gy	165/271 (60.9) 175/266 (65.8) 136/269 (50.6)	28.8 (22.3- 35.4) 25.6 (19.3- 31.8) 42.0 (34.9- 49.1)	<0.001
Breast shrinkage (moderate/marked)	50Gy 42.9Gy 39Gy	147/271 (54.6) 148/266 (55.8) 124/269 (46.1)	36.2 (29.3- 43.1) 34.2 (27.0- 41.5) 44.4 (37.0- 51.7)	0.026
Breast distortion (moderate/marked)	50Gy 42.9Gy 39Gy	132/271 (48.9) 148/266 (55.8) 115/269 (42.8)	41.5 (34.4- 48.6) 38.0 (31.4- 44.6) 51.4 (44.4- 58.4)	0.005
Breast oedema (moderate/marked)	50Gy 42.9Gy 39Gy	34/271 (12.6) 54/266 (20.3) 29/269 (10.8)	86.2 (81.8- 90.7) 78.5 (73.1- 83.9) 88.5 (84.4- 92.7)	0.004
Induration (moderate/marked)	50Gy 42.9Gy 39Gy	77/271 (28.6) 108/266 (40.8) 55/269 (20.4)	63.7 (56.6- 70.7) 48.9 (41.5- 56.4) 72.3 (65.5- 79.2)	<0.001
Telangiectasia	50Gy	37/271	81.9 (76.5-	0.065

(moderate/marked)	42.9Gy 39Gy	(13.8) 38/266 (14.3) 23/269 (8.6)	87.3) 82.0 (76.5- 87.5) 88.0 (83.0- 92.9)	
Arm oedema (moderate/marked)	50Gy 42.9Gy 39Gy	17/271 (6.3) 22/266 (8.3) 16/269 (5.9)	92.3 (88.6- 96.1) 89.5 (85.1- 93.8) 93.0 (89.2- 96.8)	0.494
Shoulder stiffness (moderate/marked)	50Gy 42.9Gy 39Gy	21/271 (7.8) 48/266 (18.1) 19/269 (7.1)	90.0 (85.6- 94.3) 78.2 (72.3- 84.0) 89.9 (85.3- 94.6)	<0.001

The estimates of late radiation effects for the 50 Gy arm were generally between those for 39 and 42.9 Gy. The only clinical parameter that failed to demonstrate a dose response between the 39 and 42.9 Gy treatment arms was arm oedema. This may reflect the small proportion of patients who underwent any form of lymphatic RT.

**Author conclusions:** An alpha/beta value of around 3 Gy for late normal tissue changes in the breast is derived from the estimated equivalence of 41.6 Gy in 13 fractions and 50 Gy in 25 fractions over 5 weeks, in line with trial predictions.

**General comments** –This is the same trial as the Owen paper.

Bates TD. The 10-year results of a prospective trial of post-operative radiotherapy delivered in 3 fractions per week versus 2 fractions per week in breast carcinoma. The British journal of radiology 1988; 61(727):625-30.

Design: RCT (1968-1974)  
Level 1+  
Country: UK, setting: Single Hospital  
Aim: Ten year follow-up of dose fractionation trial.

**Inclusion criteria**

Breast carcinoma treated by mastectomy (majority simple mastectomy)

**Exclusion criteria**

Presence of distant metastases.

**Population** number of patients = 411

**Interventions**

Many had additional removal of lower axillary lymph nodes.

N0 and N1 groups were randomized to treatment with:

N= 203 received 12 fractions in 28 days

N= 208 received 6 fractions in 18 days

Cervico-axillary chain treated with Cobalt 60 teletherapy:

Tissue dose 45-51Gy in 12 fractions over 28 days (3.75-4.25 Gy / fraction)

Or

Tissue dose 31-35Gy in 6 fractions over 18 days (5.17 – 5.83 Gy / fraction)

IMC treated with Cobalt 60 and Caesium 137 teletherapy:

Tissue dose 52Gy in 12 fractions over 28 days

Or

Tissue dose 35Gy in 6 fractions over 18 days

The chest wall was treated with X rays:

37Gy in 12 fractions over 28 days

Or

31.5Gy in 6 fractions over 18 days

**Outcomes**

Local recurrence – tumour recurrence within the irradiated volume, before and after metastases

Effects of radiation on normal tissues

**Follow up** 10 years

**Results**

8 patients were lost to follow-up

Sites of local recurrence at 10 years are shown in the following table:

Site	6 fractions (n=208)	12 fractions (n=203)
Chest wall	15	14

Regional nodes	8	10
Both	3	2
Total	26 (12.5%)	26 (12.8%)

There were more distant metastases and more deaths from all causes in the 6 fraction group, but the differences were not statistically significant. The actuarial survival rates were similar for each fractionation schedule. The actuarial local recurrence rates were similar for each fractionation schedule (10% for N0 and 17% for N1 at 10 years).

Normal tissue reactions are shown in the following table:

Outcome	6 fractions (n=208)	12 fractions (n=203)
<i>Early radiation reactions</i>		
Vomiting	4%	4%
Lassitude	58%	45%
Dysphagia	~50%	~50%
Skin reaction on chest wall at 2 weeks	Score 1.46 (mild erythema)	Score 1.62 (mild erythema)
<i>Late radiation reactions (at 6 months, 5 and 10 years)</i>		
Chest wall scores 1=minimal skin changes 2=moderate skin changes 3=severe skin changes	6 mths to 5 years 1.7; 1.4 10 years 1.5	6 mths to 5 years 1.7; 1.4 10 years 1.3
Subcutaneous fibrosis (sc, ic and axilla) 0=none 1=mild 2=moderate 3=severe	5 years 0.7 10 years 0.8	5 years 1.3 10 years 1.2
Shoulder movement (lower score =more movement)	10 years 0.13	10 years 0.82
Lymphoedema of arm 1=slight 2= moderate 3=severe	6 months 1 (14.5%) 1 year 1.07 (22%) 5 years 1.47 (18%) 10 years 1.57 (12%)	6 months 1 (13.5%) 1 year 1.05 (20%) 5 years 1.83 (27.5%) 10 years 1.89 (29.5%)
Apical pulmonary fibrosis	6 months 1.03	6 months 1.09

	1 year	1 year
	1.03	1.12
	5 years	5 years
	1.40	1.48
	10 years	10 years
	1.67	1.62

The early radiation effects on the normal tissues were similar. The late skin changes in the chest wall (treated with 70 kV X rays) were progressive and at 10 years were more marked with 6 fractions. Late subcutaneous fibrosis in the axilla (treated with cobalt-60 teletherapy), was lower in the 6-fraction group. Twelve fractions resulted in greater restriction of shoulder movement and an increased incidence of lymphoedema of the arm. The incidence of lymphoedema was higher in the N1 group than N0.

**Author conclusions:** In this trial, the 6-fraction technique showed an advantage over the 12-fraction technique. It was equally effective in controlling local recurrence and had fewer late sequelae. It was also convenient for patients and economic in the use of radiotherapy resources.

Taher AN, El-Baradie MM, Essa H, Zaki O, Ezzat S. Hypofractionation versus conventional fractionation radiotherapy after conservative treatment of breast cancer: early skin reactions and cosmetic results. Journal of Egyptian National Cancer Institute 2004 Sep;16(3):178-87.

Design: RCT (Aug 2002-May 2003)

Level 1-

Country: Egypt, setting: Single university hospital

Aim: To compare in a prospective trial the acute skin reaction and late cosmetic effects of normal fractionation versus hypofractionation radiotherapy after breast conserving surgery.

**Inclusion criteria**

Patients < 65 years with T1-2, N0, M0 tumours and  $\geq$  1cm negative surgical margin.

At least 10 dissected nodes.

Distance from midline to mid-axillary line < 25cm.

**Exclusion criteria**

Contralateral breast cancer

Multicentric disease

Serious non-malignant disease

Severe mental or physical disorders

Delay of RT treatment > 4 months after surgery

**Population** number of patients = 30

Mean age  $47.5 \pm 10$  years (range 25-65)

T stage

T 1 Group A Conventional n=1 (6.7%); hypofractionated n=7 (46.7%)

T 2 Group B Conventional n=14 (93.3%); hypofractionated n=8 (53.5%)

P=0.04

**Interventions**

Randomization (by sealed envelope) was to:

Group A: Whole breast irradiation of 50Gy in 25 fractions of 2 Gy over 5 weeks (5 fractions/ week)

Or

Group B: Whole breast irradiation hypofractionated into 42.5Gy in 16 fractions of 2.66 Gy over 5 weeks (5 fractions/ week).

Only the breast and chest wall were included in the target volume using a 6 MV linear accelerator. In Group A the tumour bed received a boost of electrons.

Patients also received systemic chemotherapy (n=20 (67%) before RT, and tamoxifen.

**Outcomes**

RTOG (LENT) scoring system

Cosmesis scored at 6, 12 and 24 months (appearance of scar, breast size, shape, nipple position, shape of areola in comparison to the untreated breast).

4 point scale : excellent (0); good (1); fair (2); poor (3)

Acute (early) skin reactions: Mild (G0-G1); severe (G2-G4)

**Follow up** Mean of 23 ± 3 months (range 18-27 months)

**Results**

T stage was the only baseline characteristic that differed significantly between groups – the data is reported in the population section.

*Acute skin reactions*

Acute skin reactions are reported in the following table:

Grade	Conventional (n=15) n (%)	Hypofractionation (n=15) n (%)	P value
0	0 (0)	2 (13.3)	
1	6 (40)	7 (46.7)	
2	9 (60)	5 (33.3)	0.47
3	0 (0)	1 (6.7)	
4	0 (0)	0 (0)	

Severe skin reactions (G2) occurred in 9 patients in the conventional group and 6 patients (5 G2 and 1 G3) in the hypofractionated group. The difference was not statistically significant. The peak incidence of severe skin reactions occurred in the 5<sup>th</sup> week of RT in the conventional group and lasted for 3 weeks. In the hypofractionated group the peak reaction occurred in the 3<sup>rd</sup> week of RT and lasted for 5 weeks.

A further comparison between groups of factors that may contribute to acute skin reactions found that none were significant. Age, menopausal status, stage (T1 or T2), pathology (ductal or lobular), breast volume, tumour volume and the interval between surgery and RT were not significantly different between groups. However the overall incidence of grade II and III acute skin reactions was found to be significantly more frequent in women with breast volumes > 1100cc when the groups were combined. There was no significant difference between groups A and B when analysed by breast volume. These group sizes were very small and may be underpowered to detect any differences. This also applied to the duration of acute skin reactions where the overall difference was significantly shorter among women with breast volumes < 1100 cc, but there were no differences in duration of reaction by breast volume when comparing groups A and B.

Factor	Conventional (group A) n=15			Hypofractionation (group B) n=15		
	Mild	Severe	P	Mild	Severe	p
Breast volume (cc)	904 ± 282	1131 ± 297	0.16	807 ± 547	1238 ± 399	0.09
<b>Incidence of severe skin reactions</b>						

Breast volume	Total	P value	Group A	Group B	P value
≤ 1100cc	7/18 (38.8%)	0.016	5/9 (55.6%)	2/9 (22.2%)	0.14
> 1100cc	10/12 (83.3%)		5/6 (83.3%)	5/6 (83.3%)	1.00
<b>Duration (weeks)</b>					
	Total	P value	Group A	Group B	P value
≤ 1100cc	2 ± 2.9	0.013	2 ± 1.4	4.5 ± 2	0.11
> 1100cc	4.8 ± 2.6		4 ± 2.4	4.5 ± 3	0.76

#### *Cosmetic outcomes*

These were classified as satisfactory – excellent or good  
Unsatisfactory – fair or poor

Cosmetic outcome	Conventional (group A) n=15	Hypofractionation (group B) n=14	Total (%)	P value
Satisfactory	4 (33.3%)	8 (66.7%)	12 (41%)	0.14
Unsatisfactory	11(65%)	6 (35%)	17 (59%)	Not reported

#### **Prognostic factors affecting cosmesis**

	Satisfactory (n=12)	Unsatisfactory (n=17)	P value	
Lumpectomy volume	329.6 ± 184.3	548.2 ± 341.1	0.05	
Lumpectomy /breast volume ratio	0.3 ± 0.2	0.5 ± 0.2	0.02	

There was a higher incidence (73%) of unsatisfactory cosmesis in patients who developed early severe skin reactions (11/15) but this was not significant (p=0.13).

Other factors found to influence breast cosmesis were lumpectomy volume and lumpectomy/breast volume. Other factors tested including fractionation group, acute skin reaction (mild or severe), age, menopausal status, stage (T1 or T2), pathology (ductal or lobular), breast volume, tumour volume, chemotherapy and the interval between surgery and RT, were not significantly different between groups.

**Author conclusions:** Preliminary results support the use of a shorter fractionation schedule of 42.5Gy/16f/22 days in patients with breast conserving surgery. The study is still going on to study the late effects on a larger number of patients for final evaluation of this regimen.

Goel A, Kaushal V, Hooda HS, Das BP. Comparison of two radiation dose schedules in post mastectomy carcinoma of the breast. Indian journal of medical sciences 2000;54(7):278-83.

Design: RCT (1989-1992) Level 1-

Country: India, setting: Single Centre

Aim: To compare two radiation dose schedules in post mastectomy carcinoma of the breast.

**Inclusion criteria** Patients surgically treated with modified radical mastectomy, Karnofsky performance status (KPS) >70

**Exclusion criteria** Patients with distant metastases, inoperable cases, fixed inoperable nodes, any surgery other than MRM, KPS < 70

**Population** number of patients = 108

Median age 46 years (31-70)

N=54 40 Gy in 17 fractions over 3.2 weeks (Group A)

N=54 45 Gy in 20 fractions over 4 weeks (Group B)

	Group A	Group B
Postmenopausal	56%	60%
Axillary mass	44%	50%
Stage III	58%	54%

### Interventions

Method of randomisation not reported.

Modified radical mastectomy

Postoperative RT to chest flap and drainage areas.

Group A: 40 Gy in 17 fractions over 3.2 weeks

Group B: 45 Gy in 20 fractions over 4 weeks

Cobalt 60 teletherapy machine

### Outcomes

Chest wall failure

Axillary node failure

Distant metastases

Skin reactions

### Follow up

### Results

4/54 patients in group A did not complete the treatment and were excluded from the study.

Results are reported in the following table.

Outcome	Group A (n=50)	Group B (n=54)
No evidence of disease at last follow-up	26 (52%)	32 (59%)
Chest wall failure	5 (10%)	3 (5.6%)
Axillary lymph node	3 (6%)	4 (7%)

failure		
Distant metastases	16 (32%)	15 (28%)
<b>Radiation reactions</b>		
Skin reactions		
Grade 0	5 (10%)	11 (20%)
Grade I	10 (20%)	16 (30%)
Grade II	25 (50%)	24 (45%)
Grade III	10 (20%)	3 (5%)
Grade IV	0	0
Difficulty in swallowing	38 (76%)	40 (74%)
Nausea/vomiting	6 (12%)	7 (13%)
Infection	2	3
Lymphedema	3	1
Shoulder restriction	1	1
Brachial plexus involved	0	0

**Author conclusions**

No statistically significant difference in local control and efficacy of these two radiation dose schedules was observed in postmastectomy carcinoma of the breast. (No statistical tests were reported).

**General comments –**

Very small sample size, may be underpowered to detect any differences between groups. No time period reported.

## Ongoing RCTs

A randomized phase III study of conventional whole breast irradiation versus partial breast irradiation for women with stage 0, I, or II breast cancer. Clinical Advances in Hematology and Oncology 2006;4(10):719-21

Design: RCT (NSABP B-39, RTOG 0413)

Country:, setting:

Aim: To compare conventional WBI with PBI following lumpectomy on local tumour control.

**Inclusion criteria** Patients undergoing BCS for stages 0, I and II breast cancer

**Exclusion criteria**

**Population** Target number of patients = 3000

**Interventions**

Random assignment to either Whole Breast Irradiation (WBI) or partial breast irradiation (PBI) after lumpectomy.

WBI:

50Gy (2Gy/fraction) or 50.4Gy (1.8Gy/fraction) to the whole breast, followed by an optional boost to 60-66.6Gy.

PBI:

34Gy in 3.4Gy fractions using multi-catheter brachytherapy OR

34Gy in 3.4Gy fractions using Mammosite catheter OR

38.5Gy in 3.85Gy fractions using 3D conformal external beam radiation

For all PBI interventions RT given to tissue surrounding lumpectomy cavity only.

**Outcomes**

Local control

Overall survival

Cosmesis

Acute and late toxic effects

**Follow up**

**Results**

Not available

**General comments** -

## Non-randomized studies

Marhin W, Wai E, Tyldesley S. Impact of fraction size on cardiac mortality in women treated with tangential radiotherapy for localized breast cancer. *International Journal of Radiation Oncology Biology Physics* 2007;69(2):483-9.

Design: Population retrospective cohort (1984-2000)

Level 2+

Country: Canada, setting: Single province

Aim: To determine whether fraction size affects the risk of cardiac mortality in women treated with adjuvant radiotherapy (RT) for left-sided breast cancer.

### Inclusion criteria

Women aged 20-80 years

Stage pTis – 2, pN0-1, M0

### Exclusion criteria

Women receiving irradiation to other sites for a second malignancy, contralateral breast primary, prior history of cancer.

Patients receiving any RT fields in addition to breast tangents and breast boosts, including regional lymph nodes (axilla, internal mammary, or supraclavicular fossa).

**Population** number of patients = 7447 records from the Oncology Reporting System database in British Columbia

Mean age 57.2 years (25-80 years)

Patient characteristics were similar between women with right and left-sided breast cancers.

Left-sided breast cancer n=3781

Right-sided breast cancer n=3666

### Interventions

BCS or mastectomy with adjuvant RT to breast or chest wall with megavoltage tangential irradiation with or without a breast boost.

21% received adjuvant chemotherapy

35% received adjuvant hormonal therapy

(not all systemic therapy was systematically recorded)

### Outcomes

Cardiac related deaths (from death records)

**Follow up** Median follow-up 7.9 years (0.3-20.5)

### Results

Deaths n=1067

9% of deaths attributed to cardiac disease

Left-sided cancer deaths n=52

Right-sided cancer deaths n=47

Patient and treatment related factors were evenly distributed between right and left sided groups.

Median RT dose was 44Gy

Median number of fractions was 16

Median fraction size 2.75Gy

Treatment characteristics by laterality are shown in the following table and were evenly distributed by site of cancer:

Characteristics	Laterality of breast cancer			
	Left (n=3781)		Right (n=3666)	
Age (yr)	≤ 60	> 60	≤ 60	> 60
Radiotherapy: Dose (Gy)				
Mean	44.19	44.03	44.15	43.85
Median	44	44	44	44
Number of fractions				
Mean	17	17	17	17
Median	16	16	16	16
Fraction size (Gy)				
Mean	2.6	2.62	2.6	2.63
Median	2.75	2.75	2.75	2.75
Fraction size (n of patients)				
≤2	342	239	361	198
>2	1846	1354	1804	1303

Treatment characteristics of women who died from cardiac causes by laterality of breast cancer:

	Laterality of breast cancer	
	Left (n=52)	Right (n=47)
Mean age (years)	71.5 ± 7	69.2 ± 8
Breast RT		
Mean dose (Gy)	42.8 ± 6	42.6 ± 6
Mean n of fractions	16.2 ± 3	15.9 ± 3
Mean fraction size (Gy)	2.7 ± 0.2	2.7 ± 0.3
Fraction size (Gy)		
≤2	4 (0.6%)	4 (0.7%)
>2	48 (1.5%)	43 (1.4%)

Treatment and patient characteristics were evenly distributed between left and right – sided cancers of women who died from a cardiac event. There were no significant differences in the number of deaths from all causes ( $p=0.3$ ) or cardiac specific deaths ( $p=0.69$ ) in women treated for left-sided vs. right-sided early stage breast cancer.

There was no significant difference in the number of cardiac deaths in women < 60 years treated for left vs. right-sided breast cancer ( $p=0.17$ ). In women > 60 years the authors suggest there was an increase in cardiac deaths in women with left-sided breast cancer, however, this was not statistically significant compared to women with right-sided breast cancers ( $p=0.39$ ).

There was no statistical difference in the rates of cardiac mortality in women treated with hypofractionated RT (>2Gy) compared to women treated with conventional fraction sizes of  $\leq 2$  Gy irrespective of laterality. In women > 60 years with left-sided breast cancer the authors suggested that adjuvant RT with fraction sizes > 2Gy may increase cardiac mortality 5-10 years after treatment, however, this was not statistically significant ( $p=0.22$ ). When comparing left with right – sided RT of > 2Gy fractions in women aged > 60 years the relative risk of cardiac death was 1.22 (95%CI 0.75-2.01) [reference right sided RT]. However, this is not significant – confidence interval encompasses 1.00. In women with right-sided breast cancer neither age, nor fraction size influenced cardiac mortality.

Relative risks of cardiovascular deaths stratified by age and fraction size are shown in the following table:

Age (years)	Fraction size (Gy)	Laterality	Cumulative incidence of cardiac death at 10 year follow-up (%)	Relative risk (95% CI) at 10 year follow-up
All ages	$\leq 2$	Right	1.01	1.00
		Left	0.96	0.95 (0.24 – 3.78)
	>2	Right	1.73	1.00
		Left	1.86	1.07 (0.68 – 1.69)
$\leq 60$	$\leq 2$	Right	0.00	1.00
		Left	0.00	Not available
	>2	Right	0.70	1.00
		Left	0.34	0.49 (0.15 – 1.62)
> 60	$\leq 2$	Right	2.68	1.00
		Left	2.37	0.90 (0.23 – 3.53)

	>2	Right	3.05	1.00
		Left	3.74	1.22 (0.75 – 2.01)

Relative risk of cardiac death for women with left-sided compared with right-sided breast cancer adjusted for age and fraction size

Since there were fewer patients in the  $\leq 2$ Gy fraction group and a short median follow-up time, the authors also suggested that the small differences found in this study may become significant over time or with larger patient numbers.

**Author conclusions:** There was no evidence for increased risk of cardiac mortality in women treated with adjuvant RT after a median follow-up of 7.9 years in our cohort. Hypofractionated adjuvant RT regimens did not significantly increase the risk of cardiac mortality.

**General comments –**

Non-fatal cardiac events may be under-represented since mortality data were collected from death certificates.

Systemic therapy may be a confounding factor for cardiac mortality. The distribution of those receiving systemic therapy was similar between groups in this study, however the database did not capture all systemic therapy in the province. The authors suggested that this would not influence their conclusions.

Wallace LM, Priestman SG, Dunn JA, Priestman TJ. The quality of life of early breast cancer patients treated by two different radiotherapy regimens. Clinical oncology (Royal College of Radiologists (Great Britain)) 1993;5(4):228-33.

Design: Cohort from RCT  
3

Level

Country:, UK setting: Single Hospital

Aim: To determine differences between radiotherapy schedules in terms of their impact on the patient's quality of life and whether measures of coping style and trait anxiety could be used to predict the subjective response to treatment.

**Inclusion criteria**

Women in the West Midlands Oncology Association (WMOA) trial who received postoperative RT after lumpectomy. Women chose whether or not to participate.

**Exclusion criteria**

**Population** number of patients = 63

N = 31 short RT course

N = 32 long RT course

Mean age short course 55.0 years.

Mean age long course 53.6 years.

**Interventions**

Lumpectomy followed by either:

40Gy in 15 daily fractions over 4 weeks (short course)

50Gy in 25 daily fractions over 6 weeks (long course)

Both groups also received a boost of 15Gy in 5 fractions over the short or long course.

Treatment was delivered by Cobalt-60 megavoltage using a 4 field technique.

The breast and ipsilateral axilla, supraclavicular and first station internal mammary lymph nodes were irradiated. All patients received tamoxifen.

**Outcomes**

Global Quality of life : five parameters- activity, daily aid from others, wellness, family support, outlook.

Hospital Anxiety and Depression Scale (HADS)

HADS anxiety score clinically significant >10.

HADS depression score clinically significant >10.

Interviews took place 7 days after completion of RT.

**Follow up** Pre and post treatment questionnaires, 6 month follow-up.

**Results**

27/63 6 were lost to follow-up at 6 months.

Pre-radiotherapy measures:

Outcome	Group short n=31	Group long n=32	P value
---------	---------------------	--------------------	---------

	Mean (95% CI)	Mean (95% CI)	
HADS anxiety	6.2 (4.5-7.9)	6.7 (5.2-8.2)	0.39
HADS depression	3.7 (2.2-5.2)	3.8 (5.1-2.5)	0.69

No differences were found between scores for the short and long course pre-RT treatment.

Post RT treatment scores for anxiety and depression:

HADS scale	1 week post RT			6 months post RT		
	Short (SE) N=31	Long (SE) N=32	P value	Short (SE) N=17	Long (SE) N=19	P value
Anxiety	3.8 (0.59)	5.2 (0.63)	0.13	3.0 (0.56)	5.3 (1.04)	0.2
Depression	3.9 (0.64)	3.4 (0.52)	0.77	2.8 (0.65)	3.2 (1.0)	0.96

On completion of treatment there was a reduction in anxiety scores overall (p=0.001).

There was no significant difference between the 2 groups (p=0.28).

Depression scores did not change significantly pre and post treatment.

Global Quality of Life scores pre and post treatment:

Global QoL	Short			Long		
	Pre (n=31)	Post (n=31)	6 months (n=17)	Pre (n=32)	Post (n=32)	6 months (n=19)
Wellness: Not up to par	11	13	4 (23%)	15	15	4 (21%)
Outlook: Positive	23	23	13 (76%)	19	16	12 (63%)

There was no statistically significant difference between the short and long groups at 6 months for positive outlook.

The treatment disruption scale showed a minimal impact of RT on patients' daily lives (family and sexual relationships, finances, work and general activities).

The symptom distress scale showed a significant increase in scores for four parameters on completion of RT (not clear whether this applied to both groups combined):

Nausea p=0.012

Tiredness p<0.001

Sleep disturbance  $p=0.02$

Skin irritation  $p<0.0001$

There was also a larger incidence of weight gain in the long course group ( $p=0.01$ )

**Author conclusions:** Overall, radiotherapy had little effect on quality of life and the differences between the two regimens were minor with significantly more of those women on the longer treatment schedule experiencing a transient weight change, disruption of private life and loss of positivity compared with those on the shorter schedule. The HADS test may be used to detect patients who may benefit from extra reassurance and/or referral for psychiatric support.

**General comments –**

Clear definitions of the measured parameters were not provided. Some of the findings have not been reported because it was not clear which groups they applied to.

Olivotto IA, Weir LM, Kim-Sing C, Bajdik CD, Trevisan CH, Doll CM, et al. Late cosmetic results of short fractionation for breast conservation. *Radiotherapy and oncology : journal of the European Society for Therapeutic Radiology and Oncology* 1996;41(1):7-13.

Design: Cohort from RCT (1986-1991)

Level 2+

Country: Canada, setting: Single Cancer Centre

Aim: Analysis of results of data on short fractionation schedules after BCS up to 5 years after completion of RT.

#### **Inclusion criteria**

Women with invasive T1 and T2 pathologically node negative breast cancer.

Lumpectomy with negative margins.

Negative axillary dissection with at least 4 nodes recovered.

#### **Exclusion criteria**

Contraindications to RT or unsuitable for RT.

Allergy to acetylsalicylic acid (ASA).

Lupus erythematosus

Scleroderma

Rheumatoid arthritis

Diabetes

**Population** number of patients = 184

Median age 54.5 years (range 28-81)

#### **Interventions**

Following BCS and axillary dissection patients were randomized to receive 325mg of enteric coated acetylsalicylic acid (ASA) or placebo daily for 1 year.

All patients had a breast dose of 44 Gy in 16 daily fractions (2.75Gy) over 22 days, paired, opposed tangential fields were used.

Cobalt -60 or 4MV photons were used.

13 patients with pathological close margins also received a boost to the tumour bed (5Gy in 2 fractions).

Median time between surgery and first day of RT was 5.6 weeks.

87% started  $\leq$  8 weeks

#### **Outcomes**

Cosmesis (patient and physician assessments)- excellent, good, fair, poor.

Breast discomfort – none, mild, moderate, severe

Erythema

Oedema

Induration

Telangiectasia

**Follow up** Median 6.7 years

#### **Results**

Actuarial overall survival at 5 years = 92% (SE  $\pm$ 3%)

Actuarial breast recurrence rate at 5 years = 6%

Cosmetic and normal tissue scores before RT and at 3 and 5 years are reported below:

	<b>Prior to RT (N=184)</b>	<b>3 yrs post RT (N=145)</b>	<b>5 yrs post RT (N=135)</b>
<b>Eligible cases</b>	<b>n (% known)</b>	<b>n (% known)</b>	<b>n (% known)</b>

### *Cosmesis*

At 5 years after RT 96% (114/119) of patients and 89% (118/133) of physicians rated the cosmetic outcome as good to excellent. The illustrations in the paper showed an initial transient period of worsening cosmesis which then improved and was stable between 2 and 5 years.

### *Other outcomes*

Breast discomfort, erythema, oedema and induration were related to both surgery and RT. 35%, 17%, 27% and 59% of patients had mild discomfort, erythema, oedema or induration respectively before commencement of RT. The RT aggravated these conditions which all showed an improvement over 1 to 3 years. At 5 years 20% had breast discomfort, 18% had induration, 6% had erythema and 3% had some degree of breast oedema. Fewer patients had these effects at 5 years than immediately after primary surgery.

The likelihood of telangiectasia was 14% (SE  $\pm$  9.7%) at 5 years. This was mild and occurred in the inframammary fold of women with large breasts.

Induration was present in 15% and 18% of patients evaluated at 3 and 5 years after RT. This was more frequent after 3 years if induration was present before initiation of RT. The difference between patients with or without induration prior to RT then assessed at 3 to 5 years was statistically significant (38% vs. 21% respectively before RT,  $p=0.022$ ).

**Author conclusions:** Results are comparable to those reported from centres employing more conventional fractionation. Short fractionation produces acceptable cosmetic results for the majority of women if there are no contraindications to RT and in the absence of significant post-operative breast induration.

### **General comments**

Although this study randomized patients to ASA or not, this was not evaluated in the analysis since the authors report that "no ASA effect was seen for any parameter evaluated" and the group is treated as a single group. For this reason this study is quality scored as a cohort.

Mladenovic J. Hypofractionated radiotherapy in elderly women with breast cancer. Journal of the Balkan Union of Oncology 2001;6(1):49-54.

Design: NRS (1 year period)

Level

3

Country: Serbia, setting: Single centre

Aim: To evaluate two different regimes of fractionation (conventional and hypofractionated) in the radiotherapy of elderly (over 65 years) women with breast cancer, and to estimate benefits and risks of the hypofractionation approach.

### **Inclusion criteria**

Histologically confirmed breast carcinoma, age 65 or over.

### **Exclusion criteria**

**Population** number of patients = 88

Group A median age 72.4 years (range 65-80)

Group B median age 67.9 years (range 65-73)

Stage I to IV

Five patients in Group A had Stage IV disease, two were unstaged.

Two patients in Group B had Stage IV disease, one was unstaged.

Thirty patients in Group A had concomitant disease.

Twelve patients in Group B had concomitant disease.

### **Interventions**

Group A: 26 had BCS and 22 biopsy only

Group B: 10 had BCS and 30 biopsy only.

Group A: N=48 treated with hypofractionated RT every 2<sup>nd</sup> day, dose 24-26Gy in 4 fractions to the breast.

Regional lymph nodes treated with 19Gy in 4 fractions every 2<sup>nd</sup> day (3 anterior fields: axillary, parasternal, supraclavicular). RT was applied using Cobalt-60 over 8 working days alternately to the breast and lymph nodes. The same treatment was repeated after 28 days.

Group B: N=40 treated conventionally with 51Gy in 16 fractions (every 2<sup>nd</sup> day) to the breast.

Regional lymph nodes treated with 45Gy in 15 fractions. Breast and lymph nodes were irradiated on alternate days over 31 working days. The breast was given a boost of 20Gy and the axilla 12Gy.

RT was completed in 41 working days.

### **Outcomes**

Acute and late complications

Relapse rate

Overall survival

**Follow up** The median follow-up in group A was 30 months (5-48) and in group B 26 months (1-45).

### **Results**

Acute and delayed radiation related side effects are listed in the following table:

<b>Outcome</b>	<b>Group A (n=48)</b>	<b>Group B (n=40)</b>
<i>Acute reactions</i>		
Erythema	91.7%	25%
Dry desquamation with hyperpigmentation	8.3%	55%
Moist desquamation	0%	20%
<i>Delayed reactions</i>		
Fibrosis of breast and axilla	37.5%	10%

No other types of delayed radiation effects occurred, e.g., brachial plexopathy, lymphoedema, fractures. There were significant statistical differences between the 2 groups for the acute reactions ( $p < 0.01$ ), and for fibrosis ( $p = 0.003$ ).

Local recurrences and metastases are shown in the following table:

<b>Outcome</b>	<b>Group A (n=48)</b>	<b>Group B (n=40)</b>
Local relapse	7 (14.6%)	6 (15%)
Local relapse and distant metastases	5 (10.4%)	6 (15%)
Distant metastases	5 (10.4%) <sup>0</sup>	8 (20%)
Total	17 (35.4%)	20 (50%)
Disease free	28 (58.4%)	15 (37.5%)
Lost to follow-up	3 (6.2%)	5 (12.5%)

There was no significant difference between groups for the total events (35.4% vs. 50%;  $p = 0.47$ )

Median relapse free interval was 11.3 months (range 4-30) in Group A and 16.2 months (range 3-32) in Group B ( $p = 0.065$ ).

Patient status at the end of follow-up is shown in the following table:

<b>Outcome</b>	<b>Group A (n=48)</b>	<b>Group B (n=40)</b>	<b>P value</b>
Alive No Evidence of Disease (NED)	27 (56.3%)	11 (27.5%)	0.009
Alive with disease	6 (12.5%)	10 (25.0%)	
Death from primary disease	6 (12.5%)	7 (17.5%)	
Death from concurrent	6 (12.5%)	7 (17.5%)	

disease			
Lost to follow-up	3 (6.2%)	5 (12.5%)	

Kaplan Meier survival curves at 3 years showed no difference between groups for overall survival ( $p=0.1$ ). However, disease free survival was better in group A than group B at 3 years ( $p=0.025$ )

**Author conclusion:** Hypofractionated radiotherapy is a suitable, effective, and comfortable therapeutic approach in the management of breast cancer in elderly women.

Marcenaro M, Sacco S, Pentimalli S, Berretta L, Andretta V, Grasso R, et al. Measures of late effects in conservative treatment of breast cancer with standard or hypofractionated radiotherapy. Tumori 2004;90(6):586-91.

Design: Non-randomised retrospective study (1999-2002)

Level 3

Country: Italy, setting: single centre

Aim: To compare the conventional schedule and a hypofractionated schedule in terms of late effects and cosmetic results in patients treated with adjuvant radiotherapy after BCS.

**Inclusion criteria**

Women with breast cancer treated with BCS.

**Exclusion criteria**

**Population** number of patients = 58

Stage pT1-T2

pN0-2

Median age 65 years (mean 61 years)

**Interventions**

Surgical interventions available for 21 and 22 patients in group A and B respectively.

Lumpectomy: 2 in group A and 6 in Group B

Segmentectomy/quadrantectomy 19 in group A and 16 in Group B

Conventional fractionation of 50 Gy in 25 daily fractions over 5 weeks (Gp A)  
n=29

Or

Hypofractionated schedule of 45 Gy in 15 daily fractions over 5 weeks (3 fractions /week)  
(Gp B) n=29

Fractionation schedules were chosen on the basis of the patients' logistical situation, e g, distance between home and RT department. No boost to the tumour bed was applied.

**Outcomes**

Late toxicity effects evaluated with SOMA-LENT scoring system (Grade 1 to 4, the higher the grade the poorer the outcome)

Cosmesis – 5 point scale (very good, good, acceptable, poor, very poor)  
evaluated by 2 observers

Patient satisfaction with cosmetic result – same 5 point scale

Skin toxicity in comparison to untreated breast

Skin elasticity measured using a dedicated device

**Follow up** Median 15 months (range 7-46 months) Group A and median 10 months in Group B.

**Results**

SOMA-LENT scores are reported in the following table:

<b>Outcome</b>	<b>Group A n=29</b>	<b>Group B n=29</b>
Pain	Grade 2-3 5 (17%)	Grade 2-3 5 (17%)
Breast oedema	Grade 2 2 (7%)	Grade 2 3 (10%)
Fibrosis	Grade 2-3 6 (21%)	Grade 2 8 (28%)
Telangiectasia	Grade 2 2 (7%)	Grade 2-3 3 (10%)
Arm oedema	Grade 2 1 Grade 4 1	Grade 2 1
Atrophy and ulcerations	No ulceration Atrophy grade 1 2	No ulceration
Breast and arm oedema	Grade 3 breast and Grade 2 arm oedema 2	Grade 3 breast and Grade 2 arm oedema 1
Ulceration or atrophy	0	0

Cosmetic evaluation results are shown below:

<b>Outcome</b>	<b>Group A</b>	<b>Group B</b>
Very good	7 (25%)	2 (7%)
Good	7 (25%)	11 (38%)
Acceptable	8 (29%)	8 (29%)
Poor	6 (21%)	8 (27%)

Median skin elasticity loss due to treatment was -4.19% in group A and -6.29% in group B. These results are not statistically different.

**Author conclusions:** LENT-SOMA toxicities were minimal and no differences were observed between groups. Few patients in the hypofractionated group had very good cosmetic results, but it is debatable if radiotherapy was the only cause. Skin elasticity was not different between groups. Our results seem to suggest that it is possible to treat patients with both schedules, with similar late toxicity

Yamada Y, Ackerman I, Franssen E, MacKenzie RG, Thomas G. Does the dose fractionation schedule influence local control of adjuvant radiotherapy for early stage breast cancer? International Journal of Radiation Oncology Biology Physics 1999;44(1):99-104.

Design: Non-randomised study (retrospective)

Level 3

Country: Canada, setting: Single centre

Aim: To explore the correlation between dose fractionation and local control for adjuvant radiotherapy of early stage breast cancer.

**Inclusion criteria**

Patients with invasive breast cancer, BCS with a 1cm clear margin. All had axillary dissection.

**Exclusion criteria**

**Population** number of patients =118 matched pairs

Group A = 512 treated 1987-1988

Group B - 118 patients were matched with group A.

Patients were matched on clinical prognostic factors: age, tumour size, receptor status, tumour grade and histology, presence or absence of DCIS, presence of capillary space involvement, axillary nodal status, surgical margin status, use of systemic therapy.

**Interventions**

Two fractionation schedules were compared:

50 Gy in 25 fractions over 5 weeks (Group A)

40 Gy in 16 fractions over 3 weeks (Group B)

Tangential parallel opposed external beams of cobalt 60 or 6 MV photons were applied to the whole breast and underlying chest wall. No boost was applied.

Patients with more than 3 involved nodes were given regional RT to the ipsilateral axilla and supraclavicular lymph nodes.

**Outcomes**

Local control in the irradiated breast (regional recurrences in lymph nodes were not considered local recurrences).

Overall breast recurrence rate (all relapses)

Survival

**Follow up** Group A median of 102 months; Group B median of 65 months

**Results**

	Group A	Group B
5 year local control	92.6%	87.6%
p=0.09		
5 year overall survival	84%	84%

**Author conclusion:** Although not statistically significant, there was a trend in the matched pair analysis which suggests that 40Gy in 16 fractions (BED = 65

cGy(4)) provides inferior local control compared to 50Gy in 25 fractions (BED = 75 cGy(4)). Moreover, the literature review demonstrates that a dose control relationship may exist for local control in the adjuvant setting. A dose fractionation schedule equivalent to 50Gy in 25 fractions to the whole breast may represent the optimal dose fractionation schedule for local control.

**General comments –**

Author conclusions were not supported by the statistical findings.

## GUIDELINES

Cancer Care Ontario Practice Guidelines Initiative  
Breast Irradiation in Women with Early Stage Invasive Breast Cancer Following Breast  
Conserving Surgery. Practice Guideline Report #1-2 .

Design: Guideline (2002)

Level 4

Country: Canada

**Inclusion criteria** Update of 1997 searches in MEDLINE, PDQ and the Cochrane Library to January 2002. Internet sites and ASCO and ESMO Proceedings also searched.

**Exclusion criteria**

**Population**

Early invasive breast cancer (Stage I –II) after BCS.

**Interventions**

**Outcomes**

**Follow up**

**Results**

Evidence.

Fractionation schedules: Four randomized trials and two retrospective studies were identified. The optimal fractionation schedule could not be established from the available data.

Recommendations.

The optimal fractionation schedule for breast irradiation has not been established and the role of boost irradiation is unclear. Outside of a clinical trial, two commonly used fractionation schedules are suggested: 50 Gy in 25 fractions to the whole breast, or 40 Gy in 16 fractions to the whole breast with a local boost to the primary site of 12.5 Gy in five fractions. Shorter schedules (e.g., 40 or 44 Gy in 16 fractions) have also been used routinely in some centres. The enrolment of patients in ongoing clinical trials is encouraged.

**General comments –**

Full guideline available from Cancer Care Ontario.

Clinical practice guidelines for the care and treatment of breast cancer

## **6. Breast radiotherapy after breast-conserving surgery**

The Steering Committee on Clinical Practice Guidelines for the Care and Treatment of Breast Cancer:

Design: Guideline (2003)

Level 4

Country: Canada

Aim: To help physicians and their patients arrive at optimal strategies for breast radiotherapy after breast-conserving surgery (BCS) for early breast cancer.

### **Inclusion criteria**

Update of the 1997 guideline.

English language literature search using MEDLINE from 1966 and CANCERLIT from 1983 to 2002. Reference lists from recent published reviews were also scanned.

### **Exclusion criteria**

#### **Population**

Early breast cancer

#### **Interventions**

#### **Outcomes**

#### **Follow up**

#### **Results**

(Only the recommendation for dose fractionation is included).

#### **Recommendation**

A number of different fractionation schedules for breast irradiation are used, the most common in Canada being 50 Gy in 25 fractions, however, recent data from a Canadian trial demonstrates that 42.5Gy in 16 fractions is comparable to the usual schedule.

#### **Evidence**

The commonest fractionation schedule used in Canada is 50 Gy in 25 fractions to the whole breast without a boost when excision margins are clear of disease. A Canadian trial compared 50 Gy in 25 fractions over 35 days with a shorter course of 42.5Gy in 16 fractions over 22 days in women with node negative breast cancer after lumpectomy (Whelan 2002). At a median follow-up of 5.8 years no difference in the rates of local recurrence or cosmetic outcome were reported. This trial was limited to patients with breasts less than 25 cm in width at the midpoint of the radiation field, and the results may not apply to women with larger breasts. It is likely that the results are generalizable to patients with node-positive disease.

#### **General comments –**

The original guideline was updated in 2003 in CMAJ. This was not available to the NCCC for copyright reasons.

**6.5 What are the indications for an external beam radiotherapy boost to the site of local excision after breast conserving surgery?**

**Short Summary**

Data from randomised controlled trials (RCTs) and non-randomized studies (NRS) were included for this topic. The most frequent study reported was the boost versus no boost EORTC 22881-10882 randomised trial. RCT data were consistent in the finding that a boost dose to the tumour bed reduced local recurrence but had little effect on overall survival. However most of the data were from the EORTC trial. One RCT compared the effects of the boost technique on local recurrence (Poortmans *et al* 2004) and found no difference between the three techniques. Most RCTs reported an association of local failure with age. The absolute failure rates and difference in failure rates between treatment groups decreased as age increased. Other factors associated with local failure were: no boost dose, high histological grade of tumour, size of the tumour, excision volume, and adjuvant systemic therapy.

Non-randomised studies reported that young age ( $\leq 45$  years), lower T status, and close final margin status ( $\leq 2$ mm) were the strongest predictors of local recurrence.

A range of cosmetic outcomes were reported and these were assessed by clinicians, patients, panels and digitizer measurements. Global cosmetic results following surgery were excellent or good (Vrieling *et al* 1999), however fibrosis and telangiectasia tended to be worse in the boost group (Bartelink *et al* 2007, Romestaing *et al* 1997).

**PICO**

POPULATION	INTERVENTION	COMPARISON	OUTCOME
Patients with invasive breast cancer (not DCIS) who have received breast conserving surgery	RT to the breast plus RT boost to the site of excision including: <ul style="list-style-type: none"> <li>• Electrons</li> <li>• Implant</li> </ul>	Breast conserving surgery alone (no RT at all) RT breast with no boost	<ul style="list-style-type: none"> <li>• Recurrence</li> <li>• Disease Free Survival (DFS)</li> <li>• Overall Survival (OS)</li> <li>• Cosmesis</li> <li>• Quality of life</li> <li>• Patient acceptability</li> </ul>

The search strategy developed from this PICO table and used to search the literature for this question can be found in Appendix A

**Evidence Summary**

A moderate volume of literature was available with search dates ranging between 1984 and 2008. The most frequent study reported was the boost versus no boost EORTC 22881-10882 randomized trial. Another RCT of a smaller French study by Romestaing *et al* (1997) was also identified. The four lower quality cohort studies considered margin status and cosmesis in relation to a boost dose of radiotherapy to the tumour bed. There were a large number of cohort studies following groups of patients given the same treatment over a period of time

(Breast Conserving Surgery [BCS], external beam irradiation and a boost to the scar) that had no comparison arm of no boost to the scar which were excluded.

Inclusion criteria for the EORTC Trial were limited to women aged less than 70 years with stage T1-2, N0-1 and M0 invasive breast cancer. Surgical excision of primary tumour was made with a 1cm margin. All patients had external wide beam irradiation of the whole breast of 50 Gy with photon beams, and a boost to the scar of 16 Gy with electrons or an iridium-192 implant.

RCT data was consistent in the finding that a boost dose to the tumour bed reduced local recurrence but had little effect on overall survival. However most of the data were from a single study, the EORTC trial. One RCT compared the effects of the boost technique on local recurrence (Poortmans *et al* 2004) and found no difference between the three techniques. Most RCTs reported an association of local failure with age. The absolute failure rates and difference in failure rates between treatment groups decreased as age increased. Other factors associated with local failure were: no boost dose, high grade of tumour, size of tumour, excision volume, and adjuvant systemic therapy.

Non-randomized studies reported that young age ( $\leq 45$  years), lower T status, and close final margin status ( $\leq 2$ mm) were the strongest predictors of local recurrence.

A range of cosmetic outcomes were reported and these were assessed by clinicians, patients, panels and digitizer measurements. Global cosmetic results following surgery were excellent or good (Vrieling *et al* 1999), however fibrosis and telangiectasia tended to be worse in the boost group (Bartelink *et al* 2007, Romestaing *et al* 1997).

### **Randomized controlled trials**

The outcomes assessed in randomized studies were mainly local recurrence, survival and cosmesis. A table is included of the collated data from RCTs for local recurrence and survival.

### **Local recurrence**

Local recurrence was reported in 6 RCTs (Antonini *et al* 2007, Bartelink *et al* 2001 and 2007, Poortmans *et al* 2004, Romestaing *et al* 1997, Vrieling *et al* 2003). Five RCTs reported on the EORTC trial, whilst Romestaing reported on a French study.

Bartelink reported trial findings after 5 years (2001) and 10 years (2007). Disease recurrence in the ipsilateral breast occurred more frequently in the “no boost” than the “boost” arm of the trial at 5 and 10 years, with a hazard ratio of 0.59 (99% CI, 0.46 to 0.76) for the boost arm in both time periods. Antonini *et al* (2007) also reported a higher incidence of local recurrence in the no boost arm with a hazard ratio of 0.55 (95% CI 0.42 to 0.73) for the boost arm at 5 years for the same EORTC trial. Similar findings were reported by Romestaing *et al* (1997) in the Lyon trial with increased incidence of local recurrence in the no boost arm, and a relative risk of recurrence of 0.34 (95% CI, 0.12-0.95) at 5 years. Confidence intervals were wider in the Lyon RCT which is more likely with smaller numbers of participants.

### *Age related local recurrence*

All the EORTC analyses found that the addition of the boost dose produced the greatest absolute benefit to the younger age groups. Both the absolute failure rates and difference in failure rates between groups decreased as age increased. Multivariate analyses of factors

associated with local failure (Antonini *et al* 2007) found younger age, no boost dose, high grade of tumour, the size of the tumour, excision volume, and adjuvant systemic therapy to be significantly associated with local failure. The multivariate model indicated that local recurrence risk decreased with increasing age for both boost and no boost groups.

At 10 years Bartelink *et al* (2007 and 2001) also reported that the observed absolute risk reduction between boost and no boost groups was larger in younger patients. The hazard ratios for local recurrence reduction favoured the boost arm for all age groups. Statistically significant reductions in the boost arm were also reported for pre- and post menopause status, tumour stages T1 and T2, and node N0 at 5 years. No difference was reported for node N1-2, however the number of events was small.

Another analysis of the EORTC trial by Vrieling *et al* (2003) of young patients and the association with patient characteristics, treatment and pathology found on multivariate analysis that age and the boost dose were the only significant factors that independently influenced local control at a median of 5 years.

#### *Type of boost technique*

Poortmans *et al* (2004) conducted an analysis of patients receiving the three different types of boost dose (electrons, photons, interstitial) delivered in the EORTC trial at 5 years. An overall local recurrence rate of 4.3% (95%CI 3.8-4.7%) was found and there did not appear to be a statistically significant difference between the three techniques although P values were not reported. The age of participants on the effect of local control was not associated with type of boost technique.

### **Non-randomized studies**

#### **Local recurrence**

Polgar *et al* (2004) in a small prospective study comparing three different postoperative irradiation techniques reported the 5- and 7-year actuarial rates of ipsilateral breast recurrence for patients treated with Accelerated Partial Breast Irradiation (APBI) as 4.4% and 9.0% respectively, for Whole Breast Radiation Therapy (WBRT) as 4.7% and 14.8% respectively, and WBRT + Tumour Bed Boost (TBB) as 5.7% and 9.5% respectively. There were no statistically significant differences between the three techniques.

In a large prospective cohort Palazzi *et al* (2006) reported 5-year local, regional, and distant control rates as 98%, 99%, and 92%, respectively for a wide range of RT techniques (60% had a boost dose). On multivariate analysis older age and medical adjuvant treatment were the strongest predictors for local control. A lower N-stage, medical adjuvant treatment, lower T-stage, and lower histological grading were predictors for disease free survival. The use of a boost dose was not significant in improving local recurrence rates after quadrantectomy and 50 Gy to the whole breast.

#### *Age related local recurrence*

When stratified by age the prospective cohort by Nueschatz *et al* (2003) reported poorer Kaplan–Meier survival estimates for patients 45 years or younger with a 12-year local failure rate of 14.5%, compared with 6.4% for patients older than 45 years of age at diagnosis (Log-Rank P = 0.01). A comparison of 12-year Kaplan–Meier local failure rates by age and Final Margin Status (FMS) showed lower failure rates for the older age group; and on univariate

analysis age, FMS, and the presence of Extensive Intraductal Component (EIC) were all significant predictors of local failure. Total excision volume, re-excision, lymph node status, and tumour size were not predictive of local failure. On multivariate analysis closer FMS, defined as either positive or  $\leq 2$  mm, were associated significantly with late ( $>5$  years) but not early ( $\leq 5$  years) local failure. Regardless of whether the model divided FMS into positive/negative or  $\leq 2$  mm/greater than 2 mm, young age remained a highly significant predictor of local failure and EIC was of borderline significance ( $P=0.02$  and  $P=0.03$  respectively). The use of a boost dose was not significant in preventing local recurrence after quadrantectomy and 50 Gy to the whole breast in this study.

Similar findings were reported in the retrospective cohort by Perez *et al.* (2003) where the overall incidence of ipsilateral breast recurrence (IBR) in patients aged  $\leq 40$  years with T1 tumours was 9.6% (10/104); and for women aged  $> 40$  years the overall incidence of IBR was 4.4% (41/935) ( $p=0.03$ ). Corresponding IBR for women with T2 tumours were 15.5% (9/58) in patients aged  $\leq 40$  years and 7.1% (18/252) in women  $> 40$  years ( $p=0.04$ ). Actuarial breast relapse rates were 7% for T1 tumours and 11% for T2 tumours over 10 years. There was no significant difference in breast relapse rates between patients treated with a boost of either electrons or interstitial brachytherapy.

#### *Local recurrence and margin status*

A small increase in breast relapse for patients aged  $< 40$  years with close or positive margins for stage T1 tumour types, was found (9% negative; 12-14% positive or close margins) in the study by Perez *et al.* (2003) at a median of 7 years follow-up. The overall differences for all margin status in stage T1 tumours between the age groups compared was statistically significant ( $p=0.03$ ) favouring those over 40 years. The increase in breast relapse was larger for stage T2 tumour groups with close margins in women  $<40$  years (13% negative; 50% close margins), with a small increase in older women. The overall difference for stage T2 tumours between age groups was also statistically significant ( $p=0.04$ ) again favouring those over 40 years. Again young age remained the strongest predictor of local failure on multivariate analysis.

### **Randomized controlled trials**

#### **Survival**

At 10 years Bartelink *et al* (2007) reported no difference in survival between the boost and no boost groups (81.7% (99% CI, 79.5% to 83.7% overall participants). There was also no difference in outcomes between the groups for breast cancer mortality, disease free survival or breast cancer related events.

Romestaing *et al* (1997) reported that the Disease Free Survival (DFS) rates at 5 years were similar between the boost and no boost groups with a relative risk for DFS of 0.63 (95% CI 0.39 to 1.01). This was also the case for overall survival, with a relative risk of 0.49 (95% CI 0.23 to 1.05) at 5 years.

### **Non-randomized studies**

#### **Survival**

Polgar *et al* (2004, Level 3) reported no statistically significant differences in either the 7-year probability of relapse-free survival (79.8%, 73.5%, and 77.7% for APBI, WBRT, and WBRT + TBB, respectively) or cancer-specific survival (93.3%, 92.9%, and 93.9% for APBI, WBRT, and WBRT + TBB, respectively).

## **Randomized controlled trials**

### **Cosmesis**

Cosmesis included a range of different measures with assessment by patients, physicians, panels and digitizers. The outcomes assessed included: fibrosis, telangiectasia, global cosmetic scores, Breast Retraction Assessment (BRA). RCTs included the EORTC studies by Bartelink *et al* (2007); Poortmans *et al* (2004) and Vrieling *et al* (1999).

#### *Global cosmetic score*

From a panel assessment 82% of patients had an excellent or good global cosmetic result following surgery (Vrieling *et al* 1999). There was a trend favouring the no boost group for better global scores and breast shape scores after 3 years. Global score changes over time for breast size, breast shape, nipple position, and shape of areola were significant in the boost arm ( $p < 0.001$ ) only. From digitizer measurements at 3 years there was an increase in mean pBRA of 0.6 in the boost group indicating an increase in nipple position asymmetry (pBRA 7.7 post-op and 8.3 at 3 years,  $p=0.05$ ), of borderline statistical significance. In the no-boost group the change in pBRA over time was not significant (mean pBRA of 7.5 postoperatively and 7.6 at 3-year follow-up,  $p = 0.94$ ).

Romestaing *et al* (1997) reported that 85% of patients were considered to have good or excellent cosmesis results with no difference between arms, and no poor results, from physician assessments.

#### *Fibrosis*

At 10 years Bartelink *et al* (2007) reported that severe and moderate fibrosis was significantly increased in both the whole breast and boost area of the boost group.

At 5 years Poortmans *et al* (2004) found that there was no significant difference in fibrosis in the boost area at 5 years between boost techniques ( $p=0.67$ ); however, there was a significant difference in fibrosis to the whole breast at 5 years between boost techniques ( $p=0.013$ ). The occurrence and grades of fibrosis in the whole breast and in the boost area were similar between the 3 boost techniques. Minor fibrosis was more common in both areas (whole breast and boost). A larger proportion of patients developed moderate to severe fibrosis at the site of primary tumour (25%) than in the whole breast (12%).

#### *Telangiectasia*

Grades 1 and 2 telangiectasia were reported as 5.9% of the no boost group and 12.4% of the boost group in the Romestaing *et al* (1997) study at 2 years. The difference was significant  $p=0.003$ .

#### *Factors influencing cosmesis*

A further multivariate analysis of the EORTC RCT data at 3 years by Vrieling *et al* (2000) found that the factors significantly associated with poorer cosmesis from panel evaluation were inferior tumour location, increased excision volume, breast complications and boost treatment. According to digitizer measurements a multivariate analysis showed that tumour location (central/superior), a large excision volume, increasing pathological tumour size and high maximum dose in the central plane were associated with an increased pBRA at 3 years, and poorer cosmetic outcome.

The prognostic factor analyses of both methods (by panel or digitizer) showed that a large excision volume, a boost dose, increased dose inhomogeneity, and the presence of postoperative breast complications had a large negative effect on cosmesis.

### **Non-randomized studies**

#### *Cosmetic outcomes*

A comparison of tumour bed boost dose delivered by interstitial brachytherapy (APBI) vs electrons or photons reported that most cosmetic results were rated as excellent/good for all techniques, however, APBI had the highest proportion (84.4%) of excellent/good results, and the differences were statistically significant ( $p=0.04$ ) favouring APBI (Polgar *et al* 2004, Level 3).

Palazzi *et al* (2006, 2++) reported overall cosmetic outcomes during a 7 year follow-up. 33% of patients scored "excellent," 47% as "good," 17% as "fair," and 3% as "poor." These scores were similar to pre-radiotherapy scores. Cosmetic failure rate increased from 18% before radiation to 20% during follow-up, suggesting that radiation did not worsen the cosmetic outcome after surgery.

#### *Telangiectasia*

When comparing APBI vs Whole Breast RT (WBRT) vs WBRT + tumour bed boost (electrons or photons) Polgar *et al* (2004) reported significantly poorer grade 2-3 telangiectasia in the WBRT+ Tumour bed boost group in comparison with the other two groups.

#### *Fibrosis*

In a comparison of APBI vs Whole Breast RT (WBRT) vs WBRT + tumour bed boost (electrons or photons) Polgar *et al* (2004) reported poorer outcomes of grade 2-3 fibrosis in both boost groups in comparison to the no boost group(WBRT), although the findings were not significant in this small study.

#### *Fat necrosis*

There were no significant differences in fat necrosis between the 3 arms of the Polgar *et al* (2004) study (APBI vs Whole Breast RT (WBRT) vs WBRT + tumour bed boost of electrons or photons).

### **Adverse effects**

One non-randomized retrospective population cohort (Paszat 2007) reported that RT treatment to the left breast and the area of the boost dose were associated with an increased Hazard ratio for time to an event of acute myocardial infarction (AMI) and time to death by AMI.

### **Guidelines**

Two guidelines were directly relevant to this topic and this was also included in section 6.1 (Jalili *et al* 2007; Whelan *et al* 2003).

**Table 5.3.1** Summary of local recurrence and survival data from RCTs

Author	Outcome	EORTC		LYON

**Evidence table**  
**Randomized Controlled Trials**

Bartelink E, Horiot J-C, Poortmans PMP, Struikmans H, Van den Bogaert W, Fourquet A, et al. Impact of a higher radiation dose on local control and survival in Breast-Conserving Therapy of Early Breast Cancer: 10 year results of the randomized Boost Versus No Boost EORTC 22881-10882 Trial. J Clin Oncol 2007 Aug 1;25(22):3259-66

Design: RCT (1989-1996) EORTC Trial  
 Level 1++

Country:9 countries, setting: 31 centres

Aim: To report on the impact of a 16-Gy boost radiation dose after (Breast Conserving Therapy) BCT on local control, fibrosis, and survival for patients with stage I and II breast cancer at 10 years follow-up.

**Inclusion criteria**

Patients with T1-2, N0-1, and M0 breast cancer (International Union against Cancer: TNM Classification).

**Exclusion criteria**

Patients aged more than 70 years, pure carcinoma in situ, multiple tumour foci in more than one quadrant, a history of other malignant disease, Eastern Cooperative Oncology Group performance score greater than 2, residual micro-calcifications on mammography, or gross residual disease in the breast after lumpectomy (unless re-excision had been performed).

**Population** number of patients = 5318

2,657 were allocated to receive no boost

2,661 were allocated to receive a boost of 16 Gy to tumour bed

Median age at treatment 55 years.

pN0 = 78%

Post menopausal 62%

T1 = 52%

T2 = 48%

Protocol deviations:

26 patients in the intervention group did not receive a boost

53 patients in the no boost group received a boost

107 patients were older than 70 years.

343 patients were delayed between surgery and the start of radiotherapy for longer than allowed by the protocol.

**Interventions**

Patients received surgical excision of the primary tumour, with a 1-cm margin of macroscopically normal tissue and an axillary dissection.

Adjuvant systemic therapy was given to patients with axillary lymph node involvement:

pre-menopausal patients received chemotherapy and post-menopausal patients received tamoxifen.

Patients not given adjuvant chemotherapy began radiotherapy within 9 weeks

after lumpectomy.

Chemotherapy was prescribed more frequently in the boost arm for premenopausal N+ patients (88% vs. 79%).

Irradiation of the whole breast delivered by two tangential megavoltage photon beams (high-energy x-ray or tele-cobalt).

Total dose of 50Gy to the original tumour bed delivered over 5 weeks, with a dose of 2Gy / fraction.

The boost dose of 16 Gy in 8 fractions delivered with electrons or tangential fields; alternatively an iridium-192 implant at a dose rate of 0.5 Gy per hour was used.

251 patients with microscopically incomplete excision in the intervention arm were also randomized to a boost dose of either 10 or 26 Gy in a separate stratum.

No extra irradiation or boost dose was delivered to the comparison arm.

### Outcomes

Local recurrence

Fibrosis:

Fibrosis scoring by treating physician - 4-point scale:

1 = none, 2 = minor, 3 = moderate, and 4 = severe

Breast cancer mortality

Survival

**Follow up** Median follow-up 10.8 years.

### Results

*Local recurrence and cumulative incidence*

Outcomes are shown in the following table:

Outcome	Boost	No boost	P value
Recurrence in ipsilateral breast	165	278	
Regional recurrence in axilla and/or supraclavicular region	56	59	
Cumulative incidence of local recurrence at 10 years	6.2% (95% CI 4.9 to 7.5)	10.2% (95% CI 8.7 to 11.8)	< 0.0001
Hazard Ratio for local recurrence as first event	0.59 (99% CI 0.46 to 0.76)		< 0.0001

Overall, 47% of the local recurrences occurred in the primary tumour bed, 10% occurred in the scar, 29% occurred outside the original tumour area, and 13% were diffuse.

A chart of cumulative incidence of recurrence in the ipsilateral breast over time by age group was reported in the paper. The cumulative incidence of local recurrences correlated significantly with the age of the patient ( $p < 0.0001$ ). The cumulative incidence was highest in the  $\leq 35$  age group, and decreased progressively with increasing age. The incidence was lowest in women aged  $> 60$  years.

The absolute risk reduction by age group at 10 years in the boost and no boost groups is reported in the following table:

Age group	Absolute risk reduction (local recurrence) and Hazard Ratios		P value
	Boost	No boost	
$\leq 40$ years	13.5%	23.9%	0.0014
41 – 50	8.7%	12.5%	
51 – 60	4.9%	7.8%	
$> 60$	3.8%	7.3%	
$\leq 40$ years	Hazard ratio 0.51 favouring boost		$p=0.0014$
41 to 50 years	Hazard ratio 0.65 favouring boost		$p=0.01$
51 to 60 years	Hazard ratio 0.64 favouring boost		$p=0.012$
$> 60$ years	Hazard ratio 0.51 favouring boost		$p=0.0008$

The largest reductions in cumulative incidence between boost and no boost arms were seen in the younger age groups. The differences between boost and no boost arms were statistically significant for all age groups.

*Distant metastases, breast cancer mortality and survival.*

The cumulative risk of distant metastases was not statistically significant different between the two groups. There were 16.1% of distant relapse events in both groups at 10 years. The cumulative incidence of second primary tumour in the contralateral breast or other sites was similar between groups ( $P>0.1$ ).

Mortality and disease-free survival were similar between groups

Deaths:

N=522 in no boost group

N= 521 in boost group

Survival at 10 years = 81.7% (99% CI, 79.5 - 83.7) for both arms.

Breast cancer mortality:

N= 344 events in no boost group

N= 346 events in boost group

Disease-free survival  $P > 0.1$  between groups  
 Overall incidence of breast cancer-related events also similar between groups.

*Fibrosis*

Severe and moderate fibrosis was significantly increased in both the whole breast and boost area.

<b>Outcome</b>	<b>Boost Cumulative incidence (99% CI)</b>	<b>No Boost Cumulative incidence (95% CI)</b>	<b>P value</b>
Cumulative incidence of severe fibrosis at 10 years	4.4% (99% CI, 3.5 to 5.7)	1.6% (99%CI, 1 to 2.3)	$P < 0.0001$
Cumulative incidence of moderate to severe fibrosis at 10 years	28.1% (99% CI, 27.6 to 28.6)	13.2% (99% CI, 11.5 to 15.0)	$P < 0.0001$

**Author conclusions**

After a median follow-up period of 10.8 years, a boost dose of 16 Gy led to improved local control in all age groups, but no difference in survival.

**General comments -**

Bartelink H, Horiot JC, Poortmans P, Struikmans H, Van den BW, Barillot I, et al. Recurrence rates after treatment of breast cancer with standard radiotherapy with or without additional radiation. The New England journal of medicine 2001;345(19):1378-87.

Design: RCT (1989-1996) EORTC Trial  
Level 1++

Country:9 countries, setting: 31 centres

Aim: To report the effect of a supplementary dose of radiation to the tumour bed on rates of local recurrence among patients receiving radiotherapy after BCS for EBC.

**Inclusion criteria**

Patients with T1-2, N0-1, and M0 breast cancer

**Exclusion criteria** Same as Bartelink 2007

**Population** number of patients = 5318

Median age at treatment 55 years.

pN0 = 78%

Post menopausal 62%

T1 = 52%

T2 = 48%

**Interventions**

2,657 were randomized to receive no boost

2,661 were randomized to receive a boost of 16 Gy to tumour bed

Patients received surgical excision of the primary tumour, with a 1-cm margin of macroscopically normal tissue and an axillary dissection.

Adjuvant systemic therapy was given to patients with axillary lymph node involvement:

pre-menopausal patients received chemotherapy and post-menopausal patients received tamoxifen.

Patients not given adjuvant chemotherapy began radiotherapy within 9 weeks after lumpectomy.

Chemotherapy was prescribed more frequently in the boost arm for pre-menopausal N+ patients (88% vs. 79%).

Irradiation of the whole breast delivered by two tangential megavoltage photon beams (high-energy x-ray or tele-cobalt).

Total dose of 50Gy to the original tumour bed delivered over 5 weeks, with a dose of 2Gy / fraction.

The boost dose of 16 Gy in 8 fractions delivered with electrons or tangential fields; alternatively an iridium-192 implant at a dose rate of 0.5 Gy per hour was used.

251 patients with microscopically incomplete excision in the intervention arm were also randomized to a boost dose of either 10 or 26 Gy in a separate stratum.

No extra irradiation or boost dose was delivered to the comparison arm.

**Outcomes**

Local recurrence defined as all recurrences in the treated breast, before or after the detection of distant metastases.

**Follow up** Median follow-up period 5.1 years, maximum 10.2 years.

**Results**

24 percent of patients required a re-excision.

Axillary dissection was performed in 99 percent of patients.

*Local recurrences*

Data for local recurrences is shown in the following table:

<b>Outcome</b>	<b>Boost (n=2661)</b>	<b>No boost (n=2657)</b>	<b>P value</b>
Local Recurrence in ipsilateral breast	N=109	N=182	
Regional recurrence in axilla and/or supraclavicular region	N=56	N=59	
Actuarial rate of local recurrence at 5 years in ipsilateral breast	4.3% (95% CI 3.8 to 4.7)	7.3% (95% CI 6.8 to 7.6)	< 0.001
Local Recurrence as first event	3.3%	5.9%	
Hazard Ratio for local recurrence as first event	0.59 (99% CI 0.43 to 0.81) favours boost		

Eighteen local recurrences occurred after another recurrence (a distant metastasis, a regional metastasis, or contralateral breast cancer) in the no boost group; and 9 local recurrences occurred in the boost group. Overall 47% of local recurrences occurred in the primary tumour bed, 9% in the scar, 29% outside the area of original tumour, and 27% diffuse throughout the breast.

From a subgroup analysis patients aged 40 years or less benefited most at five years with a local recurrence rate of 19.5% with standard treatment and 10.2% with boost radiation (hazard ratio, 0.46 [99% CI 0.23 to 0.89]; P=0.002). The boost dose was significantly more effective in all factors in the subgroup analyses. An exception was patients with N1-2 status where no significant difference in local recurrences was reported, however the sample size was small in this subgroup and may not be statistically valid (n=20 recurrences in 391 patients).

The subgroup analyses of other prognostic factors are listed in the table below:

Outcome	Actuarial 5 yr Local recurrence rate (99% CI)		Hazard Ratio (99% CI)	Reduction in annual Odds of Local Recurrence (99% CI)	P value
	Boost	No boost			
<b>AGE</b>					
≤ 40 years	10.2	19.5	0.46	54 (25-71)	0.002
41-50 years	(7.9-12.5)	(16.5-22.5)	(0.23-0.89)	38 (8-58)	0.02
51-60 years	5.8	9.5 (8.2-10.7)	Not reported	36 (0-60)	0.07
> 60 years	3.4 (2.7-4.1)	4.2 (3.5-4.9)	Not reported	32 (0-60)	0.14
	2.5 (1.9-3.2)	4.0 (3.2-4.7)	Not reported		
<b>Menopausal status</b>					
Pre-menopausal	6.8	10.3		40 (19-56)	0.001
Postmenopausal	(5.8-7.6)	(9.2-11.4)		41 (15-59)	0.004
	2.8 (2.3-3.2)	4.6 (4.1-5.2)			
<b>Tumour stage</b>					
T1	4.0	5.9 (5.2-6.6)		42 (19-59)	0.001
T2	(3.3-4.6)	6.6		39 (16-56)	0.002
	4.5 (3.9-5.2)	7.8 (7.0-8.7)			
<b>Nodal status</b>					
N0	4.2	6.9 (6.4-7.5)		43 (27-55)	0.001
N1-2 (small number of events)	(3.4-4.6)	7.5		0 (0-56)	0.89
	5.7 (3.7-7.6)	5.6 (3.7-7.4)			

At five years in the 41 to 50 years age group no differences were found in rates of metastasis or overall survival (87% and 91%, respectively). The benefit of the additional dose in local control was independent of whether the patients received adjuvant systemic treatment.

**Author conclusions**

In patients with early breast cancer who undergo breast-conserving surgery and receive 50 Gy of radiation to the whole breast, an additional dose of 16 Gy of radiation to the tumour bed reduces the risk of local recurrence, especially in patients younger than 50 years of age.

**General comments –**

This is an earlier report of the EORTC trial providing follow-up data at 5 years. Confidence intervals were reported as 95% in tables but as 99% in the text and figures.

Antonini N, Jones H, Horiot JC, Poortmans P, Struikmans H, den Bogaert WV, et al. Effect of age and radiation dose on local control after breast conserving treatment: EORTC trial 22881-10882. *Radiotherapy & Oncology* 2007;82(3):265-71.

Design: Analysis of RCT data EORTC Trial (1989-1996)  
Level 1++

Country: Europe, USA setting: Multi-centre

Aim: To determine whether the effect of an additional "boost" radiation after breast conservative therapy (BCT) on local control depends on age and evaluate the impact of a treatment policy with an age threshold.

### **Inclusion criteria**

Patients with microscopically complete excision.

### **Exclusion criteria**

251 patients with incomplete resection were not included.

**Population** number of patients = 5318

2657 to no boost arm

2661 to boost arm

Patients were stratified according to age, menopausal status, presence or absence of intra-ductal component in or adjacent to the invasive tumour, clinical tumour size, clinical nodal status, and treatment centre.

### **Interventions**

Whole breast irradiation of 50 Gy after breast conserving therapy. Intervention arm received a boost dose of 16Gy to the tumour bed.

Patients with positive lymph nodes also received systemic therapy of adjuvant CMF chemotherapy if pre-menopausal or tamoxifen (20 mg) if postmenopausal.

### **Outcomes**

Local Recurrence in the ipsilateral breast.

Univariate analyses were stratified for age, menopausal status, performance status, grade and margin of invasive tumour and DCIS according to central review or local pathologists, adjuvant chemotherapy or hormonal treatment, tumour size, clinical N stage, axillary dissection, second operation, multi-focal tumour in one quadrant, histological type, first excision microscopically complete, oestrogen and progesterone receptor status, total volume of the excision biopsy specimen, number of axillary nodes examined, and number of positive nodes (Level of significance with Bonferroni.correction applied was  $P < 0.002$ ).

Multivariate analyses were performed with treatment (boost) and age as explanatory covariates. Additional relevant clinical factors were also assessed. The interaction of the variability of the boost effect on local recurrence and patient age were of particular interest. Separate multivariate analyses were performed for margin status.

*Analysis*

Age was used as an independent factor to investigate the effectiveness of the boost treatment on local recurrence using the Cox proportional hazard model. A “missing value category” was used when data was missing from relevant factors, e.g. receptor status (30% missing), and margin of invasive tumour and DCIS (70% missing for central review; 55% for local pathology).

**Follow up**

Median follow-up 77.4 months (range: 0–147.6 months), 16 months longer than the first report on the primary endpoint (Bartelink 2001, Vrieling 2003).

**Results**

*Local recurrence*

A total of 362 local recurrences occurred.  
 5 year local recurrence rate = 94.6%  
 232 local recurrences occurred in the no boost group.  
 130 local recurrences occurred in the boost group.

The boost dose significantly changed the time to local failure ( $P < 0.0001$ ) overall patients. The number of local failures decreased by an approximate factor of 2 (HR 0.55, 95% CI 0.42 to 0.73). The cumulative incidence of local failure for boost and no boost arms differed between age groups.

Both the absolute failure rate and difference in failure rate between groups decreased as age increased as shown in the following Table.

Outcome	Patients < 40 Years	Patients > 60 YEARS
Cumulative incidence of recurrence within 5 years	No boost 19.3% Boost 9.5% Difference 9.8% (SE = 3.4%)	Difference 1.9% (SE = 0.86%)

*Univariate analyses (Table below):*

Factors that were significant by univariate Cox proportional hazard regression analysis are shown in the following Table:

Variable	Local failure at 5 yrs (95% CI)	Hazard Ratio (95% CI)	P value
<b>Age (yrs):</b>			
≤40	14.5 (11.1-	1.00	
41-50	18.0)	0.52 (0.36-	<0.0001
51-60	7.24 (5.80-	0.76)	<0.0001
>60	8.72)	0.28 (0.19-	<0.0001
	3.75 (2.84-	0.42)	
	4.66)	0.26 (0.17-	
	3.22 (2.35-	0.40)	
	4.09)		
<b>Menopausal status:</b>	8.08 (6.84-	1.00	

<b>Pre-menopausal</b>	9.33)		0.51	(0.39-	<0.0001
<b>Menopausal</b>	3.69 (3.02-4.37)		0.67)		
<b>Hormone receptor oestrogen</b>					
Negative	7.31 (5.68-9.03)		1.00		
Positive	4.53 (3.73-5.34)		0.70 (0.50-0.99)		0.0073
Unknown	5.54 (4.33-6.76)		0.76 (0.53-1.11)		0.064
<b>Hormone receptor progesterone</b>					
Negative	6.62 (5.18-8.07)		1.00		
Positive	4.61 (3.73-5.50)		0.75 (0.59-0.98)		0.031
Unknown	5.46 (4.36-6.57)		0.77 (0.59-1.10)		0.058
<b>Histology grade</b>					
Low	3.1 (1.9-4.4)		1.00		
Intermediate	5.3 (3.1-7.7)		1.04 (0.71-1.52)		0.84
High	10.0 (7.0-14.0)		2.50 (1.61-3.89)		<0.0001
No pathology review	5.4 (4.6-6.1)		1.55 (1.11-2.18)		0.011
<b>Adjuvant hormone therapy</b>					
No	6.12 (5.38-6.87)		1.00		
Yes	2.14 (1.23-3.05)		0.48 (0.30-0.75)		<0.0001

The strongest associations of increased risk of local failure were young age ( $\leq 40$  years) a high grade of invasive tumour, pre-menopausal status and no adjuvant hormonal therapy (all had  $p < 0.0001$ ). There was a weaker association between local failure and larger tumour size ( $p = 0.002$ ), negative oestrogen receptor status ( $p = 0.0073$ ), and negative progesterone receptor status ( $p = 0.031$ ). Patients with a 10 mm or more margin from the local pathology reports had a significant reduction in risk of local failure ( $P = 0.03$ ). After adjustment with the Bonferroni correction for overall statistical significance of multi-comparisons the variables that remained statistically significant were age, high grade of invasive tumour, no adjuvant hormonal treatment and pre-menopausal status.

### *Multivariate analyses*

Multivariate Cox proportional hazard regression analysis found that age, boost dose, size of excisional biopsy specimen, tumour size, high grade of invasive tumour and adjuvant systemic therapy were independent predictors of local failure. The relevant data are shown in the following Table (only data from local pathology are shown here, the paper includes data from the central review, however the differences were minor):

### *Multivariate analysis on time to local recurrence*

<b>Variable</b>	<b>Hazard Ratio (95% CI)</b>	<b>P value</b>
Age		<0.0001
Boost		<0.0003
Total size of excisional biopsy	0.86 (0.76-0.96)	0.011
Tumour size	1.27 (1.12-1.45)	0.0003
High grade	1.76 (1.06-2.92)	0.029
Adjuvant hormone therapy	0.63 (0.43-0.93)	0.021
Adjuvant chemotherapy	0.66 (0.46-0.95)	0.026

Using a natural spline regression model the data were plotted as a function of age vs. log of hazard ratio (local failure risk). The curves for the boost and no boost groups were parallel with the no boost group showing the highest risk of local failure for all ages. The relative local recurrence risk decreased with age equally for both treatment groups. A flattening of both curves occurred between the ages of 50 and 60 during menopause. A similar model with age categories of 5 year intervals also showed the same form.

### *Age selection for boost dose administration*

To assess the effectiveness of a treatment strategy by age of patient. Between the ages of 35 to 70 years a boost dose reduced the 5 year local recurrence rate from 6.9% to 3.8% for all age groups. The greatest reduction was found between the ages of 40 to 60 years. If the boost dose was limited to patients aged 50 years or less then the overall 5 year recurrence rate would be predicted as 5.1%; similarly limiting the boost to patients aged 60 years or less would reduce the predicted overall 5 year recurrence rate to 4.4%. Recurrence rates would be higher at 5 years when limiting the boost to those aged 35 years or lower (6.4%), or to those aged 40 years or lower (6.1%).

### **Author conclusions**

The relative local recurrence rate after a boost dose of 16Gy was reduced by a factor of 2 (HR = 0.55), independent of age. In younger patients a boost dose resulted in a greater absolute reduction of local failure. The relative risk reduction was however similar for all ages. Applying a treatment policy with a threshold-age of 60 would result in 0.6% increase in local failure in the total study population, while sparing the boost to 1/3 of the patients.

### **General comments –**

The authors report that one of the limitations of this study was the missing data for some of the variables including margin of invasive tumour, hormone receptor status and grade of invasive tumour. The authors added that the missing data did not influence the analysis.

Poortmans P, Bartelink H, Horiot JC, Struikmans H, Van den BW, Fourquet A, et al. The influence of the boost technique on local control in breast conserving treatment in the EORTC 'boost versus no boost' randomised trial. *Radiotherapy and oncology : journal of the European Society for Therapeutic Radiology and Oncology* 2004;72(1):25-33.

Design: RCT (1989-1996 EORTC Trial)

Level 1++

Country: Europe, setting: Multi-centre

Aim: To describe the influence of boost technique on local control and fibrosis after breast conserving therapy in the group of patients receiving a boost dose in a large prospective randomized multi-centre trial.

**Inclusion criteria**

Patients with T1-2, N0-1, and M0 breast cancer were eligible for the EORTC trial.

**Exclusion criteria**

Patients aged more than 70 years, pure carcinoma in situ, multiple tumour foci in more than one quadrant, a history of other malignant disease, Eastern Cooperative Oncology Group performance score greater than 2, residual micro-calcifications on mammography, or gross residual disease in the breast after lumpectomy (unless re-excision had been performed).

**Population** number of patients = 2661 in boost arm of trial

Patients had a complete excision of the primary tumour and were randomized to receive a boost dose of 16 Gy to the primary tumour bed.

**Interventions**

Whole-breast irradiation (WBI) was administered by two tangential megavoltage photon (high-energy X-ray or tele-cobalt) beams. A dose of 50 Gy, in 2 Gy fractions, was delivered over 5 weeks.

The target area for the boost dose was the original site of primary tumour, with a 1.5 cm safety margin around the primary tumour after microscopic complete excision, and 3 cm for invasive cancer with an extensive DCIS component.

Types of boost technique:

High energy photons - the boost dose of 16 Gy (eight fractions of 2Gy) were delivered at the centre of the tumour excision area, either as tangential or wedged oblique fields (753/2661, 29%).

Fast electrons - the 16Gy boost (eight external beam fractions of 2Gy) were delivered to a depth of Dmax with the 85% isodose encompassing the target volume (1635/2661, 63%).

Interstitial boost- 15 Gy of iridium-192 implant was delivered at a rate of 10 Gy per 24 hours (225/2661, 9%).

The choice of boost technique was not prescribed and could be individualized based on experience and on patient and tumour specific parameters.

**Outcomes**

Fibrosis was scored by the oncologist on a 4-point scale (none–minor–moderate–severe). The worst score reported over the follow-up period was used for this report.

Local recurrence by type of tumour boost.

(Data on the boost technique were missing for 22 patients and 26 patients did not receive a boost).

**Follow up**

At the time of this report, the median follow-up was 5.11 years (maximum 10.2 years).

**Results**

In the 2661 patients with a microscopically complete resection randomized to receive a boost, 234 deaths had occurred, of which 175 (74.8%) were due to breast cancer. Local failure rates were estimated using the Kaplan–Meier technique.

Local recurrence was observed in 109/2661 of patients randomized to receive an additional 16 Gy boost after 50 Gy WBI, corresponding to a 5-year actuarial local recurrence rate of 4.3% (95% CI: 3.8–4.7%).

Sites of local recurrence:

48% in the primary tumour bed

9% in the scar

28% outside the original tumour area

14% were diffuse.

The 5 year local failure rates for the 3 boost techniques are shown in the table below. Although fewer events occurred in the interstitial boost group the differences between the 3 techniques were not statistically significant in the boost area.

<b>Outcome</b>	<b>Electrons (n=1635)</b>	<b>Photons (n=753)</b>	<b>Interstitial (n=225)</b>	<b>Overall (N=2661)</b>
5 year local failure rate	n=74 4.7% (95%CI 3.6-5.9)	n=28 4.0% (95%CI 2.4-5.5)	n=6 2.5% (95%CI 0.3-4.6)	n=109 4.3% (95%CI 3.8-4.7)

Since age is the strongest prognostic factor for local control, the effects of different boost techniques were analyzed in four different age groups. No differences were found, and this excluded age as a confounding factor for treatment effects across the boost techniques.

*Fibrosis*

The findings of the grade of fibrosis by type of boost technique in the whole

breast and boost area are shown in the following table:

Type of boost	Unknown (N=48) N (%)	Electrons (N=1635) N (%)	Photons (N=753) N (%)	Interstitial (N=225) N (%)	Total (N=2661) N (%)
<b>Palpable fibrosis in whole breast</b>					
None	14 (29.2)	824 (50.4)	383 (50.9)	118 (52.4)	1339 (50.3)
Minor	12 (25.0)	575 (35.2)	243 (32.3)	78 (34.7)	908 (34.1)
Moderate	2 (4.2)	148 (9.1)	97 (12.9)	14 (6.2)	261 (9.8)
Severe	0 (0)	14 (0.9)	16 (2.1)	2 (0.9)	32 (1.2)
Unknown	20 (41.7)	74 (4.5)	14 (1.9)	13 (5.8)	121 (4.5)
% with fibrosis at 5 years (95% CI)		47.2 (44.5-49.9)	48.2 (44.4-52.1)	39.6 (33.8-46.3)	P=0.013
<b>Palpable fibrosis in boost area</b>					
None	15 (31.3)	533 (32.6)	285 (37.8)	59 (26.2)	892 (33.5)
Minor	5 (10.4)	661 (40.4)	256 (34.0)	91 (40.4)	1013 (38.1)
Moderate	4 (8.3)	320 (19.6)	165 (21.09)	51 (22.7)	540 (20.3)
Severe	0 (0)	46 (2.8)	33 (4.4)	10 (4.4)	89 (3.3)
Unknown	24 (50.0)	75 (4.6)	14 (1.9)	14 (6.2)	127 (4.8)
% with fibrosis at 5 years (95% CI)		65.6 (63.0-68.2)	61.4 (57.6-65.1)	67.2 (60.6-73.9)	P=0.67

There was no significant difference in fibrosis in the boost area at 5 years between boost techniques (p=0.67); there was a significant difference in fibrosis to the whole breast at 5 years between boost techniques (p=0.013).

The occurrence and grades of fibrosis in the whole breast and in the boost area were similar between the 3 boost techniques. Minor fibrosis was more common in both areas (whole breast and boost). A larger proportion of patients developed moderate to severe fibrosis at the site of primary tumour (25%) than in the whole breast (12%).

#### Author conclusions

Although the three groups were unequal in size, the results of the interstitial boost seem similar in terms of fibrosis and at least as good in terms of local control, despite a lower treatment volume and a longer overall treatment time.

#### General comments -

Vrieling C, Collette L, Fourquet A, Hoogenraad WJ, Horiot JC, Jager JJ, et al. Can patient-, treatment- and pathology-related characteristics explain the high local recurrence rate following breast-conserving therapy in young patients? European journal of cancer 2003;39(7):932-44).

Design: RCT (1989-1996 EORTC Trial)

Level 1++

Country: Europe, setting: Multi-centre

Aim: To identify patient, tumour and treatment related factors to explain high local recurrence rates in younger patients.

**Inclusion criteria**

Patients with T1-2, N0-1, and M0 breast cancer were eligible for the EORTC trial.

**Exclusion criteria**

Patients aged more than 70 years, pure carcinoma in situ, multiple tumour foci in more than one quadrant, a history of other malignant disease, Eastern Cooperative Oncology Group performance score greater than 2, residual micro-calcifications on mammography, or gross residual disease in the breast after lumpectomy (unless re-excision had been performed).

**Population** number of patients = 5569

Age ≤ 35 years n=156

Age 36-40 years n=314

Age 41-50 years n=1407

Age 51-60 years n=1885

Age > 60 years n=1807

Median age at treatment 55 years.

Younger women had larger clinical and pathological tumour sizes.

When age groups were classified as ≤ 40 years vs. > 40 years the difference in T1 and T2 tumour sizes was not significant (p=0.08).

Other characteristics classified as ≤ 40 years vs. > 40 years:

Number of positive nodes (N0, N1-3, N>3) p=0.06

ER positive p=0.0001

40% ≤ 40 years were ER+

54% > 40 years were ER+

PR positive p=0.0006

36% ≤ 40 years were PR+

45% > 40 years were ER+

2,657 were allocated to receive no boost

2,661 were allocated to receive a boost of 16 Gy to tumour bed

pN0 = 78%

Post menopausal 62%

T1 = 52%

T2 = 48%

## Interventions

Treatment involved tumourectomy (with a macroscopic tumour-free margin of 1 cm) and axillary dissection, followed by tangential irradiation of the whole breast of 50 Gy, with a dose per fraction of 2 Gy over 5 weeks.

Additional interventions were:

Patients with a microscopically complete excision were randomized to either no further treatment or a boost of 15 or 16 Gy (15 Gy for interstitial and 16 Gy for external beam therapy).

Patients with a microscopically incomplete excision were randomized to either a 10 Gy boost or a 25 or 26 Gy boost (25 Gy for interstitial and 26 Gy for external beam therapy).

The boost dose was delivered by 1 of 3 methods:

- i) Two external photon beams of either cobalt-60 or X-ray, 4-8 MV in the centre of tumour
- ii) One electron beam
- iii) Interstitial therapy with iridium-192 or caesium-137 wires at a dose rate of 50 cGy per hour.

## Outcomes

Local recurrence

Multivariate Cox proportional hazard regression to assess influence of prognostic factors on local control

**Follow up** Median of 5.1 years (maximum 10.2 years)

## Results

### *Local control*

The probability of ipsilateral breast recurrence at 5 years by age group is shown in the following table:

Age group	Actuarial 5 year local control rate (95% CI)
≤ 35 years	82% (75-88%)
36-40 years	85% (80-89%)
41-50 years	92% (91-94%)
51-60 years	96% (95-97%)
> 60 years	97% (96-98%)

Local control increased with age despite the addition of a boost dose ( $p < 0.0001$ ).

### *Tumour characteristics*

Younger patients had more palpable tumours which were clinically and pathologically larger ( $p = 0.001$ ). The authors suggest this may be due to the detection of tumours in women over 50 years by screening.

ER negative status was more common in younger patients ( $p = 0.001$ ).

Multivariate analysis of patient and tumour characteristics found that palpable

tumour size, re-excision, and excision volume were significantly associated with age. Odds ratios are reported in the following table:

Characteristic	Odds Ratio (99% CI)	P value
Palpable tumour size	1.41 (1.18-1.69)	0.0001
Re-excision	1.80 (1.12-2.90)	0.0001
Excision volume	0.70 (0.56-0.87)	0.0001

As well as more palpable tumours younger patients had more frequent re-excisions and smaller total excision volumes.

*Prognostic factor analysis for local control*

Multivariate Cox proportional hazard regression analysis found that age, palpable tumours and progesterone receptor status were significant for local control:

Characteristic	Hazard Ratio (95% CI)	P value
Age	0.59 (0.48-0.71)	0.0001
Tumour palpation	2.14 (1.23-3.72)	0.007
Progesterone receptor	0.66 (0.49-0.87)	0.004

Higher local recurrence rates occurred in younger patients, those with palpable tumours or progesterone negative receptor status.

At higher significance levels only age remained significant: Hazard Ratio = 0.45 (99% CI 0.35-0.59) p= 0.0001.

When a multivariate analysis was conducted on patients with a complete excision to assess the effect of the boost dose on local control, both age and the boost dose were significant. Data are reported in the following table:

Characteristic	Hazard Ratio (99% CI)	P value
Age	0.60 (0.51-0.70)	< 0.0001
Boost dose	0.51 (0.37-0.70)	0.001

**Author conclusions**

This large European Organization for Research and Treatment of Cancer (EORTC) trial demonstrated an increased local recurrence rate in young patients. Although several associations between patient, tumour and treatment factors and age were found, that might explain the high local recurrence rate in the younger patients, it appears that age itself and the boost dose were the only factors that were independently related to local control.

**General comments -**

Romestaing P, Lehingue Y, Carrie C, Coquard R, Montbarbon X, Ardiet JM, et al. Role of a 10-Gy boost in the conservative treatment of early breast cancer: results of a randomized clinical trial in Lyon, France. *Journal of clinical oncology : official journal of the American Society of Clinical Oncology* 1997;15(3):963-8.

Design: RCT (1986-1992)

Level 1+

Country: France, setting: Not clear

Aim: To define the role of a 10-Gy boost to the primary tumour in the conservative treatment of early infiltrating breast carcinoma treated by limited surgery and radiotherapy.

### **Inclusion criteria**

Women with infiltrating ductal carcinoma of the breast (< or = 3 cm in diameter) and free pathological margins. Absence of distant metastases, age < 70 years and no history of cancer (exceptions were basal skin cancer or in situ cervical carcinoma).

**Exclusion criteria** None reported.

**Population** number of patients = 1024

Intervention (boost) n= 521

No boost n= 503

10 patients in the intervention group and 12 in the comparison group did not have free margins.

Patients were randomized and stratified according to tumour stage (T1 or T2) and node status (N0 = 73%; and N1-2 = 27%)

### **Interventions**

Patients were treated by local excision (tumourectomy or quadrantectomy with a margin of 1cm), axillary dissection. Conventional 50-Gy irradiation was given in 20 fractions over 5 weeks with cobalt-60.

Patients were then randomly assigned to receive either no further treatment or a boost of 10 Gy by electrons to the tumour bed.

### **Outcomes**

Local recurrence

Overall survival

DFS

Telangiectasia:

Scored as 0 absent; 1 a few visible areas in tumour bed; 2 covering one quadrant; 3 more than one quadrant.

Cosmesis score from physician and patient reports: 1 excellent; 2 good; 3 fair; 4 poor.

**Follow up** Median follow-up time was 3.3 years by September 1994.

### **Results**

*Local recurrence*

At 5 years:

Probability of local recurrence in boost arm (10/521 patients): 3.6% (95% CI

1.8% to 7.1%)

Probability of local recurrence in no boost arm (20/503 patients): 4.5% (95% CI 2.7% to 7.4%)

Kaplan-Meier estimates for local recurrence favoured the boost arm with a statistically significant reduction in ipsilateral breast recurrence (Log rank test  $P=0.044$ ). DFS at 5 years was also significantly improved in the boost arm ( $p=0.011$ ), however there was no significant difference in overall survival at 5 years between the two groups.

Findings are reported in the following table:

Outcome	Boost N=521	No boost N=503	P value
Time to local recurrence	10 events 5.7 events/ 1000 person years	20 events 12.3 events/ 1000 person years	0.044
Relative Risk for time to local recurrence (Cox model)	0.34 (95% CI 0.12 to 0.95) favours boost		
Time to distant failure	16 events 9.7 events/ 1000 person years	21 events 12.8 events/ 1000 person years	
Disease Free Survival	46 events 25.8 events/ 1000 person years	67 events 41.3 events/ 1000 person years	
Disease Free Survival at 5 years	86% (95% CI 81.0% to 89.8%)	82.2% (95% CI 77.3% to 86.3%)	0.011
Relative Risk for Disease Free Survival	0.63 (95% CI 0.39 to 1.01) Favours boost		
Overall survival	23 events 12.6 events/ 1000 person years	29 events 17. events/ 1000 person years	
Overall Survival at 5 years	92.9% (95% CI 89.0 to 95.5%)	90.4% (95% CI 86.1 to 93.4%)	0.24
Relative Risk for Overall survival	0.49 (95% CI 0.23 to 1.05)		

#### *Telangiectasia*

At 2 years telangiectasia was recorded in 702 patients. None had grade 3 telangiectasia.

5.9% of the no boost group (n=339) and 12.4% of the boost group (n=363) reported grades 1 and 2 telangiectasia which was significant  $p=0.003$ .

#### *Cosmesis*

Physician reports: 85% of patients were considered to have good or excellent

results with no difference between arms, and no poor results. Self assessments of patients at 2 years reported no poor results (n=600), and 90% of patients scored good or excellent results with no significant difference between groups.

**Author conclusions:** Delivery of a boost of 10 Gy to the tumour bed after 50 Gy to the whole breast following limited surgery significantly reduces the risk of early local recurrence, with no serious deterioration in the cosmetic result. Additional follow-up evaluation will be required to assess the long-term results.

**General comments -**

Vrieling C, Collette L, Fourquet A, Hoogenraad WJ, Horiot J-C, Jager JJ, et al. The influence of the boost in breast-conserving therapy on cosmetic outcome in the eortc 'boost versus no boost' trial. *Int J Radiat Oncol Biol Phys* 1999;45(3):677-85.

Design: RCT  
Level 1+ EORTC Trial (1989-1996)

Country: Europe, USA, setting: Multi-centre (31)

Aim: To evaluate the influence of a radiotherapy boost on the cosmetic outcome after 3 years of follow-up in patients treated with breast-conserving therapy (BCT).

#### **Inclusion criteria**

Stage I and II (T1-2, N0-1, M0) invasive breast cancer.

#### **Exclusion criteria**

Age over 70 years; carcinoma *in situ* (CIS) without invasive tumour; residual micro-calcifications on mammogram or gross residual disease in the breast after tumourectomy (unless re-excision had been performed); tumour foci in more than one quadrant; a prior history of malignant disease; or an Eastern Cooperative Oncology Group (ECOG) performance score of greater than 2.

**Population** number of patients = 5569

Panel patients:

No boost N=367

Boost N=364

Others N=4567

Digitizer patients:

No boost N=1580

Boost N=1621

Others N=2099

#### **Interventions**

Treatment involved tumourectomy (with a macroscopic tumour-free margin of 1 cm) and axillary dissection, followed by tangential irradiation of the whole breast of 50 Gy, with a dose per fraction of 2 Gy over 5 weeks.

Additional interventions were:

Patients with a microscopically complete excision were randomized to either no further treatment or a boost of 15 or 16 Gy (15 Gy for interstitial and 16 Gy for external beam therapy).

Patients with a microscopically incomplete excision were randomized to either a 10 Gy boost or a 25 or 26 Gy boost (25 Gy for interstitial and 26 Gy for external beam therapy).

The boost dose was delivered by 1 of 3 methods:

i) Two external photon beams of either cobalt-60 or X-ray, 4-8 MV in the centre of tumour

ii) One electron beam

iii) Interstitial therapy with iridium-192 or caesium-137 wires at a dose rate of 50 cGy per hour.

The volume of the boost was defined as site of primary tumour with a safety margin of 1.5cm after microscopically complete excision, or 3cm after incomplete excision or extensive intraductal component.

Late radiation telangiectasia was avoided by placement of the most superficial needles for interstitial therapy at least 5 mm below the overlying skin surface.

### **Outcomes**

Cosmetic outcome was evaluated only for patients randomized to receive either no boost or a boost of 15 or 16 Gy since the surgical excision was microscopically complete in 95% of patients.

731 patients were assessed both postoperatively and after 3 years of follow-up. These patients were the first evaluable at both time points and not randomly selected.

The cosmetic outcome was evaluated by a panel (of 5 people), scoring 731 photographs of patients taken soon after surgery and after 3 years follow-up, and by digitizer measurements, measuring the displacement of the nipple of 3000 patients postoperatively and of 1141 patients 3 years later.

The treated breast was compared with the untreated breast for 6 items: global cosmetic result; appearance of the surgical scar; breast size; breast shape; nipple position; and shape of areola. A 4-point scale was used to score the results by averaging each score of the 5 reviewers into one of the following categories:

“0” an excellent result;

“1” a good result;

“2” a fair result;

“3” a poor result

The boost and no boost arms of the selected patients of panel and digitizer assessments were compared with the remainder of the patient population.

### **Follow up** Postoperatively and at 3 years

#### **Results**

*Panel results (n=731 from later paper 2000):*

Postoperative:

Overall patients 82% of had an excellent or good global cosmetic result. Sixteen percent scored as fair, and a small proportion had a poor result. Global cosmetic results between the two treatment arms were similar.

Of the 6 cosmetic items evaluated only the appearance of the scar differed significantly between the two arms. Patients in the boost group had a slightly higher score (median 1.0) than the no-boost group (median 0.8;  $p = 0.04$ ).

At 3 year follow-up:

86% of patients in the no-boost group had an excellent or good global result,

compared to 71% in the boost group.

13% of patients in the no-boost group had a fair global result, compared to 26% of the boost group ( $p = 0.0001$ ). These results are shown in the following table:

Global cosmetic outcomes at 3 years

Score	Global cosmetic result	No boost (%)	Boost (%)
0	Excellent	41.7	32.7
1	Good	43.0	38.2
2	Fair	13.1	25.8
3	Poor	1.3	3.3

All the cosmetic items scored significantly worse in the boost group than the no-boost group ( $p < 0.001$ ). More patients in the boost group had a fair outcome than in the no boost group. The latter group also had a higher proportion of excellent outcomes. Few patients had a poor result in either arm (0-1.6% in the no boost group; 0.6- 3.3% in the boost group).

There was a trend over time favouring the no boost group for better global scores and breast shape scores after 3 years:

Global cosmetic scores

No boost arm	21% worsened (score 0 after surgery); 11% worsened after 3 years (score 1 after surgery)
	50% improved (score 2 after surgery)
Boost arm	35% worsened (score 0 after surgery) 25% worsened after 3 years (score 1 after surgery)
	29% improved (score 1 after surgery)

Global score changes over time for breast size, breast shape, nipple position, and shape of areola were significant in the boost arm ( $p < 0.001$ ) only.

Scar score was the only item that changed significantly over time in both treatment arms ( $p < 0.0001$ ) with an overall improvement. However the trend favoured the no-boost arm where 45% of patients had an improved scar score after 3 years, compared to 34% in the boost arm.

*Digitizer results (n=1141):*

The mean pBRA (Breast Retraction Assessment) at 3 years in the no-boost group was 7.55 pBRA (95% CI, 7.11-8.02), compared with 8.26 pBRA (95% CI, 7.79-8.75) in the boost group. The difference in mean pBRA after 3 years between treatment arms was small (less than 1 pBRA); and of borderline statistical significance.

The median change in pBRA over 3 years was 0.3 (range -12.8 to +31.0); a large

proportion of patients (80%) had a change in score ranging from 26.2 to 17.0 pBRA. The change in pBRA over time in the no-boost group was not significant (mean pBRA of 7.5 postoperatively and 7.6 at 3-years,  $p = 0.94$ ). There was an increase in mean pBRA of 0.6 in the boost group which suggested an increase in nipple position asymmetry (pBRA 7.7 postoperatively and 8.3 at 3 years) of borderline statistical significance ( $p=0.05$ ).

### **Author conclusions**

These results showed that a boost dose of 16 Gy had a negative, but limited, impact on the cosmetic outcome after 3 years.

### **General comments –**

Some of the numbers (N and n values) reported in this paper were not very clear or fully explained. Patient characteristics were similar across arms at commencement of the interventions. More patients had digitizer measurements than a panel assessment, possibly because of the time involved in panel assessments. At the 3 year assessment only approximately one third of patients' data were reported for digitizer assessments (pBRA). The panel assessments were displayed as graphs with % values, no numerators or denominators were provided for % values cited in the text. The number of patients included in the table of cosmetic results at 3 years by panel assessment was also not provided.

A further analysis of this data was conducted by the authors and published in 2000. Analyses included ANOVA and reporting of Odds Ratios for cosmesis factors:

**Vrieling C, Collette L, Fourquet A, Hoogenraad WJ, Horiot J-C, Jager JJ, et al. The influence of patient, tumor and treatment factors on the cosmetic results after breast-conserving therapy in the EORTC 'boost vs. no boost' trial. *Radiotherapy & Oncology* 2000;55(3):219-32.**

Aim: To analyze the influence of different patient, tumour, and treatment parameters on the cosmetic outcome after breast-conserving therapy at 3-year follow-up.

The patient population and interventions were the same as the 1999 paper. Univariate and multivariate analyses were used to evaluate the correlation between various patient, tumour, and treatment factors and cosmesis.

### **Results**

#### *Panel analysis*

At 3 years the cosmetic outcomes were reported as:

<b>Cosmetic result</b>	<b>No boost</b>	<b>Boost</b>
Excellent	42%	33%
Good	44%	38%
Fair	13%	26%
Poor	1%	3%

On univariate analysis factors which had a significant negative impact on four or more of the six cosmetic items (global score, surgical scar, breast size, breast shape, nipple position, shape of areola) were inferior tumour location, increased pathological tumour size, increased excision volume, breast complications and boost treatment. On multivariate analysis inferior tumour location, increased excision volume, breast complications and boost treatment were significant.

The final multivariate model for the appearance of the surgical scar, breast size, breast shape and shape of areola were very similar. The final model for nipple position differed, since this was not influenced by tumour location and boost treatment.

#### *Digitizer analysis*

A univariate analysis found that tumour size, tumour location, volume of excision, maximum dose to central/superior tumour, maximum dose of boost fraction, boost treatment, and tamoxifen treatment were significant factors associated with an increased pBRA at 3 years, and poorer cosmetic outcome.

A multivariate analysis showed that tumour location (central/superior), a large excision volume, increasing pathological tumour size and high maximum dose in the central plane were associated with an increased pBRA at 3 years, and poorer cosmetic outcome.

The prognostic factor analyses by both methods showed that a large excision volume, a boost dose, increased dose inhomogeneity, and the presence of postoperative breast complications had a large negative effect on cosmesis.

**Author conclusions:** To achieve a good cosmesis, it is necessary to excise the tumour with a limited margin, to avoid postoperative complications, to assess the need for a boost in the individual patient, and to give the radiation dose as homogeneously as possible. As far as the method of evaluation is concerned, the panel evaluation is the most appropriate method for giving an overall impression of the cosmetic result after breast-conserving therapy (BCT). The use of the digitizer is recommended for comparing the cosmetic outcome of two different approaches to BCT or for analyzing cosmetic changes over time.

## Non-randomized studies

Polgar C, Major T, Fodor J, Nemeth G, Orosz Z, Sulyok Z, et al. High-dose-rate brachytherapy alone versus whole breast radiotherapy with or without tumor bed boost after breast-conserving surgery: seven-year results of a comparative study. *Int J Radiat Oncol Biol Phys* 2004 Nov 15;60(4):1173-81.

Design: Prospective non-randomized study (1996-1998)  
Level 3

Country: Hungary Setting: Single Oncology Institute.

Aim: To report 7-year results of a prospective study of accelerated partial breast irradiation (APBI) using interstitial high-dose-rate brachytherapy and compare the treatment results with standard, whole breast radiotherapy (WBRT), with or without a tumour bed boost (TBB).

### Inclusion criteria

Patients with T1N0-N1mi (single nodal micro-metastasis), tumour size  $\leq$  20mm, histological grade 2 or less; non-lobular breast cancer without the presence of an extensive intraductal component and with microscopically negative surgical margins.

### Exclusion criteria

Pure ductal or lobular carcinoma in situ; invasive lobular carcinoma; extensive intraductal component (EIC).

**Population** number of patients = 125

N=45 selected patients receiving APBI

(n=35 (78%) had axillary dissection)

N=80 were treated with 50 Gy WBRT with (n = 36) or without (n = 44) a 10-16-Gy TBB. These patients were selected from a group of 621, only those meeting the APBI criteria were included.

### Interventions

1) APBI used interstitial high-dose-rate (HDR) implants (Iridium-192) to the tumour bed after wide excision of primary tumour. A total dose of 30.3 Gy (n = 8) and 36.4 Gy (n = 37) in 7 fractions within 4 days was delivered to the tumour bed plus a 1-2-cm margin.

16% (7/45) also had adjuvant chemotherapy or hormonal therapy.

2) Conventional WBRT of tangential cobalt or 6-9MV photon fields, median dose 50 Gy (46-52Gy) after wide excision of primary tumour (n=44).

36/80 also received a tumour bed boost (TBB) of 10-16Gy of electrons (n=31) or 3 x 4.75Gy HDR-BT (n=5).

16% (13/80) also had adjuvant chemotherapy or hormonal therapy.

### Outcomes

Cosmesis (Harvard criteria)

Local recurrence- any detection of cancer in the treated breast, proven histologically.

Relapse-free survival.

Cancer-specific survival.

Elsewhere breast failure (EBF) - defined as ipsilateral LR detected at least 2 cm from the surgical clips. All other LR was classified as true recurrence/marginal miss (TR/MM).

Late side effects

**Follow up** 81 months (range 66-96) for APBI, 83 months (range 52-96) for WBRT and Boost group.

**Results**

*Breast cancer events*

The crude incidence of breast cancer related events using data from the paper are shown in the following Table:

Event	APBI n(%) (n=45)	WBRT n(%) (n=44)	WBRT + TBB n(%) (n=36)
Local recurrence	3 (6.7)	5 (11.4)	3 (8.3)
TR/MM	0 (0)	1 (2.3)	2 (5.6)
EBF	3 (6.7)	4 (9.1)	1 (2.8)
Any first relapse	8 (17.8)	11 (25.0)	7 (19.4)
Breast cancer death	3 (6.7)	4 (9.1)	2 (5.6)
Contralateral breast cancer	0 (0)	2 (4.5)	1 (2.8)

A larger proportion of patients in both WBRT groups experienced an ipsilateral local recurrence than in the APBI group. Kaplan-Meier 5 and 7 year estimates for local recurrence were not statistically significantly different between the three groups.

No statistically significant differences were found in either the 7-year probability of relapse-free survival or cancer-specific survival. The 7-year actuarial elsewhere breast failure rate was 9.0% in the APBI group and 8.3% in the WBRT +/- TBB group (p = 0.80).

Kaplan Meier estimate	APBI	WBRT	WBRT + TBB
Local recurrence 5 year actuarial rate	4.4%	4.7%	5.7%
Local recurrence 7 year actuarial rate	9.0%	14.8%	9.5%
P values for local recurrence between groups	APBI/WBRT P=0.57	WBRT/ WBRT+TBB P=0.72	APBI/WBRT +TBB P=0.78

7 year relapse-free survival	79.8%	73.5%	77.7%
Cancer-specific survival	93.3%	92.9%	93.9%

*Cosmetic outcomes* (Refer to table below)

Most cosmetic results were rated as excellent/good for all 3 radiation techniques, however, APBI had the highest proportion (84.4%) of excellent/good results. The differences were statistically significant ( $p=0.04$ ) between APBI and (WBRT/WBRT+TBB). Telangiectasia was significantly increased in the WBRT+TBB group compared to the other two groups. Findings for fibrosis and fat necrosis are reported in the following table, the differences between groups were not significant.

Outcome	APBI (n=45) n (%)	WBRT (n=35) n (%)	WBRT + TBB (n=28) n (%)
Cosmetic results	38 (84.4)	25 (71.4)	18 (64.3)
Excellent/good	7 (15.6)	10 (28.6)	10 (35.7)
Fair/poor			
Grade 2-3 telangiectasia	4.4% (2) APBI vs. WBRT $p=0.38$ APBI vs. WBRT + TBB $p=0.01$	8.6% (3)	25.0% (7)
Grade 2-3 fibrosis	20.0% (9) APBI vs. WBRT $p=0.06$ APBI vs. WBRT + TBB $p=0.68$	5.7% (2)	21.4% (6)
Fat necrosis	22.2% (10) APBI vs. WBRT +/- TBB $p=0.57$	17.1% (6)	25.0% (7)

**Author conclusions**

Accelerated partial breast irradiation using interstitial high-dose-rate implants, with proper patient selection and quality assurance, yields similar 7-year results to those achieved with standard breast-conserving therapy. APBI does not increase the risk of elsewhere breast failures.

Neuschatz AC, DiPetrillo T, Safaii H, Price LL, Schmidt-Ullrich RK, Wazer DE. Long-term follow-up of a prospective policy of margin-directed radiation dose escalation in breast-conserving therapy. *Cancer* 2003 Jan 1;97(1):30-9.

Design: Prospective cohort (1982-1994)

Level 2-

Country: USA, setting:

Aim: Long-term follow-up of a breast conserving therapy (BCT) treatment policy using margin assessment as the exclusive guide to the intensity of radiation therapy directed at the tumour bed.

### **Inclusion criteria**

Tumours of histopathological subtypes: invasive ductal (IDC), invasive ductal with associated extensive intraductal component (EIC – includes EIC and DCIS with microinvasion), invasive lobular (ILC).

All tumour excisions performed for complete tumour removal with a normal tissue margin of greater than 5 mm. Final margin status (FMS) categories were defined as greater than 5 mm, greater than 2-5 mm, greater than 0-2 mm, and positive. For margins less than or equal to 2 mm or indeterminate, re-excisions were performed if feasible.

**Exclusion criteria** None reported

**Population** number of patients = 498 women with 509 Stage I/II breast cancer

Median age 56 years (range 25-86).

### **Interventions**

All patients received whole breast irradiation to 50.0-50.4 Gy through parallel opposed tangential portals to the whole ipsilateral breast. Until 1983 whole breast treatment was delivered with a Cobalt-60 unit, and a 6-MV linear accelerator post 1983.

Final tumour bed boosts as a function of FMS were as follows:

No residual on re-excision, no boost performed;

FMS greater than 5 mm, electron boost of 10 Gy;

FMS greater than 2-5 mm, electron boost of 14 Gy;

FMS greater than 0-2 mm or positive, boost of 20 Gy with appositional electrons or Iridium-192 implant.

Cases were analyzed for local failure related to histology, age, tumour size, excision volume, re-excision, and total dose.

Additional interventions were systemic adjuvant chemotherapy for patients at risk of systemic micro-metastases. Postmenopausal women with tumours  $\geq 20$ mm and/or lymph node positivity who also had hormonally responsive tumours were prescribed tamoxifen.

### **Outcomes**

Local failure:

Classified as central -recurrence within the excision bed; peripheral-recurrence within 3 cm of the excision bed; and remote- recurrence greater

than 3 cm from the tumour bed in the ipsilateral breast. All ipsilateral breast tumour recurrences were considered local failures. Patients were censored at last follow-up or at time of death.

Survival:

Kaplan-Meier analyses of local failure stratified by FMS and age.

**Follow up** Median follow-up 121 months.

All patients examined for tumour control at 3-6 month intervals after completion of therapy.

**Results**

The extent of surgical excisions performed varied, with a mean total excisional volume of 117 cm<sup>3</sup> (range, 1–863 cm<sup>3</sup>) and a median of 79 cm<sup>3</sup>. Re-excision was performed in 55.6%; chemotherapy, tamoxifen, and implant boost were administered in a quarter of cases (24.4%, 26.3%, and 25.5%, respectively). Mean dose was 62.4 Gy.

*Final Margin Status*

FMS was strictly observed with 98.4% full compliance.

The main histological subtype was IDC (53.6%), 38.9% were EIC (including 11.6% DCIS with microinvasion), 7.3% were ILC, and less than 1% were unclassified. Stratification by margin status is shown in the table below.

*Local Failure*

Of the 509 cases 36 were ipsilateral breast carcinoma recurrences with an overall unadjusted local failure rate of 7.1%.

*Stratification by FMS* is shown in the table below with 12 year Kaplan-Meier failure rates (log-rank p = 0.009) (NRT no boost arm):

	<b>FMS positive</b>	<b>&gt;0-2mm</b>	<b>&gt; 2-5mm</b>	<b>&gt; 5mm</b>	<b>No Residual Tumour on re-excision (NRT)</b>
<b>FMS status</b>	21%	20%	17%	14%	28%
<b>K-M local failure (12yr)</b>	17%	9%	5%	0%	6%

When all cases with FMS >2mm or NRT were combined a 12 year Kaplan-Meier local failure rate of 4.6% (Log-Rank P=0.003) was obtained when compared with FMS +ve and greater than 0-2mm (see table below):

<b>FMS</b>	<b>FMS</b>	<b>FMS</b>	<b>Log Rank P value</b>
Positive	> 0 ≤ 2mm	> 2mm or NRT	0.003
Positive	> 0 mm		0.002
≤ 2mm	> 2 mm		0.003

### *Stratification by age*

When stratified by age Kaplan–Meier survival estimates for patients 45 years or younger showed a 12-year local failure rate of 14.5%, compared with 6.4% for patients older than 45 years of age at diagnosis (Log-Rank P = 0.01).

A comparison of 12-year Kaplan–Meier local failure rates by age and FMS showed lower failure rates among the older age group irrespective of margin status (see table below):

<b>Age</b>	<b>FMS +ve</b>	<b>&gt; 0-2mm</b>	<b>&gt; 2.5mm</b>	<b>&gt; 5mm</b>	<b>NRT</b>
< 45 years	25%	19%	7%	0%	5%
> 45 years	14%	5%	5%	0%	3%

A Cox proportional hazards regression model for local failure found that age, FMS and late presence of EIC were significant predictors of local failure by univariate analysis.

On multivariate analysis increased local failure was predicted by young age ( $p=0.03$ ) and FMS  $\leq 2$ mm or positive predicted late recurrence ( $> 5$  years), but not early ( $\leq 5$  years) recurrence ( $p=0.003$ ).

**Author conclusions:** Graded tumour bed dose escalation in response to FMS results in very low rates of local failure over the first 5 years for all FMS categories. However, tumours with close/positive margins have significantly increased local failure rates after 5 years of follow-up even with increased radiation boost dose. In addition, graded tumour bed dose escalation does not fully overcome the adverse influence of young age.

**General comments -**

Palazzi M, Tomatis S, Valli MC, Guzzetti R, Tonoli S, Bertoni F, et al. Impact of radiotherapy technique on the outcome of early breast cancer treated with conservative surgery: A multicenter observational study on 1,176 patients. *Int J Radiat Oncol Biol Phys* 2006 Aug 1;65(5):1361-7.

Design: Prospective cohort (1997)  
Level 2+

Country: Italy, setting: Multi-centre

Aim: To quantify the impact of radiotherapy technique on cosmetic outcome and on 5-year local control rate of early breast cancer treated with conservative surgery and adjuvant radiation.

**Inclusion criteria**

Patients with no previous treatment for breast cancer; disease limited to one breast (with or without ipsilateral axillary involvement); surgery either tumourectomy/lumpectomy or quadrantectomy, with or without axillary dissection; invasive carcinoma by pathological examination; pT-stage either T1 or T2.

(Selection biases were avoided by including patients in the database that were automatically selected on a sequential basis from the general waiting list (i.e., an average of 1 in 4 cases were assigned by secretarial staff to the single radiation oncologist participating to the study).

**Exclusion criteria**

No patient exclusions were allowed after verification of eligibility criteria.

**Population** number of patients = 1176

Age 25-50 years, 32%; 51-65 years, 44%, 66-80 years, 24%

Menopausal status: Pre 31%; Post 69%

Histological type: Invasive ductal 76%; invasive lobular 11%; other invasive 13%.

pT stage: T1a, 3%; T1b, 21%; T1c, 54%; T2, 19%

pN stage: N0, 71%; N+ (1-3 positive nodes), 21%; N+ (>3), 8%

**Interventions**

A wide range of radiotherapy techniques were used by participating centres and this was acknowledged in the report.

Treatment characteristics of study population for radiotherapy are described below:

Radiation treatment:

Use of immobilization device Yes, 17%;  
no, 83%

Treatment planning Fluoroscopic simulation, 8%; external profile-based, 20%;

CT-based, 72%

Treatment unit Telecobalt, 37%; 4-6 MV linear  
accelerator, 63%

Treatment technique	Isocentric, 71%;	nonisocentric, 29%	
Irradiation of any nodal region	Yes, 10%;	no, 90%	
Use of wedge filters	Yes, 64%;	no, 36%	
Use of portal verification	Yes, 55%;	no, 45%	
Dose to the whole breast	<50 Gy, 7%;	50 Gy, 85%;	>50 Gy, 8%
Boost dose	0 Gy (no boost), 40%;	5–18 Gy, 60%	
Total dose to tumour bed	<50 Gy, 3%;	50 Gy, 31%;	>50 Gy, 66%

Surgical procedure was quadrantectomy in 97% of patients, with axillary dissection performed in 96%.

A boost dose to the tumour bed was delivered in 60% of cases.

### Outcomes

Cosmesis – evaluated by the radiation oncologist using a 4 point scale (no, mild, intermediate or severe damage) for each of seven items.

Patients assigned a subjective 4 grade score (excellent, good, fair, poor) to the overall cosmetic outcome.

In the analysis of cosmetic outcome the last score recorded for each patient was used.

Disease-free, overall, and disease-specific survival curves were calculated using the Kaplan-Meier method, starting from the first day of radiotherapy.

Definitions:

Disease-free survival curves, all relapses and death from any cause were considered as events.

Local failure was defined as the pathologically confirmed evidence of a carcinoma of the same histological type of the original in the treated breast.

Regional failure was defined as a recurrence in the axillary, supraclavicular, or internal mammary regions.

All other recurrences were considered as distant relapses.

### Follow up

Median follow-up of surviving patients was 6.8 years (range 0.2– 8.2 years) for this analysis (September 2005). Median follow-up time for cosmetic evaluation was 4.55 years.

### Results

Univariate (log-rank test) and multivariate (backward stepwise Cox proportional hazards regression model) analyses were performed.

#### *Survival (5 year rates)*

5-year disease-free survival rate	89%
Overall survival rate	95%
Disease-specific survival rate	96%

#### *Failure rates (at 5 years)*

Local control rate	98%
Regional control rate	99%

Distant control rate

92%

On univariate analysis of the 8 radiation treatment characteristics assessed, only use of portal verification was significantly associated with improved local control ( $p=0.04$ ). The use of a boost dose was not significant after quadrantectomy and 50 Gy to the whole breast in this cohort.

On multivariate analysis older age and medical adjuvant treatment were the strongest predictors of local control. Portal verification also remained significant. A lower N-stage, medical adjuvant treatment, lower T-stage, and lower histological grading were predictors of disease free survival.

Data are shown in the following table:

Variable	Hazard ratio (95% CI)	P value
<b>Local control</b>		
Age	0.95 (0.92-0.98)	0.001
Adjuvant therapy	0.50 (0.33-0.77)	0.002
Portal verification	0.33 (0.11-0.96)	0.05
<b>Disease-free survival</b>		
pN-stage	2.09 (1.58-2.75)	<0.001
pT-stage	1.48 (1.13-1.94)	0.005
Grade	1.44 (1.08-1.93)	0.013
Adjuvant therapy	0.69 (0.55-0.85)	0.001

#### *Cosmetic outcomes*

.Overall patients subjective cosmetic outcomes were scored during follow-up as:

Excellent	33%
Good	47%
Fair	17%
Poor	3%

These scores were similar to pre-radiotherapy scores. Cosmetic failure rate increased from 18% before radiation to 20% during follow-up, suggesting that radiation did not worsen the cosmetic outcome after surgery.

Further data were reported in the following table:

Outcome	Excellent (%)	Good (%)	Fair (%)	Poor (%)
<b>Patients' subjective score</b>				
Baseline (n=1079)	29	53	17	1
Follow-up (n=944)	33	47	17	3

<b>Fibrosis</b>				
Baseline (n=1079)	62	32	6	0.2
Follow-up (n=924)	72	24	4	0.3
<b>Telangectasia</b>				
Baseline (n=1079)	97	2	0.3	0
Follow-up (n=926)	93	5	2	0.3
<b>Breast oedema</b>				
Baseline (n=1079)	61	30	8	0.4
Follow-up (n=927)	93	5	1.4	0
<b>Skin pigmentation</b>				
Baseline (n=1079)	93	6	1	0.2
Follow-up (n=926)	86	13	1	0.1

The incidence of cosmetic failure (fair to poor) was small at a median of 4.5 years follow-up.

**Author conclusions:** Radiation technical factors impacted negatively on cosmetic outcome, but had relatively small effects on local control compared with other clinical factors

**General comments -**

Perez CA. Conservation therapy in T1-T2 breast cancer: past, current issues, and future challenges and opportunities. Cancer Journal 2003 Nov;9(6):442-53.

Design: Large cohort long-term (1970-1997)      Retrospective review      Level 2-  
Country: USA, setting:

Aim: To assess the significance of patient age, race, tumour-related prognostic parameters, status of surgical excision margins, and irradiation boost on incidence of ipsilateral breast relapse, and to review current issues in the management of T1-T2 breast cancer patients with conservation therapy.

**Inclusion criteria** Records of 1037 patients with histologically confirmed stage T1 and 308 patients with T2 carcinoma of the breast treated with breast conservation therapy.

**Exclusion criteria** None specified.

**Population** number of patients = 1347

Histologically confirmed:

T1 n=1037

T2 n=308

Pathologically positive axillary lymph nodes:

T1 n=117 (11.2%)

T2 n=113 (37%)

Classification of tumours:

	Ductal	Lobular	Other histology
T1	866	64	109
T2	250	28	30

### Interventions

Wide local excision of tumour with a minimum 1 cm margin of normal tissue and irradiation to the breast.

Wide excision was performed in 412 of T1 and 123 of T2 tumours.

Quadrantectomy was performed in 77 of T1 and 31 of T2 tumours.

Axillary dissection was performed in 902 (87%) of T1 and 260 (84%) of T2 tumours.

100 patients also had irradiation to lymphatics.

Re-excision was performed in 550 (53%) of T1 patients and 154 (50%) of T2 tumours.

RT was performed using tangential fields with either Cobalt-60 or 4 or 6 MV photons with a dose of 48-50 Gy over 5 weeks.

### RT Boost:

RT boost was performed in 856 (83%) of T1 and 241 (78%) of T2 patients and delivered using 9 to 16 MeV electrons. An interstitial implant of Iridium-192 was delivered to 93 (9%) of T1 and 41 (13%) of T2 patients.

Boost doses (2Gy fractions with electrons or 10Gy/day with interstitial brachytherapy) were:

10Gy in patients with negative margins

14-16 Gy for final close margins (<3mm)

18-20 Gy for positive margins

90 (T1) and 28 (T2) patients did not receive any boost dose, usually because surgical margins were negative, and also radiation oncologist preference.

## Outcomes

Local relapse

## Follow up

The median follow-up for surviving patients was 6.6 years (range 4-30 years), with a minimum follow up of 4 years for all patients. Follow-up was complete in 99.6% of patients.

## Results

### Local relapse

There were 78 ipsilateral breast relapses (IBRs), the actuarial 10-year incidence of IBR was 7% for T1 and 11% for T2 tumours.

The overall incidence of IBR in patients with T1 tumours aged  $\leq 40$  years was 9.6% (10/104).

For women aged  $> 40$  years the overall incidence of IBR was 4.4% (41/935) ( $p=0.03$ ).

The incidence of IBR in patients with T2 tumours was 15.5% (9/58) in those aged  $\leq 40$  years, and 7.1% (18/252) aged  $> 40$  years.

Actuarial breast relapse rates were 7% for T1 tumours and 11% for T2 tumours over 10 years.

### IBR and surgical margin status

Incidence of IBR by age and margin status is shown in the following table:

Incidence of IBR by age and surgical margin status		
	Stage T1	
Margin status	Age $\leq 40$ years	Age $> 40$ years
Negative	6/65 (9%)	19/562 (3%)
Close ( $\leq 3$ mm)	2/14 (14%)	3/130 (2%)
Positive	1/8 (12%)	2/139 (2%)
Unspecified	1/17 (6%)	17/174 (10%)
Total ( $P=0.03$ )	10/104 (9.6%)	41/935 (4.4%)
	Stage T2	
Negative	4/31 (13%)	9/129 (7%)
Close ( $\leq 3$ mm)	3/6 (50%)	3/25 (9%)
Positive	0/8	4/40 (10%)
Unspecified	2/16 (12%)	2/48 (4%)
Total ( $P=0.04$ )	9/58 (15.5%)	18/252 (7.1%)

A small increase in breast relapse for patients aged  $\leq 40$  years with close or positive margins for stage T1 tumour types, was found (9% negative; 12-14% positive or close margins). The overall difference for stage T1 tumours between age groups was statistically significant ( $p=0.03$ ).

The increase in breast relapse was larger for stage T2 tumour groups with close margins in women  $\leq 40$  years (13% negative; 50% close margins), with a small increase in older women. The overall difference for stage T2 tumours between age groups was statistically significant ( $p=0.04$ ).

It should be noted that some of the subgroups for T1 and T2 tumours were very small in the

younger age group, and that no confidence intervals were reported.

*IBR and extensive intraductal component (EIC)*

There was a large increase of breast relapse for women  $\leq 40$  years with stage T1 and T2 tumours and EIC. The differences in breast relapse for T1 tumours were statistically significant between age groups, but not for stage T2 tumours.(Table below):

<b>Breast relapse and EIC</b>				
	<b>Stage T1</b>		<b>Stage T2</b>	
<b>EIC</b>	<b>Age <math>\leq 40</math> years</b>	<b>Age &gt; years</b>	<b>Age <math>\leq 40</math> years</b>	<b>Age &gt; years</b>
Yes	4/24 (17%)	8/159 (5%)	2/8 (25%)	5/48 (10%)
No	6/80 (8%)	33/776 (4%)	7/50 (14%)	13/202 (6%)
	P=0.03		P=0.07	

*Boost irradiation*

There was no significant difference in breast relapse rates between patients treated with a boost of either electrons or interstitial brachytherapy.

*T1 tumours*

For patients with T1 lesions and negative margins the boost dose did not affect the relapse rate over a 10 year period (Boost n=66, no boost n=599; P=0.95).

In contrast for patients with either close or positive margins the breast relapse rate was 10% with no boost and 2% with a boost dose of 16Gy over the same period (Boost n= 215, no boost n=6; P=0.04).

(Please note data presented graphically, and the raw data cannot be derived from these).

*T2 tumours*

For T2 tumours a subgroup of 16 patients with negative margins did not receive a boost, the relapse rate was 12% appearing earlier than those with a boost dose. The difference over 10 years was not significant (No boost n=16, boost n=143; P=0.48).

For T2 tumours and close or positive margins, 5 patients had no boost, two of these relapsed (40%). This compares with a 15% relapse rate in patients receiving a boost dose (No boost n=5; boost n= 81). The difference was significant (p=0.01) although the sample sizes compared were small.

**Author conclusions**

Surgical excision margins status following adequate doses of radiation therapy was not a predictor of ipsilateral breast relapse. In patients younger than 40 years of age with extensive intraductal component, a somewhat higher breast relapse rate was noted but not enough to preclude breast conservation therapy. A boost of irradiation did not have a significant impact in the incidence of ipsilateral breast relapse in patients with negative margins, but it was of benefit to those with close or positive margins. Close attention to surgical margin status and delivery of higher doses of irradiation to the tumour excision site in patients with close or positive surgical margins will decrease the probability of breast relapses.

**General comments –**

Although this study appears to be large, following a cohort of more than 1000 patients, some of the subgroups used in the analysis were very small, and this should be considered when interpreting the findings. Univariate analyses were conducted, when multivariate may have been more appropriate, also no confidence intervals were provided for any of the data.

## Guidelines

This guideline was also included in the related topic 23a.

Whelan T, Olivotto I, Levine M, Health Canada 's Steering Committee on Clinical Practice Guidelines for the Care and Treatment of Breast Cancer. (2003) Clinical practice guidelines for the care and treatment of breast cancer: breast radiotherapy after breast-conserving surgery (summary of the 2003 update). *CMAJ Canadian Medical Association Journal* **168**, 437-439.

Design: Guideline

(1966-2001)

Level 4

Country: Canada, setting:

**Inclusion criteria** A literature search was conducted using MEDLINE from 1966 to October 2001 and CANCERLIT from 1983 to September 2001 for a systematic review of English Language articles. A nonsystematic review of the literature was continued to April 2002.

**Exclusion criteria** Non-English language articles

### Population

**Interventions** Breast radiotherapy after BCS

### Outcomes

Local control, survival, quality of life, adverse effects of irradiation and cosmetic results.

### Recommendations:

These are listed fully in the Evidence table for topic 23a. The most relevant recommendations for this topic are listed below:

- Additional irradiation to the lumpectomy site (boost irradiation) reduces local recurrence but can be associated with worse cosmesis compared with no boost. A boost following breast irradiation may be considered in women at high risk of local recurrence.
- Physicians should adhere to standard treatment regimens to minimize the adverse effects of breast irradiation.
- When choices are being made between different treatment options, patients must be made aware of the acute and late complications that can result from radiation therapy.

An update search identified a cohort study of the risk of myocardial infarction after radiotherapy (Paszat *et al* 2007) which is relevant to this topic and to the topic of radiotherapy after breast conserving surgery.

Paszat LF, Vallis KA, Benk VM, Groome PA, Mackillop WJ, Wielgosz A. A population-based case-cohort study of the risk of myocardial infarction following radiation therapy for breast cancer. *Radiotherapy and oncology : journal of the European Society for Therapeutic Radiology and Oncology* 2007;82(3):294-300.

Design: NRS Restrospective cohort (1982-1988) Level 2+  
 Country: Canada, setting: Provincial Cancer Registry  
 Aim: To describe the risk of Acute Myocardial Infarction (AMI) after radiation therapy (RT) in a population of women with breast cancer.

**Inclusion criteria**

Women receiving post-operative RT within 12 months of diagnosis  
 Records containing a diagnosis code for ischaemic heart disease (including AMI) from this group of women  
 Only AMI cases meeting MONICA criteria were classified as validated AMI (vAMI)  
 AMI cases with cause of death as AMI who did not die in hospital, or any episode of hospital care associated with ischaemic heart disease after RT and date of death were classified as dAMI

**Exclusion criteria**

Right sided data from women with bilateral disease  
 Data from subsequent episodes of ipsilateral or contralateral breast cancer

**Population** n=6680 records

Identification of all exposed AMI cases classified as:

vAMI n= 121

dAMI n= 92

A random sample from the exposed population as a sub-cohort n=619

vAMI n= 9/619

dAMI n= 8/619

**Interventions**

Post-operative RT within 12 months of diagnosis  
 There was a large variation in radiation exposure:  
 Photon energy cobalt-60 to 6MV  
 Dose to breast or chest wall 40-50 Gy  
 Daily fractions 2.0 -2.67 Gy

50% received anterior boost after WBRT – exceptions were those receiving post-mastectomy chest wall irradiation.

Variations were found in the magnitude of boost dose and volume of target area:

Boost dose 5 – 20 Gy

Daily fractions 2.0 – 3.0 Gy

Anterior boost field volume 25 – 144 cm<sup>2</sup>

**Outcomes**

Risk factors for AMI following radiotherapy (only results of multivariate analysis included)  
 vAMI and dAMI were mutually exclusive categories.

**Follow up** Minimum of 13.5 years from date of last RT treatment

**Results**

Multivariate case-cohort Cox modelling was performed and the results are shown in the following table:

*Adjusted case-cohort model of time to dAMI*

Variable	Adj vAMI <60 yr HR (95% CI)	Adj vAMI ≥60 yr HR (95% CI)	Adj vAMI HR (95% CI)	Adj dAMI HR (95% CI)
Age at RT	NA	NA	2.32 (1.51-3.58)	7.11 (3.51-14.42)
Smoking history before RT	2.38 (1.21-4.70)	1.54 (0.85-2.78)	1.71 (1.11-2.64)	0.77 (0.41-1.44)
MI history before RT	4.01 (1.26-12.77)	1.67 (0.74-3.78)	2.01 (1.03-3.90)	1.68 (0.82-3.43)

Left breast	0.86 (0.44-1.68)	1.96 (1.09-3.54)	1.42 (0.92-2.17)	1.07 (0.65-1.72)
Daily dose >2.5Gy	0.48 (0.10-2.35)	1.18 (0.55-2.51)	0.97 (0.50-1.90)	1.37 (0.73-2.56)

*Effect of age*

Only univariate data were available for the effect of age on death by AMI because few events occurred in women < 60 years.

Smoking history and MI history increased the risk of vAMI in both age groups. There was a higher risk of vAMI in women ≥ 60 years with left breast irradiation and a daily dose ≥ 2.5 Gy.

*Risk of dAMI or vAMI - all factors*

Smoking history, MI history and left breast irradiation increased the risk of dAMI and vAMI in all age groups. The risk of dAMI was greater with a daily dose ≥ 2.5 Gy than that for vAMI (not significant from confidence intervals).

*Effect of age and anterior boost field on dAMI and vAMI*

The variation in area of the anterior boost field was associated with an increase in vAMI and dAMI in women receiving left-sided RT compared with right-sided RT.

Adjusted HR of time to vAMI from multivariate analysis were:

Age ≥ 60 years HR = 2.65 (95% CI 1.21 – 5.83)

Boost area HR = 1.02 (95% CI 1.00 – 1.03)

Adjusted HR of time to dAMI from multivariate analysis were:

Age ≥ 60 years HR = 1.01 (95% CI 1.01 – 1.03)

Boost area HR = 1.02 (95% CI 1.02 – 1.03)

Risk factors for AMI (increasing age, smoking history, previous MI history) were strongly associated with time to vAMI and time to dAMI. However, anatomic factors such as RT to the left breast and the volume of the boost area are associated with an added risk of AMI.

**Author conclusions**

The risks of vAMI and dAMI following RT for BrCa are related to anatomic sites of RT (left breast, area of anterior left breast boost field, and anterior IMC field).

**General comments –**

The rationale and methodology for statistical tests were not reported. P values for HRs were not provided. It was not always clear whether the authors were referring to results from univariate or multivariate analysis.

An update search identified another guideline (Jalali *et al* 2007) which has been included in the following table.

## Ongoing studies

Poortmans P, Collette L, Horiot JC, Van den Bogaert W, Fourquet A, Kuten A, et al. Impact of the boost dose on local control and survival in patients with early stage breast cancer after a microscopically incomplete lumpectomy: 10 years results of the randomized EORTC boost trial 22881/10882. *Radiother Oncol* 2006;81:S19.

No details of the abstract provided.

Romestaing P, Lehingue Y, Delaunay D, Carrie C. Role of a 10-Gy boost in the conservation treatment of early breast cancer: results of a randomized clinical trial in Lyon, France [abstract]. *International Journal of Radiation Oncology Biology Physics* 2001;51(3 Suppl 1):3-4.

**Results:** At 5 years the Kaplan-Meier estimate of local relapse rate was 3.6% in the boost group and 4.5% in the no boost group ( $P=0.044$ ). After adjustment for the main prognostic variables such as the presence of an extensive in situ component in the tumour periphery, maximum diameter of the tumour, degree of histological differentiation, age at inclusion, no free margins, the relative risk was still significantly lower for the boost group ( $P$  value not reported). The occurrence of local relapse for 768 patients at 10 years was 26 in the boost group vs. 36 in the control group. However, only 4 patients died of cancer in the control group vs. 10 in the boost group.

## Health Economics Summary

The only included study assessing the cost-effectiveness of an additional RT boost after BCS was conducted in USA. Hayman et al (2000) conducted a cost-utility analysis comparing treatment with an electron-beam boost versus treatment without the boost in EBC patients with stage I or II tumours and negative margins, who had undergone BCS in combination with RT. They adapted a previously published Markov model, considering a 10-year time horizon with 1-year cycles. A probabilistic sensitivity analysis using Monte-Carlo simulation was conducted by assigning distributions to the utility scores; deterministic sensitivity analyses were performed as well. Baseline rates were derived from the NSABP B-06 trial, while effectiveness of RT boost was obtained from the only RCT available at the time the study was conducted (which had been conducted in Lyon, France). Utility scores used for the estimation of QALYs were obtained through the standard gamble technique from 97 BC patients; expert judgment was used to estimate utilities of metastatic states (whose rate was the same across groups and therefore did not affect cost-effectiveness). The cost analysis seemed to have been conducted appropriately, although resources used were not reported separately from the unit costs. Overall, the study appeared to have been appropriately conducted, although it presented some minor limitations. The authors concluded that the addition of a RT boost after BCS and RT on EBC patients with stage I and II tumours and negative margins do not seem to be cost-effective, unless the patients place an unexpectedly large utility on small reductions in the likelihood of local recurrence or unless the cost of the RT boost decreases considerably (less than one half its actual USA cost), conditions that do not seem likely to be found in clinical practice. As the authors reported, omitting RT boost among EBC women with negative margins after BCS would lead to very important savings. They recommended to reconsider whether a RT boost should be used on EBC patients (with stage I and II tumours) and negative margins since, as they estimated, dropping the RT boost in USA would lead to an annual savings of approximately \$135 million (i.e. from  $\frac{3}{4}$  of 150,000 women diagnosed with BC each year in the USA who would have negative margins).

Although the applicability of the study to the UK context is very limited given potential differences in clinical practice and unit costs, it is important to take into account that this study conducted extensive sensitivity analyses and a probabilistic sensitivity analysis (using Monte Carlo simulation) on the utility scores used to estimate QALYs (which were the parameters influencing more the results obtained). The results of the Monte Carlo simulations showed that the RT boost would be cost-effective in 0.085% of the simulations only. Additionally, deterministic sensitivity analyses showed that the costs of the RT boost should decrease to less than half the current cost, or the decrease in local recurrence should increase from 20% to 63% in order to make the RT boost cost-effective (i.e. less than \$50,000 per QALY) within the USA setting considering women aged 60.

## Health Economics Evidence Tables

### Non-UK Economic Evaluations: full studies

Hayman JA, Hillner BE, Harris JR, Pierce LJ and Weeks JC. Cost-effectiveness of adding an electron-beam boost to tangential radiation therapy in patients with negative margins after conservative surgery for early-stage breast cancer. *Journal of Clinical Oncology*, 2000. 18(2): p. 287-295.

#### **Design:**

##### Type of economic evaluation:

Cost-utility analysis that assessed whether or not the use of an electron-beam boost was cost-effective in EBC patients with negative margins. A previously published Markov model was adapted for the study, considering a 10-year time horizon with 1-year cycles. A probabilistic sensitivity analysis using Monte-Carlo simulation was conducted by assigning distributions to the utility scores. Additionally, deterministic sensitivity analyses were performed. Some assumptions considered were: adjuvant treatment did not depend on whether patients received boost; if local recurrence occurred, patients were treated with mastectomy followed by reconstructive surgery; the addition of the boost had not impact on distant metastasis. The perspective adopted was societal. Future costs and benefits were discounted at a 3% discount rate.

##### Clinical effectiveness:

Baseline rates were derived from the NSABP B-06 trial, while effectiveness of RT boost was obtained from the only available RCT (conducted in Lyon, France).

Utility scores used for the estimation of QALYs were obtained through the standard gamble technique from 97 BC patients; expert judgment was used to estimate utilities of metastatic states (whose rate was the same across groups and therefore had not impact on cost-effectiveness).

##### Cost estimation:

The cost categories included were: direct medical costs (i.e. facility and professional costs), time and transportation. The sources of the cost data were reported and seemed to be appropriate for the study question (i.e. USA sources). The cost analysis seemed to have been conducted appropriately, although resources used were not reported separately from the unit costs.

**Country:** USA, **setting:** Societal

#### **Inclusion criteria**

Patients diagnosed with EBC (stage I or II) who had undergone BCS and axillary dissection and had completed 5 weeks of daily treatment with tangential radiation therapy to the entire breast.

#### **Exclusion criteria**

None stated

#### **Population**

A hypothetical cohort

#### **Interventions**

Treatment with an electron-beam boost versus treatment without it after BCS.

#### **Results –**

OUTCOME OF INTEREST	With electron-beam boost	Without electron-beam boost
Costs (\$)	32,192	21,184
QALYs	7.1640	7.1575
ICER (\$ per QALY)	308,923	-

The results of threshold analyses showed that the relative reduction in local recurrences with the beam boost would need to increase from 20% to 63% to make the boost cost-effective at a threshold of \$50,000 per additional QALY gained (as usually considered in USA), which is unlikely to happen in clinical practice. Additionally, the cost of the boost should be reduced from \$2,400 to \$754 (i.e. the equivalent of 2 boost treatments) to make the boost cost-effective.

The results of the base-case analysis were very sensible to variations in the utility scores: if the utility of local recurrence increased from 0.92 to 0.925, the ICER would drop under \$50,000 per QALY. The Monte Carlo simulations resulted in a mean ICER of \$70,859 per QALY (95% CI: \$53,141 to \$105,182); the ICER was under \$50,000 just in 0.85% of the simulations.

**Authors' conclusions –**

The authors concluded that the use of a RT boost on EBC patients (with stage I and II tumours) and negative margins should be reconsidered since this intervention would not be cost-effective unless the patients place an unexpectedly large utility value on small reductions on the local recurrence rate or the cost of the boost diminishes considerably, both conditions unlikely to be met in clinical practice. The authors estimated that dropping the RT boost in USA would lead to an annual savings of approximately \$135 million (i.e. from <sup>3</sup>/<sub>4</sub> of 150,000 women diagnosed with BC each year in the USA who would have negative margins).

**General comments –**

The study appeared to have been appropriately conducted, overall. The choice of clinical studies to provide data to populate the model seemed to be non-systematic and arbitrary, although the authors reported some justification for the studies chosen: the RCT used in the model for baseline recurrence rates had used RT according to USA clinical practice, while the French study was the only available assessing the effectiveness of a RT boost, according to the authors.

## **6.6 What are the indications for radiotherapy to the supraclavicular fossa, internal mammary chain and axilla?**

### **Short Summary**

Since there were few studies that directly addressed this question the available literature was grouped into those studies comparing surgery and regional node irradiation with mastectomy and axillary dissection or mastectomy only (Fisher *et al* 2002, Overgaard *et al* 1999, Ragaz *et al* 2005, Wallgren *et al* 1986); studies comparing Breast Conserving Surgery (BCS) with or without axillary dissection or axillary radiotherapy (Louis-Sylvestre *et al* 2004, Pejavar *et al* 2006, Veronesi *et al* 2005); studies applying radiation to the internal mammary lymph nodes (Arriagada *et al* 1988, Grabenbauer 2004, Kaija & Maunu 1995, Obedian and Haffty 1999, Vinod and Pendlebury 1999); one retrospective cohort of patients receiving breast conserving surgery with axillary dissection and no regional node irradiation (Livi *et al* 2006); a retrospective study of predictors of regional nodal failure where only a small proportion of patients received regional radiotherapy (Grills *et al* 2003); and two retrospective studies of node ratios as prognostic factors (Fortin *et al* 2006, Tai *et al* 2007).

The evidence from four strong RCTs delivering regional nodal irradiation (axilla, supraclavicular and internal mammary lymph nodes) after mastectomy found a reduction in local and regional recurrence rates in the RT group in both lymph node-positive and negative women. An exception occurred in one trial of lymph node-positive women where no difference in recurrence rates was found in the RT group (Fisher *et al* 2002). Overall survival was improved in the RT arm from two of these trials (Overgaard *et al* 1999, Ragaz *et al* 2005), however no difference in overall survival was reported in the remaining two trials (Fisher *et al* 2002, Wallgren *et al* 1986).

The evidence from two well conducted RCTs including women with clinically negative lymph nodes in which the interventions were BCS and breast radiotherapy with or without radiotherapy to the axilla (Veronesi *et al* 2005), or BCS and breast radiotherapy followed by axillary dissection or axillary radiotherapy (Louis-Sylvestre *et al* 2004) reported no difference between arms for disease free survival. The incidence of axillary metastases was not significantly different in the study by Veronesi *et al* (2005), but was significantly increased in the axillary radiotherapy arm compared to axillary dissection in the trial by Louis-Sylvestre *et al* (2004). Evidence comparing axillary dissection and axillary radiotherapy after BCS and radiotherapy to the breast in node positive and negative women found no difference between groups in lymph node recurrence (Pejavar *et al* 2006).

Radiation to the internal mammary chain (IMC) lymph nodes was assessed in one RCT (Kaija and Maunu 1995) after BCS with axillary dissection and breast radiotherapy. No significant differences in local and distant relapse rates were reported, however, the follow-up time was short (2.7 years). A systematic review also suggested that the short observation time was not sufficient to allow any conclusions as to the value of IMC irradiation (Vinod and Pendlebury 1999).

Evidence from observational studies reported conflicting findings for distant metastases and survival with or without IMC node irradiation. Arriagada *et al* (1988) found a benefit of IMC irradiation in these outcomes to patients with medial tumours, whilst Obedian & Haffty (1999) found no difference regardless of tumour location. In another cohort of patients (Grabenbauer

2004) overall survival and systemic disease free survival were comparable when patients were treated with radiotherapy to the IMN for medial tumours, but radiotherapy was omitted for lateral tumours.

A large cohort study that did not treat the regional lymph nodes of patients with radiotherapy (Livi *et al* 2006) assessed locoregional and node relapses (axilla, IMC or supraclavicular fossa) over a median of 8 years. Most patients were lymph node-negative at diagnosis. Multivariate analyses showed that node relapse were more likely in women with more than three positive lymph nodes, pathological T2 tumours and angiolymphatic invasion. Locoregional recurrences were also associated with these characteristics as well as younger age groups.

A further observational study determined the incidence and risk factors for regional nodal failure in a cohort of patients receiving BCS, axillary dissection and radiotherapy to the breast alone, a proportion of these (13%) also received radiotherapy to the regional lymph nodes (Grills *et al* 2003). A subgroup analysis found that axillary failure was significantly higher in patients with 4 or more positive lymph nodes who did not receive regional node irradiation (RNI); however supraclavicular failure was significantly higher in patients with 1-3 positive nodes who did receive RNI. However, rates of failure for lymph node-negative and all lymph node-positive patients were not significantly different between those receiving RNI and no RNI. Overall survival and distant metastases free survival were lowest in patients with positive nodes who received RNI compared with those not receiving RNI. Node-negative patients receiving RNI also had lower overall survival and distant metastases free survival rates. A multivariate analysis of all patients found that the only significant independent predictor of RNF was the maximal size of the nodal metastasis.

Two observational studies assessed the percentage (Fortin *et al* 2006) or ratio (Tai *et al* 2007) of involved nodes. Fortin *et al* (2006) assessed the effects on regional node failure, and Tai *et al* (2007) assessed the effects on survival. Regional radiotherapy was found to be more effective in patients with medium to high node ratios than low node ratios in both studies.

**PICO**

POPULATION	INTERVENTION	COMPARISON	OUTCOME
Patients with operable invasive breast cancer who have received surgery (mastectomy or breast conserving surgery) – need	RT to any of the following sites: <ul style="list-style-type: none"> <li>• supraclavicular fossa</li> <li>• internal mammary chain</li> <li>• Axilla – but they need to be considered separately, also dependent on what axillary surgery has been done i.e.</li> </ul>	Surgery alone (mastectomy or breast conserving surgery)	<ul style="list-style-type: none"> <li>• Disease Free Survival (DFS) each site</li> <li>• Overall Survival (OS)</li> <li>• Recurrence</li> <li>• Quality of life</li> <li>• Patient acceptability</li> <li>• Cosmesis</li> </ul>

to avoid palliative surgery	clearance or less than a clearance. For im nodes need to know whether sentinel node positive as some techniques for snb do show up im nodes		
-----------------------------	---	--	--

The search strategy developed from this PICO table and used to search the literature for this question can be found in Appendix A

### Evidence Summary

The literature search identified papers published between 1978 and 2007. One systematic review included RCTs and non-randomized studies (Vinod & Pendlebury 1999). Three high quality RCTs (1++) compared regional node irradiation with no irradiation to the regional nodes (Fisher *et al* 2002, Ragaz *et al* 2005, Overgaard *et al* 1999). Two lower quality (1+) smaller RCTs (Louis-Sylvestre *et al* 2004, Wallgren *et al* 1986) compared surgery with radiotherapy (RT) to the breast and regional lymph nodes. Another two lower quality (1+) RCTs compared axillary RT with surgery alone (Veronesi *et al* 2005), or surgery with axillary dissection with or without RT to the Internal Mammary Node Chain [IMN or IMC] (Kaija & Maunu 1995). Seven non-randomized studies, four guidelines and three expert reviews were also included.

There were variations in treatment options and heterogeneity of the patient population which limited the applicability of the findings from these studies. The non-randomised studies were considerably heterogeneous and mainly retrospective cohort designs.

RCT evidence was consistent in reporting that regional irradiation reduced the local recurrence rate. One RCT found that isolated axillary recurrences were lower after AXD than axillary RT (Louis-Sylvestre *et al* 2004). Overall survival was less consistent between studies with some trials reporting improved survival after regional RT, and others reporting no difference between the RT and no RT groups.

### Regional node irradiation (axilla, supraclavicular and IMC nodes)

#### Level 1++

Two strong RCTs compared radical or modified radical mastectomy and axillary dissection with or without RT to the regional nodes (Overgaard *et al* 1999, Ragaz *et al* 2005). Both groups were given chemotherapy in the Canadian trial (Ragaz *et al*), and both groups were given tamoxifen in the Swedish trial (Overgaard *et al*). Both these trials enrolled high risk node positive patients.

#### Local Recurrence

Locoregional recurrences were lower in the RT group for both RCTs

Ragaz *et al* 2005 28% vs. 10% (CT vs. CT+RT) for any recurrence before systemic relapse

Overgaard *et al* 1999 29% vs. 4% p <0.001 (Tam vs. Tam + RT) RR 0.64 (0.54-0.77)

favouring RT for any recurrence at 2 years.

When recurrences by node status were compared in the study by Overgaard *et al*, any recurrence was twice as likely in N>3 patients than N0-3 patients at 2 years:  
N0-3 vs N>3: RR 2.18 (95% CI 1.80-2.64)  $p<0.001$

Survival free of isolated locoregional recurrence in the study by Ragaz *et al* (2005) was significantly longer in the RT group (90% with RT and chemotherapy vs. 74% with chemotherapy alone) RR 0.36 (0.18-0.71)  $p=0.002$ .

#### *Overall survival*

All survival outcomes were improved for the RT group compared to chemotherapy alone at 20 years in the Canadian trial (Ragaz *et al* 2005). (Only overall survival is reported here, the other outcomes are reported in the table at the end of this summary).

Ragaz *et al* (2005) Overall survival 37% vs 47% (CT vs CT+RT) RR 0.73 (95% CI 0.55 - 0.98)  $P = 0.03$ .

There were no significant differences in survival outcomes when comparing node status (N1-3 or N≥4) although survival was improved in the RT group.

Overall Survival in the Swedish trial was 36% (Tam vs. tam+RT) [95% CI 33-40] vs. 45% [95% CI 41-49] providing a 9% absolute benefit for RT. RR 0.68 (0.55-0.83) favouring RT for survival to 4 years. Death after 4 years was almost twice as likely in patients with N>3 positive nodes than N0-3 nodes: RR 1.97 (95% CI 1.58-2.45)  $p<0.001$ .

A third strong three arm RCT by Fisher *et al* (2002) reported findings for node negative and node positive patients. Comparisons were made between all 3 arms (RM vs.TM no AXD vs.TM+RT) for node negative women, and between 2 arms (RM vs.TM+RT) for node positive women.

#### *Local recurrence*

##### *Node negative*

There was a statistically significant difference between the 3 groups of women with negative nodes for the cumulative incidence of local or regional recurrence ( $p=0.002$  for 3 way comparison). The rate was lowest in the total mastectomy with RT group, indicating a significant benefit of RT in reducing local recurrence. In contrast there were no statistically significant differences between the 3 groups in the cumulative incidence of distant recurrence as a first event ( $p=0.61$ ).

##### *Node positive*

Among women with positive nodes, there were no significant differences between the RM and TM + RT groups for cumulative incidence of local or regional recurrences ( $p=0.67$ ). Similarly there were no significant differences between the RM and TM + RT groups for the incidence of regional recurrence or the incidence of distant recurrence ( $p=0.44$ ). However there was a significant reduction in the incidence of local recurrence after radiation therapy.

#### *Distant-Disease-free Survival and Overall Survival*

There were no significant differences in distant-disease-free survival among the groups of women with negative nodes at 25 years ( $p = 0.63$  for the three-way comparison). Among women with positive nodes, there was no significant difference in distant-disease-free survival between the radical mastectomy and total mastectomy plus radiation therapy groups

There were no significant differences in overall survival among the groups of women with negative nodes at 25 years ( $p=0.68$  for the three-way comparison). In women with positive nodes there was also no significant difference in overall survival between the radical mastectomy and total mastectomy plus radiation therapy groups ( $p=0.49$ ).

The findings validate earlier results showing no advantage from radical mastectomy and fail to show a significant survival advantage from removing occult positive nodes at the time of initial surgery or from radiation therapy.

### **Level 1+**

An earlier RCT by Wallgren *et al* (1986) compared MRM alone with MRM and pre- or postoperative RT to the breast and regional nodes.

#### *Local recurrence*

There was a significant reduction in the cumulative incidence of locoregional disease in node negative patients at 11 years after MRM with postoperative RT compared to surgery alone (2.5% vs. 20%;  $p<0.001$ ). The corresponding cumulative incidences in patients with lymph node metastases were 13% after MRM+ RT and 45% for surgery alone ( $p<0.001$ ).

#### *Distant metastases (cumulative incidence)*

Distant metastases were reduced in node positive patients treated with surgery and postoperative RT compared to no RT at 11 years (47% vs. 60%  $p=0.01$ ). There was no difference in cumulative incidence of distant metastases in node negative patients (approx 20% at 11 years,  $p=0.82$ ).

#### *Breast cancer deaths*

The cumulative incidence of breast cancer deaths for node negative patients was not statistically significantly different between postoperative RT and surgery alone (approx 7% from survival curve,  $p=0.78$ ). The survival gain for node positive patients in the postoperative RT group (54%) at 8 years vs. 47% in the surgery only group was also not statistically significant ( $p=0.09$ ).

A subgroup analysis of the ratio of death rates was generally lower for the irradiated patients than the surgery only group but none of the factors compared reached statistical significance. Included in this comparison were bilateral and ipsilateral irradiation to the IMC nodes, and site of tumour (lateral, medial or central).

### **BCS with or without axillary dissection or axillary RT**

#### **Level 1+**

Two RCTs assessed the effects of axillary dissection or axillary RT in women with N0 nodes. Veronesi *et al* (2005) compared BCS and RT to the breast + boost with or without axillary only RT. These women had tumours <1.2cm in diameter.

#### *Axillary metastases*

There were 4 clinically overt axillary metastases, one in the RT group and 3 in the no RT group:

Overall incidence 0.7% (95% CI 0.1-2.0%).

*Disease free survival at 5 years (includes any event)*

No difference between arms 96% (95%CI 94.1-97.9)  
A hazard ratio of 1.59 (0.65-3.89) was reported (no direction of effect reported).

The authors concluded that the rate of axillary metastases in women treated by breast conservation without any axillary treatment was much lower than expected, leading to the hypothesis that occult axillary metastases might not progress to overt clinical metastases, and secondly, that occult metastases can be kept under control by axillary RT. (It should be noted that these participants were N0 with tumours <1.2cm).

Louis-Sylvestre *et al* (2004) compared BCS and breast RT with either axillary dissection or axillary RT.

#### *Isolated axillary recurrences*

These were lower in the group with axillary dissection (1%) than in the group with axillary RT (3%) at 15 years (RR 0.33 (95% CI, 0.11 to 0.98)  $P = 0.04$ ).

Rates of overall survival, DFS, ipsilateral local recurrences and distant metastases or supraclavicular node involvement were not statistically different between groups. The authors concluded that at 15-year follow-up axillary dissection and axillary radiotherapy provided identical survival, although local control was better with axillary dissection.

### **Level 3**

A NRS by Pejavar *et al* (2006) followed women treated with BCS followed by RT to the breast and a tumour bed boost. The 69% of patients receiving axillary dissection (AXD) were also irradiated in the supraclavicular nodes if node positive (26%). IMC irradiation was individualized in these patients. The 31% who received axillary RT were also irradiated in the supraclavicular nodes, again IMC irradiation was individualized.

There were no significant differences in the regional nodal control rates when analyzed as a function of regional treatment (AXD vs. regional nodal radiation) at 5 and 10 years:

Node recurrence free rates:

	5 years	10 years
RT with AXD	98.3%	97.4%
RT with no AXD	98.5%	97.9%

Possible prognostic factors for nodal recurrence were evaluated including age, race, stage, AXD status, pathologic lymph node status, chemotherapy, hormonal therapy, and oestrogen /progesterone receptor status. In a multivariate analysis age, race, and pathological nodal status remained independent significant predictors of nodal failure.

Age <35 yrs  $p < 0.0001$

N+ve  $p < 0.0001$

Non-Caucasian  $p = 0.003$

The authors concluded that in patients undergoing BCS+RT, both regional nodal irradiation and AXD (including SNB) resulted in equally high rates of regional nodal control.

### **Radiation to the Internal Mammary Chain Nodes (IMC or IMN)**

#### **Level 1+**

One RCT (Kaija & Maunu 1995) investigated patients with Stage I-II invasive breast cancer who were treated with BCS (segmental resection and axillary dissection) followed by radiotherapy. Randomisation was to a target volume of the ipsilateral parasternal area including the internal mammary chain (IMC-RT) or omitting the IMC (no IMC-RT). There was no significant difference in local and distant relapse rates between treatment groups after a median follow-up time of 2.7 years. The authors concluded that the short observation time in the present study did not allow any conclusions as to the comparative value of internal mammary chain irradiation in preventing breast cancer recurrences.

One systematic review of 6 RCTs published before 1998 (Vinod & Pendlebury 1999) examined the effects of IMC irradiation in breast cancer. The conclusion was that the only RCT evidence from one small trial (Kaija & Maunu 1995) found no difference between groups randomized to receive (Internal Mammary Node Chain) IMC irradiation or no IMC irradiation in relapse rates at 2 years. It was too early to assess the effects on local recurrences or survival. They also reported that the survival advantage in medial or central and axillary node-positive tumours from IMC irradiation, is not supported by this early data (2.7 years) from a single small RCT.

The remaining 5 trials in this review administered regional irradiation to the axilla, supraclavicular fossa and IMC. The chest wall was also irradiated in some trials. One randomized trial of patients with high risk operable breast cancer showed a survival advantage to post-mastectomy irradiation, but the contribution of IMC irradiation could not be separated out. The authors suggest there is no advantage to elective IMC irradiation. The only indication would be for palliative management of positive IMC nodes.

### **Level 3**

Arriagada *et al* (1988)

In a large retrospective cohort of N+ patients the long term effects of treatment of the IMC by IMC dissection (IMCD) or RT were assessed for the risk of death or metastasis. For a total of 1195 patients there was a beneficial effect of treatment of the internal mammary chain (IMC) [vs. no treatment to the IMC] on the risks of death (RR 1.6 P=0.01) and distant metastasis (RR 1.5 P=0.05) in a subgroup of patients with medial tumours. No statistically significant differences were found for mortality and metastases for all patients, or for a subgroup of patients with lateral tumours. It should be noted that there were many changes in treatment protocols over the course of this study.

Obedian & Haffty (1999)

In a cohort of 984 patients treated with BCS and RT to the breast with and without RT to the IMC nodes found no significant differences between the IMC+RT and IMC-noRT groups for overall survival (72% IMC+RT vs. 84% IMC-noRT, p = NS) or distant metastasis-free survival (77% IMC+RT vs. 87% IMC-noRT, p = NS). A further subset analysis of node positive patients showed no benefit in the IMC+RT group regardless of age, number of nodes, location (medial vs. lateral or right vs. left), or type of irradiation (deep tangent vs. separate field). The findings for medial tumours contradict the earlier findings of the NRS by Arriagada *et al* (1988).

### **Level 4**

Grabenbauer 2004

An overview of four selected non-randomised studies also found that overall survival, breast cancer specific survival and disease-free survival were significantly improved in patients with lateral than medial tumours. The data from a cohort of patients at the centre where this paper originated found that overall survival and systemic disease free survival were comparable when patients were treated with RT to the IMN for medial tumours (using a mixed beam to the breast and IMN), but RT was omitted for lateral tumours (RT to breast only):

Kaplan-Meier curves for overall survival were 79.1% and 64% at 5 and 10 years for medial tumours (n=330) with RT to the IMN, and 76.2% and 60.3% for lateral tumours (n=492) (p=0.2) with no IMN irradiation.

Systemic Disease-Free Survival from Kaplan-Meier curves were 72.6% and 70.1% at 5 and 10 years for medial tumours (n=330) with RT to the IMN, and 72.9% and 65.5% for lateral tumours (n=492) (p=0.3) with no IMN irradiation.

### **No node irradiation Level 3**

In a large cohort study by Livi *et al* (2006) all patients received BCS with axillary dissection and breast RT. Locoregional recurrences occurred in 224/4185 patients (5.3%). Sites of recurrence were the breast (3.9%), axilla (0.3%), supraclavicular area (0.8%), and IMC (0.3%).

A multivariate analysis for locoregional recurrence in the breast, supraclavicular, axillary and internal mammary nodes found that Grade 3 tumour (p=0.01), age at presentation (p=0.001), more than three positive lymph nodes (p=0.004), pT2 (p=0.001) and angiolymphatic invasion (p=0.02) were statistically significant parameters.

A multivariate analysis for Node Relapse (NR) found pT2 (p=0.02), angiolymphatic invasion (p=0.002) and more than three positive lymph nodes (p=0.001) were statistically significant.

### **Limited node irradiation Level 3**

A NRS (Grills *et al* 2003) of mainly N0 patients given BCS and axillary dissection, then RT to the breast alone (87%) or RT to the breast and regional nodes (13%) assessed predictors of Regional Nodal Failure (RNF) and conducted a series of complex analyses.

#### *Regional nodal failure with and without Regional Nodal Irradiation (RNI)*

10 year actuarial failure rates in the axilla were significant in patients with  $\geq 4$  positive nodes only (0% with RNI, 5% without RNI; p=0.027). For supraclavicular fossa failure a significant difference was reported in patients with 1-3 positive nodes only (8% with RNI, <1% without RNI; p=0.004). No statistically significant differences were reported between patients receiving RNI and no RNI in patients with no positive nodes (N0), unknown node status (Nx) or all N+ patients. A multivariate analysis of all patients found that the only significant independent predictor of RNF was the maximal size of the nodal metastasis (p = 0.013).

#### *Survival with and without Regional Nodal Irradiation*

An analysis by node status found that node-negative and patients with 1–3 positive nodes receiving RNI had statistically significant lower survival rates. NX patients and those with  $\geq 4$  positive nodes receiving RNI had similar survival rates to patients not treated with RNI. The number of lymph nodes excised also had an impact on overall survival, with 10-year survival rates of 33%, 65%, and 69% in patients with  $< 6$ , 6-10, and  $> 10$  nodes excised, respectively ( $P = 0.05$ ).

## Node ratios

### Level 3

Two NRS looked at the percentage or ratio of involved nodes on regional node failure and survival.

Fortin *et al* (2006) assessed whether the percentage of positive nodes could be used to select patients for regional RT. Amongst patients not receiving regional radiotherapy, the percentage of involved nodes was significantly associated with axillary failure. Ten-year axillary control rates were 97% and 91% when the percentage of involved nodes was  $< 50\%$  and  $\geq 50\%$ , respectively ( $p = 0.007$ ).

Regional radiotherapy was significantly associated with a decrease in overall regional failure (axillary and/or supraclavicular), regardless of the percentage of involved nodes when compared with no regional radiotherapy. However, regional radiotherapy reduced the axillary failure rate (2% vs. 9%,  $p = 0.007$ ) only when more than a specific percentage of nodes was involved ( $\geq 40\%$  if N1-3 and  $\geq 50\%$  if  $N > 3$  nodes).

The authors concluded that the percentage of involved nodes should be taken into consideration in selecting patients for regional radiotherapy. Irradiation of the axilla should be reserved for patients with a specific ratio of: more than 40% involved nodes if N1-3 positive, and 50% or more involved nodes if N3+ positive nodes.

The second NRS by Tai *et al* (2007) examined the node ratio in relation to supraclavicular and axillary RT (SART). The NR correlated significantly with the primary tumour size, clinical stage group, pathological stage group and the risk of any first recurrence. For a low NR, the 10-year overall survival rate with and without SART was 57% and 58% ( $p = 0.18$ ), and the cause-specific survival rate was 68% and 71% ( $p = 0.32$ ), respectively. For a medium NR, the 10-year overall survival rate with and without SART was 48% and 34% ( $p = 0.007$ ), and the cause-specific survival rate was 57% and 43% ( $p = 0.002$ ), respectively. For a high NR, the 10-year overall survival rate with and without SART was 19% and 10% ( $p = 0.005$ ), and the cause-specific survival rate was 26% and 14% ( $p = 0.005$ ), respectively. The authors concluded that Node Ratio is a useful prognostic factor, and the study demonstrates that for patients with 10 or more nodes resected, regional RT significantly improves survival for the MNR and HNR groups, but not for the LNR group.

The node ratios calculated in these two studies were essentially measuring the same parameter. Fortin *et al* (2006) focussed on the selection of patients and node failure, whilst Tai *et al* (2007) examined the effects on survival. Regional radiotherapy was found to be more effective in patients with medium to high node ratios than low node ratios in both studies.

Study	Design	Tumour / patient characteristics	Intervention comparators	Outcome
Veronesi <i>et al</i>	RCT	N0 (not clinically)	BCS +/- axillary RT	Axillary metastases:

2005 1+	N=435 Median 5 yr	palpable) Tumours <1.2cm		No difference between arms N=4 (0.7%) 95% CI 0.1-2.0% <b>5 year DFS:</b> No difference between arms 96% (95%CI 94.1-97.9) <b>Hazard ratio:</b> 1.59 (0.65-3.89)
Kaija & Maunu 1995 1+	RCT N=266 2.7 yr	Stage I-II N0 87% N positive 13%	BCS and axillary dissection, breast RT +/- IMC RT	No significant difference in local and distant relapse rates between treatment groups at 2.7 years
Wallgren <i>et al</i> 1986 1+	RCT N=960 11 yr	Stage I-III N0-N1	Modified Radical Mastectomy Three groups: Preoperative RT Postoperative RT Surgery alone  RT to breast, chest wall, supraclavicular, axilla and IMC	<b>Recurrence rate</b> RT vs surgery: 0.65 (p<0.001)  <b>Sites of recurrence:</b> Chest wall + nodes RT 46(7%) vs. no RT 84 (26%) p<0.001  All recurrences RT 199 (31.1%) vs. no RT 135 (42.1%)  <b>Survival</b> No difference between groups for breast cancer deaths or all cause mortality at 8 years.
Louis-Sylvestre 2004 1+	RCT N=658 15 yr	N0 (No clinically involved lymph nodes) M0 Tumour size: 19% ≤1cm. 48% 1-2cm. 33% > 2cm.	BCS and breast RT + axillary dissection or axillary RT  All had boost  After axillary dissection included RT to IMC and supraclavicular nodes in patients with nodal metastases.  In the axillary RT group the IMC were also irradiated.	<b>Isolated axillary recurrences</b> were lower in the group with axillary dissection (1%) than in the group with axillary RT (3%) at 15 years.  RR 0.33 ( 95% CI, 0.11 to 0.98) <i>P</i> = 0.04  Rates of overall survival, DFS, ipsilateral local recurrences and distant metastases or supraclavicular node involvement were not statistically different between groups.
Fisher <i>et al</i> 2002 1++	RCT N=1765 25 yr	N0 (n=1079) N +ve (n=586) Tumour size 3.7cm +/- 2.0cm	3 groups: Radical Mastectomy (RM) Total Mastectomy without axillary dissection (TM) TM+RT  RT delivered to breast, supraclavicular nodes, IMC. Women with positive nodes also received a boost dose to chest wall.	<b>Cumulative incidence</b> of local or regional recurrence ( <i>p</i> =0.002 for 3 way comparison) in N0. Rate lowest in TM + RT group. Node positive- no significant difference between TM+RT and RM groups. <b>Distant-Disease free Survival</b> No significant differences between treatment groups for women with negative nodes or positive nodes. <b>Overall survival</b> No significant differences between treatment groups for women with negative nodes or positive nodes.
Ragaz <i>et al</i> 2005 1++	RCT N=318	Premenopausal N positive (pathological)	Modified radical mastectomy + Level I and II axillary dissection +/- RT to chest wall, regional lymph nodes including bilateral IMC.  Both groups had chemotherapy (CT)	<b>Isolated locoregional disease</b> was lower in the RT group at 20 years 18% vs. 7% (CT vs. CT+RT) <b>Any locoregional disease</b> 28% vs. 10% (CT vs. CT+RT) <b>Survival free of isolated regional disease</b> 74% vs 90% (CT vs CT+RT) RR, 0.36; 95% CI, 0.18 to 0.71; <i>P</i> = 0.002 <b>Survival free of regional disease at any time</b> 61% vs 87% (CT vs. CT+RT) RR= 0.32 (95% CI, 0.18 to 0.57; <i>P</i> < 0.001) <b>Event free survival</b> higher in RT group 25% vs 35% (CT vs CT+RT) RR, 0.70; 95% CI, 0.54 to 0.92; <i>P</i> = 0.009 <b>Breast cancer free survival</b> higher in RT group 30% vs 48% (CT vs CT+RT) RR, 0.63; 95% CI, 0.47 to 0.83; <i>P</i> = 0.001 <b>Systemic breast cancer free survival</b> higher in RT group 31% vs 48% (CT vs

				CT+RT) RR, 0.66; 95% CI, 0.49 to 0.88; <i>P</i> = 0.004 <b>Breast cancer specific survival</b> higher in RT group 38% vs 53% (CT vs CT+RT) RR, 0.67; 95% CI, 0.49 to 0.90; <i>P</i> = 0.008 <b>Overall survival</b> higher in RT group 37% vs 47% (CT vs CT+RT) RR, 0.73; 95% CI, 0.55 to 0.98; <i>P</i> = 0.03 There was no significant difference between N1-3 and N4+ patients for any of these outcomes.
Overgaard <i>et al</i> 1999 1++	RCT N=1375	Postmenopausal Stage I 24% Stage II 44% Stage III 16% N0 10% N1-3 58% N>3 33% Tumour size <2.1cm 38% 2.1-5.0cm 49% >5.0cm 12%	Total mastectomy with axillary-node dissection (Level I-II).  RT to chest wall, mid axilla (supraclavicular, infraclavicular and axilla) and bilateral IMC  Comparison group was tamoxifen alone with no RT.	<b>Any recurrence after 2 yrs (n=879)</b> N0-3 vs N>3 RR 2.18 (95% CI 1.80-2.64) <i>p</i> <0.001  Tam alone vs RT+ Tam RR 0.64 (95% CI 0.54-0.77) <i>p</i> <0.001  <b>Death after 4 years (n=877)</b> N0-3 vs N>3 RR 1.97 (95% CI 1.58-2.45) <i>p</i> <0.001  Tam alone vs RT+ Tam RR 0.68 (95% CI 0.55-0.83) <i>p</i> <0.001

## Evidence table

### Systematic review of RCTs

Vinod, S. K. & Pendlebury, S. C. 1999, "Review of internal mammary chain irradiation in breast cancer", <i>Breast</i> , vol. 8, no. 5, pp. 245-250.	
Design: Systematic review Country: Australia Aim: To assess the effectiveness of and indications for irradiation of the internal mammary chain (IMC) in the treatment of breast cancer through a review of the literature.	Level 1+
<b>Inclusion criteria</b> Literature search 1966-1998 of the MEDLINE database for English Language articles and a search of reference lists of identified papers, for those assessing the effect of internal mammary chain irradiation in operable breast cancer.	
<b>Exclusion criteria</b>	
<b>Population</b>	
<b>Interventions</b> The effectiveness of IMC irradiation in early stage and locally advanced breast cancer. Irradiation of the axilla, chest wall or breast was also included and taken into consideration. Systemic therapy was not accounted for.	
<b>Outcomes</b> Local control Survival	
<b>Follow up -</b>	
<b>Results</b>	
<i>Methods</i> In most studies the effect of IMC irradiation alone could not be separated from supraclavicular fossa irradiation as the two sites were treated together. Irradiation of the axilla, chest wall or breast was also taken into account. The grading of studies was: Level I Systematic reviews of RCTs Level II At least one RCT Level III Controlled trial with no randomization, cohort, case control studies or multiple time series with and without intervention. Level IV Expert opinion This system differs from NICE grading where Level 1 includes SRs of RCTs and single RCTs.	
<i>Findings</i> Six RCTs and 9 retrospective series in early stage breast cancer.	
<b>RCTs</b> Included RCTs were: Cancer Research Campaign Working Party. Cancer Research Campaign (King's/Cambridge) Trial for early breast cancer. A detailed update at the tenth year. <i>Lancet</i> 1980 July: 55–60.  Fisher B, Redmond C, Fisher E R et al. Ten year results of a randomized clinical trial comparing radical mastectomy and total mastectomy with or without radiation. <i>N Engl J Med</i> 1985; 312: 674–681. (NSABP-04).  Host H, Brennhord I O, Loeb M. Postoperative radiotherapy in breast cancer – long term results from the Oslo Study. <i>Int J Radiation Oncology Biol Phys</i> 1986; 12: 727–732.  Wallgren A, Arner O, Bergstrom J et al. Radiation therapy in operable breast cancer. Results from the Stockholm Trial on adjuvant radiotherapy. <i>Int J Radiat Oncol Biol Phys</i> 1986; 12: 533–537.	

Kaija H, Maunu P. Tangential breast irradiation with or without internal mammary chain irradiation: results of a randomized trial. *Radiother Oncol* 1995; 36: 172–176. (Finland).

Ragaz J, Jackson S M, Le N et al. Adjuvant radiotherapy and chemotherapy in node-positive premenopausal women with breast cancer. *N Engl J Med* 1997; 337: 956–962. (Canada).

<b>RCT Intervention</b>	<b>Findings</b>
CRC N=2800 Clinical stage I or II. Simple Mastectomy vs. simple mastectomy + RT to chest wall, IMC, SCF, axilla.	Local recurrence free survival improved in RT group. Overall survival – no significant difference between groups. Medial tumours- no survival benefit with RT.
NSABP-04 N=1665 Node positive randomized to radical mastectomy or simple mastectomy and regional node irradiation (IMC, SCF, axilla). Node negative randomized to radical mastectomy, simple mastectomy, or simple mastectomy and regional node irradiation.	No difference between any of the groups for disease-free survival or overall survival. Regional node irradiation did not provide a benefit over mastectomy alone in women with node negative or positive tumours.
Oslo N=1115 Phase I: All women had radical mastectomy, then randomized to observation or RT (200 kv. x-ray) to axilla, IMC, SCF and chest wall. Phase II: RT delivered with Co-60 and chest wall RT omitted.	A decrease in local recurrence but no effect on overall survival. Subgroup analysis of women with stage II medial and central tumours found a trend of improved survival with Co-60 than x-ray RT. Significant excess of non-breast cancer deaths in Co-60 group.
Stockholm N=960 3 arms Preoperative RT to IMC, SCF, axilla, breast. Postoperative RT to IMC, SCF, axilla, chest wall. Modified radical mastectomy alone.	RT significantly reduced local recurrence, but no difference in overall survival at 10 years. Node positive with RT had a significant reduction in incidence of distant metastases.
Finland N=270 BCS and axillary dissection for Stage I-II breast cancer. RT was given to all but randomized to include the IMC or omit the IMC.	At 2 years no significant difference in relapse between the 2 groups.
Canada N=318 Premenopausal women with positive axillary nodes randomized to RT (IMC, SCF, axilla, chest wall) or observation.	Local recurrences reduced by 56% with RT. Breast cancer specific survival increased by 29% with RT (p=0.05) A non-significant 8% increase in overall survival with RT.

**Key:**

IMC = Internal Mammary Chain

RT = Radiotherapy

SCF = Supraclavicular Fossa

**Author Summary of RCTs**

- The addition of radiotherapy consistently reduced the rate of local recurrence.
- The actual benefit of IMC treatment is unknown as sites of relapse were not reported.
- No trials found a significant advantage in overall survival, even when the subgroups of medial and central cancers were analysed.
- Only one trial reported a cancer specific survival and showed a significant improvement (Ragaz 1997).

The authors point out the limitation of the trials in assessing survival since radiotherapy related deaths may negate any overall survival benefit.

**Non-Randomised Studies (NRS)**

9 retrospective studies were identified:

Arriagada R, Le M G, Mouriessse H et al. Long-term effect of internal mammary chain treatment. Results of a multivariate analysis of 1195 patients with operable breast cancer and positive axillary nodes. *Radiother Oncol* 1988; 11: 213–222.

Study Intervention	Findings
<p>Arriagada N=1195 Operative breast cancer (&lt;7cm) and positive axillary nodes treated by modified radical mastectomy and complete axillary dissection. RT to chest wall, SCF and axilla. 4 groups: No IMC treatment (n=135) IMC dissection only (n=102) IMC radiotherapy only (n=523) IMC RT and dissection (n=435)</p>	<p>In the three groups with IMC treatment the risks of death and metastasis were the same. When these groups were combined and compared to the no IMC treatment group there was a trend toward improved survival in the treated arms (<math>P=0.06</math>). A subgroup analysis reached statistical significance for medial tumours (10-year survival 58% vs 48%, <math>P=0.05</math>) only. Conclusions were that treatment of the IMC was beneficial in improving survival for axillary node-positive medial tumours.</p> <p>These findings are based on subgroup analyses of a retrospective study. Different treatment policies were adopted over sequential time periods and the possibility exists for staging biases.</p> <p><i>This study is included in the observational evidence</i></p>
<p>Regnier N=787 Surgery and postoperative RT to chest wall and regional nodes.</p>	<p>Change in policy of IMC treatment with time. Prior to 1974 the IMC was treated with a single anterior field to a dose of 27.5 Gy. From 1974 onwards the IMC was boosted to 40 Gy for medial cancers.</p> <p>Survival correlated with the higher dose to the IMC, however the distribution of prognostic factors between the two groups was not reported.</p>
<p>Montague N=1111 Radical mastectomy (n=301) Radical mastectomy then RT to SCF and IMC (n=368) Preoperative RT to SCF, IMC and axilla then radical mastectomy (n=442)</p>	<p>Axillary nodal positivity was 12%, 64% and 29% respectively in the 3 groups. There was no difference seen in 10-year survival rates.</p> <p>This was interpreted as being a result of IMC and SCF radiation. This study is limited by use of retrospective data and the omission of prognostic factors between groups that may affect outcomes.</p>
<p>Chahbazian N=225 Node negative operable breast cancer. Radical mastectomy (n=136) Radical mastectomy then RT to SCF and IMC (n=89)</p>	<p>RT group showed a significant survival advantage for medial tumours. No advantage for lateral tumours.</p>
<p>Roseman</p>	<p>RT decreased local recurrences and improved disease-</p>

N=134 Surgery alone (n=118) Surgery and postoperative RT to IMC and SCF (n=17)	free survival in those with medial tumours.
Cappellini (Case –control) N=128 Node negative breast cancer. Post-operative radiotherapy.	No significant difference in recurrence or survival.
Rubin N=230 IMC recurrence identified.	16/230 had an IMC recurrence over 10 years. Of these 32% had received RT.
Shiba N=183 Radical mastectomy with parasternal node dissection or radiation to the parasternal region. Women with medial or central tumours.	No differences in overall survival at 10 years.
Schmolling N=411 Breast preservation versus mastectomy.	IMC RT did not impact on survival rates.
<p><b>Locally advanced breast cancer</b> 2 RCTs looked at operable locally advanced disease.</p> <p>Rutqvist L, Cedermark B, Glas U et al. Randomised trial of adjuvant tamoxifen combined with postoperative radiation therapy or adjuvant chemotherapy in postmenopausal breast cancer. <i>Cancer</i> 1990; 66: 89–96.</p> <p>Overgaard M, Hansen P S, Overgaard J et al. Postoperative radiotherapy in high-risk premenopausal women with breast cancer who receive adjuvant chemotherapy. <i>N Engl J Med</i> 1997; 337: 949–955.</p>	
Rutqvist N=427 Postmenopausal women with high risk breast cancer (T>30mm or node positive) randomized postmastectomy to: Radiotherapy alone Radiotherapy and tamoxifen Chemotherapy alone Chemotherapy and tamoxifen RT included chest wall, axilla, SCF and IMC.	The addition of radiotherapy significantly reduced local failure and improved relapse-free survival. There was a trend toward reduced distant metastases ( $P=0.06$ ) but no difference in survival.
Overgaard N=1708 Premenopausal women with T3, T4 or node-positive breast cancer. All patients had mastectomy then randomized: Chemotherapy alone Chemotherapy in combination with radiotherapy to the chest wall, axilla, SCF and IMC.	At 10 years 45% of the chemotherapy alone group and 54% of the radiotherapy group were alive ( $P<0.001$ ).
<p><i>Summary of locally advanced disease</i> Post-mastectomy radiation was delivered to the chest wall and all nodal regions. It is difficult to assess the contribution of IMC radiation alone to these results.</p> <p><b>Author conclusions</b> In early stage breast cancer some retrospective data suggested that IMC irradiation improved survival in medial or central and axillary node-positive tumours, this was not supported by the randomized data (from one RCT). Two randomized trials were of high risk operable breast cancer. One showed a survival advantage to post-mastectomy irradiation, but the contribution of IMC irradiation could not be delineated. Based on the best current evidence, there is no advantage to elective IMC irradiation. The only indication is for positive IMC nodes where the management aim is palliative.</p> <p><b>General comments –</b> Many of the trials included in this review have been updated since publication in 1999.</p>	

## Randomized controlled trials

Veronesi, U., Orecchia, R., Zurrada, S., Galimberti, V., Luini, A., Veronesi, P., Gatti, G., D'Aiuto, G., Cataliotti, L., Paolucci, R., Piccolo, P., Massaioli, N., Sismondi, P., Rulli, A., Lo, S. F., Recalcati, A., Terribile, D., Acerbi, A., Rotmensz, N., & Maisonneuve, P. 2005, "Avoiding axillary dissection in breast cancer surgery: a randomized trial to assess the role of axillary radiotherapy", *Annals of oncology : official journal of the European Society for Medical Oncology / ESMO.*, vol. 16, no. 3, pp. 383-388.

Design: RCT (1995-1998)

Level 1+

Country: Italy, setting: Italian Oncological Senology Group: Multicentre

Aim: To assess the role of axillary radiotherapy (RT) in reducing axillary metastases in patients with early breast cancer who did not receive axillary dissection.

### Inclusion criteria

Women aged > 45 years with a unifocal breast carcinoma maximum size of 1.2cm (determined during operation), and no palpable axillary nodes.

### Exclusion criteria

Patients with non-invasive carcinoma or a history of previous malignant disease.

**Population** number of patients = 435

Patients were randomized to either no axillary RT (n=214) or axillary RT (n=221)

The median age was 57 years (interquartile range 52–63) with no difference between the two groups. 41% were < 55 years.

60% of tumours were 0.6-1.0cm.

9% of tumours were 1.2-1.5cm.

Breast tumour was non-palpable in 241 patients (55.4%), and clinically palpable in 194 (44.6%).

No palpable axillary nodes.

### Interventions

Wide resection or quadrantectomy (1-2 cm margin of normal tissue) of the primary carcinoma. Quadrantectomy for tumours in the upper outer quadrant were performed without removal of any axillary node. Where lesions were non-palpable, the removed specimen was X-rayed to check that the tumour had been removed completely. The size of the lesion was determined macroscopically in the operating theatre. The final histological size measurement was concordant in most cases. However, in 9.2% of cases (20 in each group), size was in excess of 1.2 cm.

Radiotherapy given by X-Ray photons from a 6MV linear accelerator to produce two opposed tangential fields. The 100% tumour dose was 50 Gy in 25 fractions of 2Gy each. An additional boost to the tumour bed of 6–15MeV electrons (10 Gy in five fractions of 2 Gy each) was given to all patients.

In the intervention arm the axillary region was irradiated with two parallel (non-divergent) opposed fields (antero-posterior postero-anterior). The total dose of 50 Gy in 25 fractions of 2Gy given with a 6MV linear accelerator.

### Outcomes

Axillary metastases

Local recurrence

Distant metastases

Breast cancer deaths

Overall deaths

### Follow up

All patients received quarterly clinical examination and annual mammography, chest X-ray, liver ultrasound and bone scan. If an enlarged axillary node was found during follow-up, complete axillary dissection was performed. Median follow-up was 63 months (range 2–108 months). Four patients were lost to follow-up (0.7%).

## Results

Significantly fewer patients in the no axillary RT arm received no adjuvant treatment of tamoxifen or chemotherapy (11.7% no RT vs 18.5% with RT to axilla,  $p=0.046$ ).

Table of events related to primary tumour:

Events related to primary tumour	No axillary RT	Axillary RT	Log rank test
Appearance of overt axillary metastases	3	1	0.295
Local recurrence	1	1	0.979
Second ipsilateral breast cancer	0	3	0.095
Distant metastases	8	3	0.107
Total events related to primary	12	8	0.305
Other events:			
Contralateral breast cancer	7	4	0.306
Other primary cancer	4	4	0.916
Total first events	23	16	0.185
Deaths due to breast cancer	5	2	0.227
Deaths due to other causes	7	0	0.006
Total deaths	12	2	0.005

Generally, fewer events occurred in the RT arm (exceptions local recurrence, second ipsilateral breast cancer). Additional information reported was that of the 324 patients in both groups with a primary carcinoma less than 1cm in diameter, only one (0.3%) developed overt axillary metastases.

The Log rank test was used to compare survival estimates. Further data are reported in the following table:

INTERVENTION	PATIENTS	Events related to primary tumour	DFS RESULT
Axillary RT	221	8	Kaplan-Meier Log rank test P=0.3039
No axillary RT	214	12	
Total	435	Overall clinically overt axillary metastases: N=4 (0.7%) 95% CI 0.1-2.0%	
	Axillary metastases: RT group n=1 (0.5%) No RT group n=3 (1.5%)		
<b>Outcome</b>	<b>RT</b>	<b>No RT</b>	<b>Overall</b>
<b>5 year DFS</b>	96.9% (95%CI 94.3-99.4)	95.1% (95%CI 92.2-98.1)	96% (95%CI 94.1-97.9)
<b>Hazard ratio</b> (Direction of effect not specified in paper)			1.59 (0.65-3.89)

DFS = any event (axillary metastases, local recurrence, ipsilateral carcinoma or distant metastases) related to primary cancer (excludes contralateral breast cancer and any other cancer).

There were no significant differences between groups for DFS.

The Hazard Ratio for DFS was very wide (0.65-3.89) possibly due to the low number of events.

## Author conclusions

The rate of axillary metastases appearing in women treated by breast conservation without any axillary treatment was much lower than expected, leading to the hypothesis that occult axillary metastases might not progress to overt clinical metastases, and secondly, that occult metastases can be kept under control by axillary RT. (For tumours less than 1.2cm).

## General comments -

Kaija, H. & Maunu, P. 1995, "Tangential breast irradiation with or without internal mammary chain irradiation: results of a randomised trial", *Radiotherapy & Oncology*, vol. 36, no. 3, pp. 172-176

Design: RCT (1989-1991) Level 1+  
Country: Finland, setting: University Centre

**Inclusion criteria**

Unilateral stage I or II invasive breast cancer

**Exclusion criteria**

Two patients with distant metastases and two who refused radiotherapy were excluded.

**Population** number of patients = 270 eligible, 266 entered the trial.

A table of patient, tumour and treatment characteristics from the paper is shown below:

Variable	IMC-RT	No IMC-RT
Age (years)	58.3	57.9
Mean tumour size (cm)	1.4	1.4
Node positive	19	16
Breast left/right	54/48	58/42
Location (%)		
Lateral	75	77
Medial	17	15
Central	8	8
Mean radiation dose	49.7	49.1
Adjuvant systemic therapy (%)	9	7

**Interventions**

All patients had BCS (segmental resection and axillary dissection) followed by radiotherapy. Randomisation was to a target volume of the ipsilateral parasternal area including the internal mammary chain (group 1, IMC-RT) or omitting the IMC (group 2, no IMC-RT).

The RT dose was delivered using the medial and lateral tangential field technique with 5MV photon beams 4-8 weeks after surgery.

The total radiation dose determined varied during the time period of the study. 50 Gy photons + 10 Gy electron boost or 54 Gy photons or 50 Gy photons, were given in five fractions per week at a daily dose of 2 Gy. The dose variation was due to changing practice in the clinic.

71 patients received 50 Gy photons + 10 Gy electron boost

44 patients received 54 Gy photons

146 patients received 50 Gy photons without boost.

The dose inhomogeneity within the target volume was within 10% in most cases.

**Outcomes**

Local and distant relapse

Radiation pneumonitis

Radiation fibrosis

Skin reactions

**Follow up**

Clinical examination 3 monthly and chest X-ray twice a year. Median follow-up 2.7 years.

Data for 263/270 (97.4%) patients were available for analysis.

**Results**

The main purpose of the study was to follow skin and pulmonary complications.

*Skin reactions*

These were common in both groups, with 90% of patients having some skin reaction.

Skin reaction	IMC RT N (%)	No IMC RT N (%)	Total N (%)
None	10 (8)	14 (11)	24 (10)
Mild	45 (35)	45 (34)	90 (35)
Moderate	42 (32)	36 (27)	78 (29)
Severe	34 (25)	37 (28)	71 (26)

Total	131 (100)	132 (100)	263 (100)
-------	-----------	-----------	-----------

### *Lung reactions*

Acute reactions were more common in the IMC-RT group, but the difference was not significant (18 vs. 14%). Lung reactions were mainly mild or moderate, with 2 severe cases in the IMC-RT group. Acute reactions disappeared within 6 months.

11% of patients had lung fibrosis which was more common in the IMC-RT group but not statistically significant ((14 vs. 7%,  $p < 0.06$ ).

15% of patients had respiratory symptoms.

<b>Lung and respiratory events</b>	<b>IMC RT N (%)</b>	<b>No IMC RT N (%)</b>	<b>Total N (%)</b>
Acute lung reactions			
None	107 (82)	112 (86)	219 (84)
Mild	16 (12)	13 (10)	29 (11)
Moderate	5 (4)	6 (4)	11 (4)
Severe	2 (2)	0 (0)	2 (1)
Lung fibrosis			
None	112 (86)	122 (93)	234 (89)
Mild	11 (8)	7 (5)	18 (7)
Moderate	8 (6)	2 (2)	10 (4)
Respiratory symptoms			
No	110 (84)	112 (85)	222 (85)
Yes	21 (16)	19 (15)	40 (15)

There was no significant difference in relapse rates between treatment groups after a median follow-up time of 2.7 years.

### **Author conclusions**

The short observation time in the present study does not as yet allow any conclusions as to the comparative value of internal mammary chain irradiation in preventing breast cancer recurrences. So far there is not any significant difference between treatment groups.

Radiation of internal mammary chain after conservative surgery for early breast cancer did not lead to an increase in clinically important skin or pulmonary complications. Whether it prevents recurrences or increases the cancer risk to the other breast is too early to say in view of the short observation time.

### **General comments -**

Louis-Sylvestre, C., Clough, K., Asselain, B., Vilcoq, J. R., Salmon, R. J., Campana, F., & Fourquet, A. 2004, "Axillary treatment in conservative management of operable breast cancer: dissection or radiotherapy? Results of a randomized study with 15 years of follow-up", *Journal of clinical oncology : official journal of the American Society of Clinical Oncology*, vol. 22, no. 1, pp. 97-101

Design: RCT (1982-1987) Level 1+  
Country: France, setting: single institution  
Aim: To update a study comparing axillary dissection with radiotherapy to the axilla.

#### **Inclusion criteria**

Patients  $\leq$  70 years with no history of previous cancer, presenting with a unilateral invasive carcinoma less than 3 cm, no clinically involved axillary lymph nodes, and non-metastatic disease (N0 M0).

#### **Exclusion criteria**

**Population** number of patients = 658

Group A (axillary dissection) n=326

Group B (axillary RT) n=332

Mean age at randomization 52 years in group A and 50.6 years in group B.

19% (126/658) of tumours were  $\leq$ 1cm.

48% (314/658) of tumours were 1-2cm.

33% (218/658) of tumours were larger than 2cm.

#### **Interventions**

All patients had a wide local excision and breast irradiation. Randomisation was to axillary dissection (group A) or axillary RT (group B).

Axillary dissection (group A) was limited to the Level I and lower Level II nodes (inferior to the axillary vein). After axillary dissection those patients with metastatic nodes received RT to the supraclavicular and internal mammary lymph nodes. Patients with a central or medial tumour also received systematic radiation therapy to the internal mammary lymph nodes.

In group B, no axillary dissection was performed. Irradiation to the breast included radiotherapy to axillary and internal mammary lymph nodes.

All patients received radiotherapy to the breast at a dose of 55 Gy, over 6 weeks.

All patients received a boost of 10 to 15 Gy to the tumour bed.

Axillary nodes received a 50-Gy dose; internal mammary nodes and supraclavicular nodes received a 45-Gy dose.

ER positive postmenopausal women received tamoxifen depending on physician choice.

Patients with more than one metastatic lymph node received adjuvant hormonal or chemotherapy depending on menopausal status.

#### **Outcomes**

Overall survival

Disease free survival

Metastases

Local recurrences

Axillary recurrence (isolated) – considered to be lymph node recurrences.

NB Recurrences in the supraclavicular lymph node considered to be metastases.

#### **Follow up**

Patients had a physical examination every 3 months for 1 year, then every 6 months for 5 years, and annually thereafter.

Mammography was performed annually.

Median follow-up was 180 months (range 12-221 months).

11 patients lost to follow-up at 5 years, and 58 at 10 years.

## Results

There were more patients aged less than 35 years in group B (n=26) than in group A (n=9). More patients in Group A received chemotherapy (19 vs. 9) and hormonal therapy (14 vs. 8) than those in Group B.

322 patients had an axillary dissection (320 in group A, 2 in group B).

Of these 68 had metastatic lymph nodes (21%):

39 patients (57%) had one metastatic node

23 patients (34%) had two or three metastatic nodes

6 patients (9%) had more than three metastatic nodes.

Results at 60, 120 and 180 months are reported in the table below. At six months there was an overall survival advantage in the axillary dissection group, however this was not observed on later follow-up.

Table of outcomes at 60, 120, 180 months

Outcome	Time (months)	Axillary dissection		Axillary RT		P
		Kaplan-Meier estimate [%](SD)		Kaplan-Meier estimate [%](SD)		
Overall survival	60	96.6%	(1)	92.4%	(1.5)	NS
	120	86.6%	(1.9)	83.6%	(2.1)	
	180	75.5%	(2.7)	73.8%	(2.7)	
Disease free survival	60	83.3%	(2)	82.0%	(2.1)	NS
	120	72.6%	(2.5)	72.0%	(2.5)	
	180	64.3%	(2.9)	65.5%	(2.7)	
Metastases	60	10.8%	(1.7)	12.8%	(1.9)	NS
	120	18.3%	(2.2)	21.0%	(2.3)	
	180	25.8%	(2.6)	24.9%	(2.5)	
Local recurrences	60	7.2%	(1.4)	7.1%	(1.4)	NS
	120	12.6%	(1.9)	11.8%	(1.8)	
	180	17.2%	(2.4)	16.3%	(2.3)	
Axillary recurrences (isolated)	60	0.6%	(0.4)	2.2%	(0.8)	0.04
	120	1%	(0.6)	3%	(1)	
	180	1%	(0.6)	3%	(1)	

Key: SD = standard deviation; NS = not significant

The rates of overall survival, disease free survival, ipsilateral local recurrences and distant metastases or supraclavicular node involvement were not statistically different between the two groups at 180 months (15 years).

Isolated axillary recurrences (without concomitant breast recurrence) were lower in group A at 60, 120, and 180 months (5, 10, 15 years respectively): the rate was 1% in group A versus 3% in group B at 180 months (RR, 0.33; 95% CI, 0.11 to 0.98;  $P = 0.04$ ). Seventeen patients developed an axillary recurrence (five in group A and 12 in group B). Five of these had a concomitant breast recurrence. Of the remaining 12 patients with no concomitant breast recurrence, 3 were in group A and 9 in group B. One patient with a lymph node metastasis on initial axillary dissection developed an axillary recurrence.

## Author conclusions

At 15-year follow-up axillary dissection and axillary radiotherapy provide identical survival, although local control is better with axillary dissection. The morbidity of the association between sentinel node biopsy and subsequent axillary radiotherapy remains to be evaluated.

## General comments -

Wallgren, A., Arner, O., Bergstrom, J., Blomstedt, B., Granberg, P. O., Raf, L., Silfversward, C., & Einhorn, J. 1986, "Radiation therapy in operable breast cancer: results from the Stockholm trial on adjuvant radiotherapy.[erratum appears in Int J Radiat Oncol Biol Phys 1987 Jan;13(1):149]", *International Journal of Radiation Oncology, Biology, Physics*, vol. 12, no. 4, pp. 533-537.

Design: RCT (1971-1976) Level 1+

Country: Sweden, setting: 5 surgical departments in Stockholm

Aim: To update an earlier study of pre- and postoperative radiotherapy in operable breast cancer.

**Inclusion criteria**

Women aged less than 71 years with Stage I-III operable breast cancer

**Exclusion criteria**

Not reported.

**Population** number of patients = 960

Mean age 54.4 years (28-70 years)

Pre-menopausal 38.7%

Postmenopausal 61.3%

Medial tumour 20.7%

Lateral tumour 55.9%

Other site 23.4%

Clinical stage I 11.6%

II 77.1%

III 11.3%

**Interventions**

Patients were stratified by age (< 50 years or older), node status (N0 or N1), tumour size ( $\leq 20$ , 21-50, or  $> 50$ mm) and randomised to 3 groups:

Preoperative RT

Postoperative RT

Surgery alone (control)

Surgery consisted of a total mastectomy and axillary dissection with preservation of the pectoral muscles (modified radical mastectomy).

Radiotherapy total dose was 45 Gy.

Radiotherapy target volumes for the first 2 years were the chest wall and preoperatively the breast, axillary, supraclavicular and both internal mammary lymph node chains (IMC) (n=327). To decrease the risk of radiation pneumonitis the contralateral IMC were excluded during the remaining period (n=588).

Surgery was delayed for 6 weeks after preoperative RT.

**Outcomes**

Local and regional recurrence only counted if occurring before or in combination with distant metastases)

Relapse free survival (survival to loco-regional or distant relapse or death from any cause)

Overall survival

Breast cancer deaths (when metastatic disease known )

Time to first event, relapse or death.

**Follow up**

All patients were followed to death or the end of 1984.

8-14 years, mean 11 years.

**Results**

*Recurrence*

An improvement in recurrence free survival was found in the two irradiated groups, this did

not decrease over time (Kaplan-Meier curve).

The ratio of recurrence rates for irradiated patients vs. surgery alone is shown in the table. After 10 years the ratio of 1.04 indicates a similar rate of events between RT and surgery alone groups.

The mean difference in time to first event, relapse or death between RT groups and surgery alone was 15 months (SE 3.6 months).

The frequency and sites of recurrence within the chest wall, nodes or distant recurrences for the first 8 years are shown in the table. More surgery only patients experienced a recurrence than irradiated patients. Although distant metastases were also more frequent in the surgery only group, the difference was not significant (p value not reported).

*Cumulative incidence of locoregional disease*

The cumulative incidence of locoregional disease in histologically confirmed node negative patients at 11 years was 2.5% in those irradiated postoperatively and 20% in the surgery only group (p<0.001).

In patients with lymph node metastases the corresponding cumulative incidence was 13% after RT and 45% for surgery alone (p<0.001).

The graph of cumulative incidence (in the original paper) for node negative and node positive disease in the 2 groups (postoperative RT vs. surgery alone) showed a higher incidence in node positive patients with no statistically significant difference between postoperative RT and no RT groups (p=0.09). Similarly for node negative patients the cumulative incidence is lower and not statistically significantly different between the 2 groups (p=0.78).

*Cumulative incidence of distant metastases*

No difference was found between postoperative RT and no RT groups with node negative disease (Approx 20% at 11 years, p=0.82). The cumulative incidence was higher for node positive patients, but a lower rate of distant metastases occurred following postoperative RT (47% at 11 years) than for the no RT group (60% at 11 years, p=0.01).

<b>OUTCOME OF INTEREST</b>	<b>Time period</b>	<b>RT vs. Surgery</b>	
Recurrence rate	Entire period	0.65 (p<0.001)	
	0-5 years	0.63 (p<0.001)	
	5-10 years	0.64 (p=0.002)	
	After 10 years	1.04	

<b>Frequency and site of recurrence at 8 years</b>	<b>RT group n (%) 639 patients</b>	<b>No RT group n (%) 321 patients</b>	
All chest wall	33 (5.2)	62 (19.3)	
All nodes	19 (3.0)	42 (13.1)	
All distant	191 (29.9)	110 (34.3)	
Chest wall + nodes	46 (7)	84 (26)	P<0.001
All recurrences	199 (31.1)	135 (42.1)	

*Survival*

There were 372 deaths from all causes.

Surgery only 132 deaths

Preoperative RT 121 deaths

Postoperative RT 119 deaths.

The difference of 5% between irradiated and non-irradiated patients at 8 years was not statistically significant.

The cumulative incidence of breast cancer deaths for node negative patients was not statistically significantly different between postoperative RT and surgery alone (approx 7% from survival curve, p=0.78). The survival gain for node positive patients in the postoperative RT group (54%) at 8 years vs. 47% in the surgery only group was also not statistically

significant (p=0.09).

*Subgroup analyses*

The ratio of death rates was generally lower for the irradiated patients but none of the factors compared reached statistical significance.

Subgroup	N of patients Pre or postoperative RT (n=639). Surgery (n=321)	Ratio of death rates RT/no RT	P value
Clinical stage			
Stage 1	140	0.70	0.43
Stage 2	702	0.79	0.07
Stage 3	118	1.23	0.39
Menopausal status			
Premenopausal	335	0.85	0.44
Postmenopausal	625	0.88	0.35
Site of tumour			
Medial	202	0.69	0.12
Central	229	1.11	0.66
Lateral	529	0.86	0.29
Treatment of internal mammary nodes			
Bilateral	372	0.76	0.10
Ipsilateral	588	0.97	0.85
All patients	960	0.88	0.24

**Author conclusions**

Preoperative radiotherapy reduced the incidence of local and regional recurrence and of distant metastases (in node positive patients), and also the mortality, as compared with the surgery only group. Postoperative radiotherapy as given in this trial gave almost equal reduction of local and regional recurrence but did not diminish the frequency of distant metastases or the mortality.

**General comments -**

Fisher, B., Jeong, J. H., Anderson, S., Bryant, J., Fisher, E. R., & Wolmark, N. 2002, "Twenty-five-year follow-up of a randomized trial comparing radical mastectomy, total mastectomy, and total mastectomy followed by irradiation.[see comment]", *New England Journal of Medicine*, vol. 347, no. 8, pp. 567-575.

Design: RCT (1971-1974) Level 1++

Country: USA, setting:

Aim: To determine whether patients with either clinically negative or clinically positive axillary nodes who received local or regional treatments other than radical mastectomy would have outcomes similar to those achieved with radical mastectomy.

This RCT was also included in **Chapter 5.4** (Which groups of patients should receive chest wall radiotherapy after mastectomy?) and is duplicated here.

**Inclusion criteria**

Women with primary operable breast cancer

**Exclusion criteria**

**Population** number of patients = 1665 randomized

A total of 1079 women with clinically negative axillary nodes:

Radical mastectomy (RM) n=362

Total mastectomy (TM) without axillary dissection but with postoperative irradiation (RT) n=352

Total mastectomy plus axillary dissection n=365 (only if they developed positive nodes)

A total of 586 women with clinically positive axillary nodes:

Radical mastectomy n=292

Total mastectomy without axillary dissection but with postoperative regional irradiation (n=294).

About 70% of women in each group were 50 years or older at time of entry. On pathological examination, the mean (SD) diameter of the largest tumour was 3.3 +/- 2.0 cm in women with negative nodes and 3.7 +/- 2.0 cm in women with positive nodes.

**Interventions**

Radiotherapy was delivered with supervoltage equipment. Women with negative nodes received 50 Gy in 25 fractions; node positive women received an additional boost of 10 to 20 Gy. A dose of 45 Gy in 25 fractions was delivered to both the internal mammary nodes and the supraclavicular nodes. Tangential fields were used to treat the chest wall with 50 Gy in 25 treatments. None of the women received adjuvant systemic therapy.

**Outcomes**

Disease free survival (DFS)

Relapse free survival

Distant disease free survival

Overall survival

**Follow up**

87% were followed for at least 25 years. Data collected up to March 2001.

**DFS and RFS**

Outcomes for disease free survival and recurrence free survival at 25 years follow-up by node status are reported in the Table below. There were no significant differences between treatment groups for either of these outcomes at 25 years in node positive and node negative participants.

OUTCOME OF INTEREST	Radical mastectomy (RM)	Total mastectomy and irradiation	Total mastectomy (TM)	Statistic
---------------------	-------------------------	----------------------------------	-----------------------	-----------

<b>(TM+RT)</b>				
<b>DFS (25 yrs) NO</b>	19% (SE2%)	13% (SE2%)	19% (SE2%)	$p=0.65$
Hazard Ratios (not clear from paper which is the reference set)	RM vs. TM+RT: 1.06 (95% CI 0.90 to 1.25, $p=0.49$ ) TM vs. RM: 1.07 (95% CI 0.91 to 1.27, $p=0.39$ ) TM+RT vs. TM: 1.02 (95% CI 0.87 to 1.21, $p=0.78$ )			
<b>DFS (25 yrs) Positive nodes</b>	11% (SE2%)	10% (SE2%)		
Hazard Ratio	RM vs. TM+RT: 1.12 (95% CI 0.94 to 1.33, $p=0.20$ )			
<b>RFS (25 yrs) NO</b>	53% (SE3%)	52% (SE4%)	50% (SE3%)	$p=0.46$
Hazard Ratios	RM vs. TM+RT: 0.96 (95% CI 0.76 to 1.21, $p=0.74$ ) TM vs. RM: 1.14 (95% CI 0.91 to 1.42, $p=0.27$ ) TM+RT vs. TM: 1.18 (95% CI 0.94 to 1.48, $p=0.15$ )			
<b>RFS (25 yrs) Positive nodes</b>	36% (SE3%)	33% (SE3%)		
Hazard Ratio	RM vs. TM+RT: 1.09 (95% CI 0.89 to 1.35, $p=0.40$ )			

### **Time to first event**

Twenty percent of women with negative nodes and 13% of women with positive nodes were alive and event-free after 25 years of follow-up (See Table below). Most first events were related to distant recurrences of tumour and to deaths unrelated to breast cancer, irrespective of node status. The detection of cancer at other sites was relatively infrequent. There was little difference in the frequency of events either among the groups with negative nodes or between those with positive nodes (no statistical data were provided for these comparisons).

### **Node negative**

There was a statistically significant difference between the 3 groups of women with negative nodes for the cumulative incidence of local or regional recurrence ( $p=0.002$  for 3 way comparison). The rate was lowest in the total mastectomy with RT group, indicating a significant benefit of RT in reducing local recurrence. In contrast there were no statistically significant differences between the 3 groups in the cumulative incidence of distant recurrence as a first event ( $p=0.61$ ). [p values were reported in the Figures associated with these findings in the original paper].

Event	Women with negative nodes			Women with positive nodes		All (N=1665)
	RM (n=362)	TM (n=365)	TM+RT (n=352)	RM (n=292)	TM+RT (n=294)	
Any event	281 (78%)	287 (79%)	292 (83%)	254 (87%)	258 (88%)	1372 (82%)
Any recurrence	135 (37%)	156 (43%)	131 (37%)	165(57%)	168(57%)	755 (45%)
Local	19 (5%)	26 (7%)	5 (1%)	23 (8%)	8 (3%)	81 (5%)
Regional	15 (4%)	23 (6%)	15 (4%)	22 (8%)	33 (11%)	108 (6%)
Distant	101 (28%)	107 (29%)	111 (32%)	120 (41%)	127 (43%)	566 (34%)
Contralateral breast cancer	19 (5%)	26 (7%)	32 (9%)	13 (4%)	15 (5%)	105 (6%)
2 <sup>nd</sup> primary cancer	23 (6%)	19 (5%)	28 (8%)	12 (4%)	17 (6%)	99 (6%)
Dead, no evidence of cancer	104 (29%)	86 (24%)	101 (29%)	64 (22%)	58 (20%)	413 (25%)
Alive, event free	81 (22%)	78 (21%)	60 (17%)	38 (13%)	36 (12%)	293 (18%)

KEY:

Any recurrence excludes contralateral breast recurrence

Second primary cancers exclude breast cancers

### **Positive nodes**

Among women with positive nodes, there were no significant differences between the RM and TM + irradiation groups for cumulative incidence of local or regional recurrence ( $P=0.67$ ). Similarly there were no significant differences between the RM and TM + irradiation groups for the incidence of regional recurrence or the incidence of distant recurrence ( $P=0.44$ ). However there was a significant reduction in the incidence of local recurrence after radiation therapy. [p values were reported in the Figures associated with these findings in the original paper].

### **Distant-Disease-free Survival and Overall Survival**

There were no significant differences in distant-disease-free survival among the groups of women

with negative nodes at 25 years ( $p = 0.63$  for the three-way comparison). Among women with positive nodes, there was no significant difference in distant-disease-free survival between the radical mastectomy and total mastectomy plus radiation therapy groups (See Table below).

There was no significant difference in overall survival among the groups of women with negative nodes at 25 years ( $p=0.68$  for the three-way comparison). In women with positive nodes there was also no significant difference in overall survival between the radical mastectomy and total mastectomy plus radiation therapy groups (See Table below).

OUTCOME OF INTEREST	Radical mastectomy (RM)	Total mastectomy and irradiation (TM+RT)	Total mastectomy (TM)	Statistic
<b>Distant-DFS (25 yrs) NO</b>	46% (SE3%)	38% (SE3%)	43% (SE3%)	$p=0.63$
Hazard Ratios	RM vs. TM+RT: 1.08 (95% CI 0.88 to 1.34, $p=0.44$ ) TM vs. RM: 1.10 (95% CI 0.89 to 1.35, $p=0.39$ ) TM+RT vs. TM 1.02 (95% CI 0.83 to 1.25, $p=0.85$ )			
<b>Distant-DFS (25 yrs) Positive nodes</b>	32% (SE3%)	29% (SE3%)		
Hazard Ratio	RM vs. TM+RT: 1.07 (95% CI 0.87 to 1.32, $p=0.51$ )			
<b>Overall Survival (25 yrs) NO</b>	25% (SE3%)	19% (SE2%)	26% (SE3%)	$p=0.68$
Hazard Ratios	RM vs. TM+RT: 1.08 (95% CI 0.91 to 1.28, $p=0.38$ ) TM vs. RM: 1.03 (95% CI 0.87 to 1.23, $p=0.72$ ) TM+RT vs. TM 0.96 (95% CI 0.81 to 1.13, $p=0.60$ )			
<b>Overall Survival (25 yrs) Positive nodes</b>	14% (SE2%)	14% (SE2%)		
Hazard Ratio	RM vs. TM+RT: 1.06 (95% CI 0.89 to 1.27, $p=0.49$ )			

### **Positive Axillary Nodes after Total Mastectomy without Radiation Therapy**

A total of 68 of 365 women with negative nodes who underwent total mastectomy without radiation therapy (18.6%) subsequently developed pathologically positive ipsilateral nodes. Involved nodes were identified within 2 years after surgery in 51 of the 68 women, > 2 < 5 years after surgery in 10 women, >5 <10 years after surgery in 6 women, and > 10 < 25 years after surgery in 1 woman. The median time from mastectomy to the identification of positive axillary nodes was 14.8 months (range, 3.0 to 134.5).

### **Author conclusions**

The findings validate earlier results showing no advantage from radical mastectomy. Although differences of a few percentage points cannot be excluded, the findings fail to show a significant survival advantage from removing occult positive nodes at the time of initial surgery or from radiation therapy.

### **General comments –**

In the discussion the authors report that an important finding of the study was that about 40% of women with clinically negative nodes treated with radical mastectomy had pathological confirmation of tumour-positive axillary lymph nodes. Since the women were randomized to treatment groups, an estimate of about 40% of those undergoing total mastectomy alone having positive nodes that were not removed at the time of initial surgery is also assumed. About half of these women subsequently received a diagnosis of positive axillary nodes as a first event. Some investigators suggest that the frequency of delayed occurrence of positive axillary nodes is underestimated because patients with nodes that became positive after a distant recurrence should also have been included in the analysis. They suggest that axillary dissection in all women with clinically negative axillary nodes is justified. This suggestion may be relevant to achieving local control of disease; however, the data from this trial indicate that leaving positive nodes unremoved did not significantly increase the rate of distant recurrence or breast-cancer-related mortality.

Another point was made about there being no survival advantage for the RT plus total mastectomy group with negative nodes at 25 years follow-up. These findings agree with two other studies at 10 year follow-up (Cancer Research Campaign. Br Med J 1976;1:1035-8;

Cancer Research Campaign Working Party Lancet 1980;2:55-60), but differ from 3 studies reporting a 10% decrease in overall survival (Overgaard *et al* 1997, 1999; Ragaz *et al* 1997). They suggest that the use of systemic therapies in conjunction with postoperative RT may have relevance to these variations.

Ragaz, J., Olivotto, I. A., Spinelli, J. J., Phillips, N., Jackson, S. M., & Wilson 2005, "Locoregional radiation therapy in patients with high-risk breast cancer receiving adjuvant chemotherapy: 20-year results of the British Columbia randomized trial", *Journal of the National Cancer Institute*, vol. 97, no. 2, pp. 116-126.

Design: RCT (1979-1986) Level 1++  
 Country: Canada, setting: Multi-centre  
 Aim: To determine the survival impact of locoregional radiation therapy in premenopausal patients with lymph node-positive breast cancer treated by modified radical mastectomy and adjuvant chemotherapy.

**Inclusion criteria**

Premenopausal women with breast cancer and pathologically positive axillary lymph nodes.

**Exclusion criteria**

Distant metastases, no other concomitant malignant disease. Macroscopic residual tumour.

**Population** number of patients = 318

**Interventions**

Modified radical mastectomy and axillary lymph node dissection before randomization  
 N=164 received RT and chemotherapy  
 N=154 received chemotherapy alone.  
 128 ER positive patients were further randomized to oophorectomy or no oophorectomy.  
 RT given by 5 field technique:  
 Chest wall 37.5Gy in 16 daily fractions for 3-4 weeks  
 Mid axilla dose of 35Gy in 16 fractions (supraclavicular/axillary field)  
 Internal mammary-chain (bilateral) 37.5Gy in 16 fractions.

**Outcomes**

Event free survival (interval from date of diagnosis to: locoregional or systemic breast cancer recurrence, second malignancy, death from any cause).  
 Disease free survival: (interval from date of diagnosis to date of first breast cancer recurrence-locoregional or systemic).  
 Systemic disease-free survival (interval from date of diagnosis to date of first systemic breast cancer recurrence).  
 Breast cancer-specific survival.  
 Overall survival (diagnosis to date of death from any cause).  
 Locoregional recurrence (in chest wall or regional lymph node areas- axillary, supraclavicular, internal mammary areas).

**Follow up**

20 year follow-up (median follow up for live patients: 249 months)

**Results**

A median of 11 axillary nodes were removed.  
 191/318 had suffered a breast relapse  
 190/318 had died (170 from breast cancer and 20 from other causes).

*Locoregional recurrence*

Isolated locoregional recurrences and any locoregional recurrences before systemic relapse were reduced in the RT arm in comparison to no RT. Consequently survival free of isolated locoregional and locoregional recurrence at any time was significantly improved in the RT arm compared with no RT. (See Table below):

Outcome	RT + chemotherapy	Chemotherapy	Relative Risk (95% CI)
Isolated locoregional recurrence	12/164 (7%)	27/154 (18%)	RR= 0.36 (95% CI, 0.18 to 0.71; P = 0.002) Favours RT
Survival free of isolated locoregional recurrence	90%	74%	
Any locoregional recurrence before systemic relapse	17/164 (10%)	43/154 (28%)	

Survival free of locoregional recurrence at any time	87%	61%	RR= 0.32 (95% CI, 0.18 to 0.57; <i>P</i> < 0.001) Favours RT
--	-----	-----	---

### Survival

Survival outcomes at a follow-up of 20 years are shown in the Table below.

Fewer events occurred amongst patients assigned to RT and chemotherapy for all outcomes (upper section of table). All survival Relative Risk values favoured the RT arm compared with no RT.

Outcome	Chemotherapy		RT + chemotherapy		RR (95% CI) p
	Survival (%)	n events/N patients	Survival (%)	n events/N patients	
Event free survival	25	116/154	35	105/164	0.70 (0.54 to 0.92) p=0.009
Breast cancer free survival	30	107/154	48	84/164	0.63 (0.47 to 0.83) p=0.001
Systemic breast cancer free survival	31	104/154	42	84/164	0.66 (0.49 to 0.88) p=0.004
Breast cancer specific survival	38	95/154	53	75/164	0.67 (0.49 to 0.90) p=0.008
Overall survival	37	101/154	47	89/164	0.73 (0.55 to 0.98) p=0.03

### Comparison by lymph node status

Event free survival					
N1-3 (n=183)	32	62/92	44	51/91	0.71 (0.49 to 1.03)
N≥ 4 (n=112)	12	47/54	26	44/58	0.68 (0.45 to 1.03) *P=0.8
Breast cancer free survival					
N1-3 (n=183)	41	53/92	57	38/91	0.64 (0.42 to 0.97)
N≥ 4 (n=112)	12	47/54	34	38/58	0.59 (0.38 to 0.91) *P=0.7
Systemic breast cancer free survival					
N1-3 (n=183)	44	50/92	58	38/91	0.68 (0.45 to 1.04)
N≥ 4 (n=112)	11	47/54	33	38/58	0.63 (0.41 to 0.97) *P=0.7
Breast cancer specific survival					
N1-3 (n=183)	53	43/92	64	31/91	0.67 (0.42 to 1.06)
N≥ 4 (n=112)	17	46/54	35	37/58	0.66 (0.43 to 1.01) *P=0.9
Overall survival					
N1-3 (n=183)	50	49/92	57	41/91	0.76 (0.50 to 1.15)
N≥ 4 (n=112)	17	46/54	31	40/58	0.70 (0.46 to 1.06) P=0.7

\*P = p value for interaction between subgroups for lymph node status

A further subgroup analysis was conducted by lymph node status (lower section of table): Analysis was by N1-3 vs. N≥4. All survival outcomes were consistently improved with the addition of RT. There were no statistically significant differences between survival outcomes for the N1-3 subgroup compared with N≥4.

The authors suggest that optimal locoregional therapy for high risk breast cancer may involve adequate axillary surgery and RT, but also RT to the internal mammary chain. It is not possible to determine from this study whether the benefit of radiation therapy observed would be compromised if the irradiated fields to the IMC were reduced (ipsilateral vs. bilateral).

### Toxicity

The rate of non-breast cancer deaths was 8.5% (14/164) among patients treated with CT and RT, compared to 3.8% (6/154) of patients treated with CT alone (p=0.11).

Three (1.8%) cardiac deaths occurred in the CT+RT group vs. one (0.6%) in the CT group (p=0.622).

Arm oedema occurred in 15 (9.1%) of the CT+RT group, and 5 (3.2%) of the CT group (p=0.035). Six vs. one required intervention.

Limited asymptomatic apical lung fibrosis was seen in all RT treated patients, one (0.6%) developed interstitial pneumonitis.

**General comments -**

Overgaard, M., Jensen, M.-B., Overgaard, J., Hansen, P. S., Rose, C., Andersson, M., Kamby, C., Kjaer, M., Gadeberg, C. C., Rasmussen, B. B., Blichert-Toft, M., & Mouridsen, H. T. 1999, "Postoperative radiotherapy in high-risk postmenopausal breast-cancer patients given adjuvant tamoxifen: Danish Breast Cancer Cooperative Group", *Lancet*, vol. 353, no. 9165, pp. 1641-1648

Design: RCT (1982-1990)

Level 1++

Country: Sweden, setting: Multi-centre

Aim: To compare adjuvant tamoxifen alone with tamoxifen plus postoperative radiotherapy in a randomised trial among postmenopausal women who had undergone mastectomy.

#### **Inclusion criteria**

Postmenopausal women with high-risk breast cancer, younger than 70 years of age. High risk status was defined as node positive, tumour size greater than 5 cm, invasion to skin or pectoral fascia, or any combination of these. Postmenopausal status defined as 5 years or more of amenorrhoea or, for women who had undergone hysterectomy, age over 55 years.

#### **Exclusion criteria**

Metastatic distant disease, macroscopic residual tumour.

**Population** number of patients = 1375 evaluable (1460 randomized)

Median age 62 years (range, 42-69 years).

Median tumour size 2.5cm (range, 0.2-13cm)

N0 n=132 (10%)

N1-3 n=794 (58%)

N>3 n=448 (33%)

Stage I 24%

Stage II 44%

Stage III 16%

Tumour size:

<2.1cm 38%

2.1-5.0cm 49%

>5.0cm 12%

#### **Interventions**

Surgery was total mastectomy with axillary-node dissection (removal of the central axillary lymph nodes involving level I and part of level II). The pectoral fascia was stripped leaving the major and minor pectoral muscles. A median of 7 lymph nodes were removed.

Radiotherapy target volume included the surgical scar and regional lymph nodes (the supraclavicular, infraclavicular, and axillary nodes, and internal mammary nodes in the four upper intercostal spaces). The dose was 50.0 Gy in 25 fractions in 35 days, or 48.0 Gy in 22 fractions over 38 days.

Randomization was to adjuvant tamoxifen (30 mg daily for 1 year) alone (689) or with postoperative radiotherapy to the chest wall and regional lymph nodes (686).

#### **Outcomes**

Overall survival (all deaths from any cause)

Locoregional recurrence was first site of failure (chest wall, axilla, supra/infraclavicular), alone or together with distant metastases (diagnosed within 1 month).

Disease-free survival was defined as freedom from locoregional or distant recurrence, cancer in opposite breast, other malignant disease, or death without recurrence.

#### **Follow up**

Median follow-up 123 months, and for those alive at the time of evaluation 119 months (range 77-166).

#### **Results**

Median time to death 46 months (range, 1-160 months).

732/1376 (53%) developed a recurrence.

819 patients had died (59%) at time of analysis.

*Local and distant recurrence*

Overall frequency of locoregional recurrence as first site of recurrence was 8% in RT + tamoxifen group and 35% in the tamoxifen only group.

*Overall survival*

There was a 9% absolute benefit in OS for the RT + tamoxifen group (45% [95% CI 41-49] vs. 36% [95% CI 33-40])

Site of first recurrence	RT plus tamoxifen (n=686) (%)	Tamoxifen only (n=689)	All patients (N=1375)
Distant metastases	269 (39%)	169 (25%)	438 (32%)
Locoregional	30 (4%)	203 (29%)	233 (17%) (p<0.001)
Distant metastases and locoregional	22 (3%)	39 (6%)	61 (4%)
All recurrences	321 (47%)	411 (60%)	732 (53%)

Site	(n=637)	(n=444)	(n=1081)
Chest wall	31 (16)	123 (17)	154 (33)
Axillary nodes	9 (2)	73 (8)	82 (10)
Supra/infraclavicular	7 (2)	29 (8)	36 (10)
Axilla and chest wall	3 (1)	9 (2)	12 (3)
Axilla and S/I nodes	0	5 (2)	5 (2)
Chest wall and S/I	2 (1)	3 (2)	5 (3)
All recurrences	52 (22)	242 (39)	294 (61)

Numbers in parentheses = numbers with concurrent distant metastases

The major prognostic factors in primary breast cancer were found to be tumour size, number of affected nodes, and grade of cancer from a multivariate analysis. The addition of RT seemed to be beneficial.

The addition of RT reduced locoregional recurrence. Most recurrences were in the chest wall for both treatment groups. Recurrences at other regional sites were generally lower with RT (test of significance not reported). Supraclavicular and infraclavicular recurrences were associated with distant recurrences in both groups. Axillary and chest wall recurrences more commonly occurred alone.

In patients with less advanced disease (tumours < 5cm) disease-free survival (37% [95% CI 32-42] for RT vs. 25% [21-30] for tamoxifen only; p<0.01) and overall survival (47% [95% CI 42-52] for RT vs. 40% [35-44] for tamoxifen only, p<0.07) were better in the RT group.

The survival analysis results shown in the table below indicate an effect of time since surgery on survival, with the RT group benefiting the most, and those with fewer positive nodes benefiting most in the short term. For long-term effects, the number of positive lymph nodes, and radiotherapy, were the only variables of independent significant importance.

**Cox proportional hazard model by time since surgery**

Adjusted estimates	Any recurrence after 2 years (n=879)		Death after 4 years (n=877)	
	Relative risk (95% CI)	p	Relative risk (95% CI)	p
Positive nodes				
0-3	1.00		1.00	
>3	2.18 (1.80-2.64)	<0.001	1.97 (1.58-2.45)	<0.001
Radiotherapy				
Tamoxifen alone	1.00		1.00	
RT and tamoxifen	0.64 (0.54-0.77)	<0.001	0.68 (0.55-0.83)	<0.001

**Author conclusions**

Postoperative radiotherapy decreased the risk of locoregional recurrence and was associated with improved survival in high-risk postmenopausal breast cancer patients after mastectomy and limited axillary dissection, with 1 year of adjuvant tamoxifen treatment. Improved survival in high-risk breast cancer can best be achieved by a strategy of both locoregional and systemic

tumour control.

**General comments -**

Olivotto, I. A., Chua, B., Elliott, E. A., Parda, D. S., Pierce, L. J., Shepherd, L., Vallow, L. A., White, J. R., & Whelan, T. J. 2003, "A clinical trial of breast radiation therapy versus breast plus regional radiation therapy in early-stage breast cancer: The MA20 trial", *Clinical Breast Cancer*, vol. 4, no. 5, pp. 361-363.

Design: RCT – description of procedures  
Country: Multinational, setting: Hospital

**Inclusion criteria**

Patients with invasive breast cancer who are node positive (if node negative then tumour size > 2.0cm); BCS plus axillary sampling; systemic therapy with chemotherapy, hormones or both; moderate to high risk of regional recurrence; ECOG performance status of 0-2 and life expectancy > 5 years.

**Exclusion criteria**

Metastatic or locally advanced disease; residual disease in axilla after dissection; pregnancy.

**Population** number of patients = 784 in Dec 2003, planned accrual 1822.

**Interventions**

Stratification of patients by number of positive nodes, number of nodes removed, type of chemotherapy and/or hormonal therapy, treatment centre.

Randomization to standard breast RT vs standard breast RT + RT to the regional lymph nodes.

The axilla is treated only if there are < 4 involved nodes or < 10 lymph nodes recovered.

**Outcomes**

**Follow up**

**Results**

Recruitment complete Feb 2007.

**General comments -**

## Ongoing trials

### MA20

#### **A Phase III Study of Regional Radiation Therapy in Early Breast Cancer**

Eligibility: Pre or post menopausal women with node positive and high risk node-negative breast cancer treated by breast conserving therapy and currently accepted adjuvant chemotherapy and/or hormonal therapy

Objectives: To determine if regional radiation therapy (to the ipsilateral supraclavicular, axillary and internal mammary nodes) in addition to breast radiation prolongs survival in women with early breast cancer compared with breast radiation alone. To compare disease free survival, isolated local regional disease-free survival, and distant disease free survival. To evaluate toxicity. To evaluate quality of life. To determine the cosmetic outcome of these two treatment approaches.

NCT Registration ID (from clinicaltrials.gov): NCT00005957

Participation: Not limited.

Coordination: Intergroup(NCIC CTG)

Status: Closed

Activation Date: December 14, 1999 , Closing Date: February 02, 2007

Chairs: (Canada) Dr. Timothy J. Whelan, Juravinski Cancer Centre at Hamilton Health Sciences, 1(905) 387-9711 Ext. 64509

## Observational Studies (e.g. Prospective Cohort or Retrospective Cohort or Case Series):

### Surgery and radiotherapy to the breast (and tumour bed) with or without regional RT to nodes

Livi, L., Paiar, F., Simontacchi, G., Barca, R., Detti, B., Fondelli, S., Bastiani, P., Santini, R., Scotti, V., Bianchi, S., Cataliotti, L., Mungai, V., & Biti, G. 2006, "Loco regional failure pattern after lumpectomy and breast irradiation in 4185 patients with T1 and T2 breast cancer. Implications for nodal irradiation", <i>Acta Oncologica</i> , vol. 45, no. 5, pp. 564-570		
Design: Non-randomised study (NRS) Cohort	(1980-2001)	Level 3
Country: Italy, setting: Single university centre		
Aim: To determine incidence and risk factors for loco regional failure (LRR) (breast, supraclavicular, axillary and internal mammary nodes) and indications for nodal irradiation.		
<b>Inclusion criteria</b>		
Patients without clinical and radiographic evidence of local or distant recurrence after surgery at the time of the first evaluation in the radiotherapy unit.		
No previous malignant disease.		
<b>Exclusion criteria</b>		
<b>Population</b> number of patients = 4185		
Median age 55 years (range 19-86)		
pT1	66.4%	
pT2	33.6%	
N0	69%	
N1-3	20%	
N>3	9%	
ER negative	14%	
ER positive	55%	
Unknown	31%	
<b>Interventions</b>		
Wide excision n=919		
Quadrantectomy n=3266		
Axillary dissection n=3889 (93%)- median 16 nodes removed.		
RT to whole breast with tangential fields (mean dose 50Gy in 2Gy fractions, photons), then tumour bed boost (6-10Gy for negative margins and 14-16Gy positive margins, electrons).		
972 (23.3%) did not receive a boost.		
No RT to nodes.		
924 (21%) received chemotherapy.		
1504 (36%) received tamoxifen.		
<b>Outcomes</b>		
Locoregional recurrence (LRR) –in breast, supraclavicular, axillary and internal mammary nodes. Defined as first site of recurrence and when loco-regional failure was followed by distant metastases not before 6 months.		
Node relapse (NR) any relapse in axilla, internal mammary chain or supraclavicular fossa.		
Supraclavicular relapse (SCR)		
<b>Follow up</b>		
Median 8 years (range 3mths to 20 years)		
<b>Results</b>		
Most of the data were descriptive, however a multivariate analysis was also conducted using variables considered to be of clinical significance as well as statistically significant variables.		
<i>Survival</i>		
Breast cancer deaths	526/4185	(12.5%)
Other deaths	176/4185	(4.2%)
Alive	3512/4185	(83.9%)
Actuarial cause specific survival:		

3 years 5 years 10 years  
 96.9% (SE± 0.2%) 93.1% (SE± 0.4%) 83.7% (SE± 0.6%)

**Locoregional recurrence**

LRR median time for all relapses 3.9 years (6 mths-19 years)

224/4185 (5.3%) had locoregional failure.

Median time to node relapse 2.7 years

Site of relapse:

Breast 166/4185 (3.9%)

NR (any relapse in axilla, internal mammary chain or supraclavicular fossa) 58/4185 (1.3%)

SCR (supraclavicular relapse) 33/4185 (0.7%)

The distribution of sites of recurrence in breast and node areas are listed in the table below:

**Sites of locoregional recurrences**

Site of recurrence	N of patients (n=224/4185)	%
Breast		
Non-operated quadrant	46	17
Index quadrant	110	36
Unknown quadrant	8	3
Multicentric relapse	2	0.7
Supraclavicular	33	15
Axilla	14	6
Internal mammary chain	11	5

(Note- percentage values do not add up to 100)

Rates of locoregional recurrences by site are listed in the following table:

Outcome	3 year actuarial rate	5 year actuarial rate	10 year actuarial rate
LRR	2.3% (SE± 0.2%)	4.3% (SE± 0.4%)	7.4% (SE± 0.5%)
SCR	0.6% (SE± 0.1%)	0.9% (SE± 0.2%)	1% (SE± 0.1%)
NR	1.0% (SE± 0.1%)	2.0% (SE± 0.2%)	2% (SE± 0.2%)

**LRR by age group**

Less than 40 years at diagnosis LRR (14.4%, 49/339)

40-49 years LRR (8.2%, 83/1006)

50-59 years LRR (4.2% 56/1310)

60-69 years LRR (2.8%, 31/1101)

70-79 years LRR (1.2%, (5/400)

> 80 years LRR (0%, 0/29)

Higher rates of LRR were observed in younger age groups than older age groups (p=0.00001). A further analysis of LRR by site of relapse and age distribution is shown in the following table.

**Correlation between age and LRR**

Age	N of patients	Breast	Node relapse	SCR
<40 years	339	44 (12%)	5 (1.4%)	2 (0.5%)
40-49	1006	65 (6.4%)	18 (1.7%)	11 (1%)
50-59	1310	36 (2.7%)	20 (1.5%)	10 (0.7%)
60-69	1101	19 (1.7%)	12 (1%)	8 (0.7%)
70-79	400	2 (0.5%)	3 (0.7%)	2 (0.5%)
>80	29	0	0	0

Univariate analyses of LRR, NR and SCR found significantly more recurrences in pT2 tumours than pT1, and in women with N3+ than N0 axillary lymph nodes.

LRR	pT1 4% (110/2779)	pT2 9.1% (114/1406)	P=0.0002
NR	pT1 0.8% (25/2779)	pT2 2.3% (33/1406)	P=0.04
SCR	pT1 0.5% (14/2779)	pT2 1.3% (19/1406)	P=0.02
LRR	N0	N<3	P=0.3
LRR	N0	N3+	P=0.02

LRR	N1-3	N3+	P=0.05
SCR	N0 0.4% (12/2870)	N1-3 0.9% (8/823)	P=0.9
SCR	N0 0.4% (12/2870)	N3+ 3.3% (13/392)	P=0.01
NR	N0 0.8% (24/2870)	N1-3 1.7% (14/823)	N3+ 4.8% (19/392) P=0.007

Similar analyses for patients with positive angiolymphatic invasion found 6% (29/485) of LRR occurred versus 3% (61/2068) for those with negative angiolymphatic invasion ( $p=0.001$ ). When comparing positive angiolymphatic invasion with positive axillary lymph nodes, there was no statistically significant difference for NR in patients with positive lymph nodes ( $p=0.6$ ). The difference was statistically significant ( $p=0.0001$ ) for patients with negative lymph nodes.

A poorer prognosis ( $p=0.002$ ) was found in high grade tumours compared with intermediate and low-grade tumours (LRR rates of 3.1% (24/754), 1.8% (14/775) and 1.2% (7/575) respectively).

Other prognostic factors including site of tumour, extracapsular extension, multifocality and different histological types, did not show any statistical significance on univariate analysis for LRR, NR and SCR.

A multivariate analysis of prognostic factors for LRR found that Grade 3 tumour ( $p=0.01$ ), age at presentation ( $p=0.001$ ), more than three positive lymph nodes ( $p=0.004$ ), pT2 ( $p=0.001$ ) and angiolymphatic invasion ( $p=0.02$ ) were statistically significant parameters. In the multivariate analysis for NR pT2 ( $p=0.02$ ), angiolymphatic invasion ( $p=0.002$ ) and more than three positive lymph nodes ( $p=0.001$ ) were statistically significant. These findings are reported in the following tables.

#### Multivariate analysis for LRR

Parameter	Hazard ratio (95% CI)	p value
<b>Grade</b>		
G1	1	
G2	1.3 (0.5-3.2)	0.54
G3	2.6 (1.1-5.9)	0.01
<b>Age (years)</b>		
50-59	1	
< 40	2.2 (1.6-3.1)	<0.001
40-49	1.3 (1.0-1.7)	0.003
60-69	0.6 (0.4-0.9)	0.01
70-79	0.4 (0.2-0.8)	0.01
>80	0.4 (0.4-7.0)	0.45
<b>Lymph node status</b>		
Negative	1	
N+ 1-3	0.9 (0.7-1.2)	0.7
N+ >3	1.6 (1.1-2.3)	0.004
<b>Angiolymphatic invasion</b>		
None	1	
Present	1.5 (1.1-2.2)	0.002
pT1	1	
pT2	1.4	<0.001

#### Multivariate analysis for NR

Parameter	Hazard ratio (95% CI)	p value
<b>Lymph node status</b>		
Negative	1	
N+ 1-3	1.7 (0.8-3.2)	0.11
N+ >3	4.8 (2.5-9.1)	<0.001
<b>Angiolymphatic invasion</b>		
None	1	
Present	3.18 (1.4-6.8)	0.002
pT1	1	
pT2	1.8 (1.07-3.1)	0.002

**Author conclusions**

It is not necessary to prescribe nodal irradiation to patients with negative or one to three positive axillary nodes. Regarding patients with more than three positive axillary nodes, the number of isolated Nodal Relapse is also small to routinely justify a node irradiation.

**General comments -**

Fortin, A., Dagnault, A., Blondeau, L., Thuc, T. T., & Larochelle, M. 2006, "The impact of the number of excised axillary nodes and of the percentage of involved nodes on regional nodal failure in patients treated by breast-conserving surgery with or without regional irradiation", *International Journal of Radiation Oncology Biology Physics*, vol. 65, no. 1, pp. 33-39.

Design: NRS Cohort (1972-1997) Level 3

Country: Canada, setting: Single hospital

Aim: After breast-conserving surgery, recommendations for regional nodal radiotherapy are usually based on the number of positive nodes. This number is dependent on the number of nodes removed during the axillary dissection. This study examines whether the percentage of positive nodes may help to select patients for regional radiotherapy.

**Inclusion criteria**

Node positive, stage T1-T2 invasive breast cancer who had received at least 44Gy RT to the breast.

**Exclusion criteria** Not reported

**Population** number of patients = 1372

Median age 53 years (LQ 45, UQ 62)

T1 690 patients

T2 678 patients

Median number of nodes excised 11

N1-3 922 patients

N>3 446 patients (N>7 =156 patients)

472 (34%) patients had regional irradiation:

217 (23.5%) with N1-3

255 (55%) with N>3 nodes

96 (61%) with N>7 nodes

**Interventions**

Breast conservation surgery usually consisted of a lumpectomy with wide margins.

RT to the whole breast was a dose of either 50 Gy or 45 Gy in 25 or 20 fractions respectively over 4 weeks.

Those receiving regional RT were treated with 44Gy through an anterior supraclavicular-axillary field with a posterior axillary boost. The supraclavicular fossa received a dose of 40 Gy given at 3 centimeters.

Patients receiving regional RT n=477

Patients not receiving regional RT n=904

Nodal irradiation was carried out at the discretion of the radiation oncologist and varied over the years. In the first years of the study, all node-positive patients received locoregional radiotherapy. Later some oncologists only irradiated patients with more than 3 positive nodes.

**Outcomes**

Regional failure (axilla, supraclavicular)

Percentage of positive nodes was defined as the quotient of positive nodes over nodes removed.

**Follow up**

Patients were followed at regular intervals of every 3 to 6 months for the first 5 years and then every year. Median follow-up of patients not receiving regional RT was 5.4 years.

**Results**

The number of positive nodes was directly proportional to the number of nodes removed ( $p < 0.00001$ ).

**a) Impact of number of nodes removed (% of involved nodes) on axillary failure in patients not receiving regional radiotherapy**

Of 904 patients (no regional RT) 710 had N1-3 and 194 had N>3

Median follow-up 5.4 years.

Negative hormone receptor status (logrank  $p= 0.009$ ) and local failure (logrank  $p= 0.008$ ) were the only factors associated with axillary failure.

The authors reported a trend for patients with extracapsular extension (ECE) to have more axillary failure ( $p = 0.1$ ).

Those factors that were not statistically significant were:

Age <40 vs. > 40 years

T stage T1 vs T2

Number of positive nodes (N1-3, N4-8, N>8)

Histology

Grade 1 vs. grade 2-3

Node size <2cm vs > 2cm

ECE no or not specified vs. yes

Hormone therapy

Chemotherapy

*Axillary control vs. number of nodes removed*

For patients with > 10 nodes (complete) removed or incomplete axillary dissection there was no difference in axillary control in the overall group or in the subgroups of patients with 1–3 positive nodes or >3 positive nodes.

There was no difference in axillary control when patients were grouped by number of nodes removed (1–6 nodes, 7–10 nodes, 11–16 nodes, and >16 nodes). The number of nodes removed did not influence the axillary failure rate.

*Axillary control vs. percentage of positive nodes*

Positive nodes were classified into three categories:

For patients with 1–3 positive nodes:

<20%, 20–40%, and ≥40%.

For patients with >3 positive nodes:

<20%, 20–50%, and ≥50%.

Axillary control rates were found to be the same in the lower node groups (<20% and 20–40% for N1–3 or <20% and 20–50% for N>3) and were combined as (<40% for N1–3 and <50% for N > 3). The crude and 10 year axillary control rates are shown in the following table for patients not receiving regional RT.

**Axillary control and percentage of involved nodes**

Percentage involved nodes	Crude failure rates	10 year axillary control	p value (log-rank)
<b>All patients</b>			
<40	11/753 (1.5%)	97.5	0.007
≥40	7/151 (4.5%)	91.3	
<b>N 1-3</b>			
<40	9/670 (1.3%)	97.5	0.08
≥40	2/43 (4.6%)	93	
<b>N &gt;3</b>			
<50	2/84 (2.4%)	98	0.3
≥50	5/102 (4.7%)	91	

(For "All patients" percentage of involved nodes was ± 40% if N1-3 and ± 50% if N>3)

From the table there were significantly more axillary failures in patients classified as ≥40/50% when all patients were analyzed. The authors suggest that the differences between the percentage of involved nodes in N1-3 and N>3 subgroups were not significant because of low patient numbers.

Cox modelling of all Node positive patients showed that the percentage of positive nodes (hazards ratio = 3.6,  $p = 0.02$ ) and local failure (hazards ratio = 3.1,  $p = 0.04$ ) were associated with axillary failure, whilst the number of nodes removed, T stage, age, grade, and systemic

treatment were not significant.

**b) Impact of regional RT by % of involved nodes**

477 consecutive node positive patients received axillary RT.

Results for axillary, supraclavicular, regional, and locoregional control in patients receiving regional radiotherapy and those not receiving regional radiotherapy classified by node status are shown in the following table. Confidence intervals for hazard ratios were not reported, significant differences in bold font.

	Group	No regional RT (N and 10 yr control)	Regional RT (N and 10 yr control)	P value (log-rank)	Cox adjusted hazards ratio and p value	
<b>Axillary failure</b>	All N+	98% (N=904)	96.5% (N=477)	0.2	0.5 p=0.2	
	Ratio <40	97.5% (n=753)	99% (n=234)	0.7	0.5 p= 0.4

	Ratio ≥40	82%	94%	<b>0.01</b>	<b>0.32 p=0.01</b>	

**Axillary failure**

For all node positive patients regional RT was beneficial for patients classified as ≥40%/50% of positive nodes (p=0.01) from the figure of the probability of axillary control shown in the original paper. It was not beneficial for patients with lower percentages of positive nodes. In patients with N1-3 and N>3 positive nodes, regional RT also reduced axillary failure rates in patients with a high percentage of positive nodes but this was not statistically significant.

**Supraclavicular and locoregional failure**

For all node positive patients, regional RT reduced the rate of supraclavicular failure in groups of patients with a high percentage and a lower percentage of positive nodes. For N1-3 and N>3 subgroups the decrease was not statistically significant (low statistical power).

RT reduced the locoregional failure rates (axillary or supraclavicular) for all patient subgroups, although there was a tendency for those with higher ratios of involved nodes to receive regional RT (selection bias).

**Summary (from paper):**

- The number of nodes removed did not have an impact on axillary failure in node-positive patients treated by breast conserving surgery and radiotherapy to the breast alone.
- The percentage of involved nodes was associated with axillary failure. In patients with >40% (for N1–3 positive nodes) and >50% (for N > 3 positive nodes), the rates of axillary failure were significantly increased.
- In patients with a high percentage of involved nodes, regional radiotherapy was

associated with increased axillary control.

- Regional radiotherapy did not increase the rate of axillary control for patients with lower percentages of involved nodes.
- Regional radiotherapy was associated with better regional control (axillary or supraclavicular control), even among patients with lower percentages of involved nodes.

**Author conclusions**

The percentage of involved nodes should be taken into consideration in selecting patients for regional radiotherapy. Irradiation of the axilla should be reserved for patients with a specific ratio of > 40% involved nodes if N1-3 and  $\geq 50\%$  involved nodes if N > 3 nodes.

**General comments -**

Pejavar, S., Wilson, L. D., & Haffty, B. G. 2006, "Regional nodal recurrence in breast cancer patients treated with conservative surgery and radiation therapy(BCS plus RT)", *International Journal of Radiation Oncology Biology Physics*, vol. 66, no. 5, pp. 1320-1327.

Design: NRS Cohort (1973-2000) Level 3

Country: USA, setting: Single institution

Aim: To review regional lymph node management in a large cohort of conservatively treated breast cancer patients with the aim of describing treatment practices, to identify the incidence and predictors of nodal relapse.

**Inclusion criteria**

Women with Stage I to II invasive breast cancer treated with conservative surgery followed by RT to the breast.

**Exclusion criteria**

None reported

**Population** number of patients = 1920

Mean age 56.4 years, median 57 yrs. 65% ≥ 50 yrs

T1 80%

T2 20%

Negative surgical margins 52%

Unknown margins 32%

**Interventions**

All patients had conservative surgery followed by RT with tangential fields to the intact breast with 4-6 MeV linear accelerators. A median dose of 48Gy (40-60Gy) was delivered over 5-7 weeks in daily 2Gy fractions. An electron beam boost to the tumour bed of 64Gy (50-72Gy) was also applied.

1330 (69%) of patients had axillary lymph node dissection (more frequently in later years).

Most axillary dissections (AXDs) were Level I and II, and 65% had > 10 nodes sampled.

346/1330 patients (26%) had pathologically involved lymph nodes.

Regional lymph node irradiation was administered to the majority of patients.

- 1) Patients undergoing AXD (1330, 69%) were treated to the breast alone if pathologically node-negative, or to the breast and supraclavicular nodes if pathologically node-positive. There was a general policy to include the supraclavicular fossa (without axillary radiation) in all node-positive patients, including those with 1-3 positive nodes (46Gy, depth 3cm). Radiation treatment to the internal mammary nodes was highly individualized and delivered with alternating photons and 13MeV electrons (median dose 46Gy, depth 3 cm).
- 2) Patients with no AXD (590, 31%).

Supraclavicular and axillary nodes were irradiated, with or without an additional internal mammary field.

Axillary lymph nodes were irradiated by extending the lateral border of the supraclavicular field laterally to include the entire humeral head and clear all axillary contents.

A total median dose of 46 Gy at 3 cm was prescribed.

The patients undergoing SNLB are not reported in the evidence table.

Treatment characteristics reported in the paper are shown below:

**Treatment characteristics (n=1920)**

	% (n)	Median dose
--	-------	-------------

<b>Axillary dissection</b>

SC = supraclavicular  
IM = internal mammary

### Outcomes

Breast failure- histologically confirmed tumour in the ipsilateral breast.

Regional node relapse- clinical failure in the ipsilateral axilla, supraclavicular fossa, infraclavicular fossa, or internal mammary chain as first sight of failure.

Distant failure - any clinical and/or radiographic evidence of metastatic disease.

Patients with recurring carcinoma in the breast and pathologic nodes at the time of breast failure, but without clinical signs of regional nodal failure, were not classified as nodal relapses.

**Follow up** Median 13 years.

### Results

Regional nodal relapses n= 36

5 year and 10 year actuarial nodal recurrence-free rates of 98% and 97%, respectively.

The crude survival and recurrence statistics of the 1920 patients are listed in the table below.

Of these 36 relapses:

18 (50%) occurred in the axilla

14 (39%) in the supraclavicular fossa

2 (5.6%) in the infraclavicular fossa

1 (2.8%) in the internal mammary chain

1 (2.8%) in an unclear location.

More than half (20) were in-field failures.

<b>Pattern of failure</b>	<b>Percentage (n)</b>
Patient status:	
No evidence of disease (alive or dead)	89.6 (1720)
With disease (dead)	10.3 (198)
With disease (alive)	0
Unknown	0.1 (2)
Nodal relapse	1.9 (36)

Breast relapse	8.8 (169)
Distant relapse	13.6 (262)

Patterns of nodal relapse by treatment technique and node status for the 36 nodal relapses are shown in the following table:

### Nodal relapse patterns

	% (n)
<b>Nodal status</b>	
No axillary dissection	33.3 (12)
Axillary dissection	66.7 (23)
Node positive	69.6 (16)
Node negative	30.4 (7)
<b>Treatment technique</b>	
Tangents only	25.0 (9)
Tangents + nodal RT	75.0 (27)
SC	37.0 (10)
SC, axilla	11.2 (3)
IM, SC	14.8 (4)
IM, SC, axilla	37.0 (10)

There were no significant differences in the regional nodal control rates when analyzed as a function of regional treatment (AXD vs. regional nodal radiation).

Recurrence free rates between patients undergoing AXD and those receiving nodal irradiation without AXD were similar. The nodal recurrence free rates are reported below:

	5 years	10 years
Patients with AXD (+ SC RT if node +ve)	98.3%	97.4%
Patients with no AXD (+ SC and axillary RT)	98.5%	97.9%

Nodal control rates differed for age, race, pathological node status and systemic treatment regimes.

### Node control rates by node status

Pathological Node status	Node control rate
N0	98.7%
N1-3	97.8%
N-4-10	92.4%
N>10	82.9%
Caucasian patients (10 yr)	98.1%
African- American (10yr)	91.8%
Age < 35 yr (10 yr)	92.9%
Age 36-49 yr (10 yr)	95.6%
Age > 50 yr	98.8%
No chemotherapy (10 yr)	98.7%
Chemotherapy treated	94.2%
No hormone therapy	96.8%
Hormone therapy	99.4%

Chemotherapy patients were more likely to be node positive and in the subset of node positive patients, there was no difference in nodal control as a function of chemotherapy.

Possible prognostic factors for nodal recurrence were evaluated including age, race, stage, AXD status, pathologic lymph node status, chemotherapy, hormonal therapy, and oestrogen /progesterone receptor status. A univariate chi-squared analysis found that age <40 years, non Caucasian race, and positive pathologic nodal status significantly correlated with increased risk of nodal relapse. In a multivariate step-wise regression model, age, race, and pathological nodal status remained independent significant predictors of nodal failure. The values are reported in the table.

### Prognostic factors for nodal recurrence

Variable	P value
Age < 35 year	<0.0001
Pathological node positive	<0.0001

Non-Caucasian	0.003
Histology	0.055
T stage	0.06
Axillary dissection	NS
Margin status	NS
Family history	NS
ER status	NS
PR status	NS

Actuarial survival rates were poor with patients having axillary relapse only having a better prognosis at 5 years than those failing in the supraclavicular fossa, infraclavicular fossa or internal mammary chain.

Actuarial survival values at 5 and 10 years after nodal relapse are reported below:

	5 year actuarial survival	10 year actuarial survival
Nodal recurrence	31%	12%
Axilla relapse alone	44.2%	NR

Patients failing in the axilla also developed distant metastases less often than patients failing at other sites (5 yr actuarial distant relapse-free rates 13% vs <7%). The numbers were too small to draw firm conclusions.

**Author conclusions:**

In patients undergoing BCS+RT, both regional nodal irradiation and AXD (including SNB) resulted in equally high rates of regional nodal control. Nodal RT may also be an effective treatment for SN-positive patients.

**General comments -**

Tai, P., Joseph, K., Sadikov, E., Mahmood, S., Lien, F., & Yu, E. 2007, "Nodal ratios in node-positive breast cancer--long-term study to clarify discrepancy of role of supraclavicular and axillary regional radiotherapy", *International Journal of Radiation Oncology, Biology, Physics*, vol. 68, no. 3, pp. 662-666.

Design: NRS registry data (1981-1995) Level 3

Country: Canada. setting: Single province

Aim: To study the absolute number of involved nodes/the number of nodes examined or the nodal ratio (NR) in breast cancer. The primary study endpoint was to evaluate the role of supraclavicular and axillary radiotherapy (SART) according to the NR.

**Inclusion criteria**

Node positive patients from register with ≥10 nodes dissected

**Exclusion criteria**

Not reported

**Population** number of patients = 1985

1255 had ≥10 nodes dissected

Mean age 62 (range 36-94) years

Other characteristics:

	<b>LNR</b>	<b>MNR</b>	<b>HNR</b>
Patients	667	389	199
Premenopausal	149 (22%)	72 (19%)	39 (20%)
Postmenopausal	501 (75%)	298 (77%)	149 (75%)
Pathological stage:			
T1	334 (50%)	128 (33%)	46 (23%)
T2	269 (40%)	189 (49%)	80 (40%)
T3	26 (3.9%)	37 (9.5%)	32 (16.1%)
T4	21 (3.1%)	30 (7.7%)	35 (17.6%)

>9	0 (0%)	46 (11.8%)	179 (90%)

LNR = Low Node Ratio

MNR= Medium Node Ratio

HNR = High Node Ratio

**Interventions**

The surgical treatments included lumpectomy (n= 286, 23%) or mastectomy (n= 969, 77%).

Patients undergoing RT had different combinations of fields applied at the discretion of the radiation oncologists and included breast or chest wall, supraclavicular fossa, axilla, and/or internal mammary chain.

Systemic treatments included chemotherapy (461/1255, 37%) with cyclophosphamide, methotrexate and 5-fluorouracil; 5-fluorouracil, adriamycin, and cyclophosphamide; adriamycin and cyclophosphamide; and/or tamoxifen (646/1255, 51%).

Patients were divided into one to three, four to nine, and more than nine involved nodes. The patients were categorized into three NR groups: low (LNR ≤25%), medium (MNR >25% to ≤75%), and high (HNR >75%). This categorization followed previous studies using British Columbia data and American data.

**Outcomes**

Time to first recurrence  
 OS (Overall survival)  
 Cause Specific Survival (CSS)

**Follow up** Not reported

**Results**

Median number of nodes examined was 14 (range 10-38).  
 Median number of positive nodes 3 (1-38)

NR Categories:

LNR = 667

MNR=389

HNR=199

The NR were found to correlate significantly with primary tumour size, clinical stage group, pathological stage group and the risk of any first recurrence as shown in the table below:

**Association of NR and tumour characteristics**

Characteristic	LNR	MNR	HNR	P (chi-square test)
<b>Primary tumour size (cm)</b>				$2.2 \times 10^{-16}$
≤ 2	334	128	46	
> 2 to ≤ 5	269	189	80	
> 5	47	67	67	
<b>Clinical stage</b>				$5.5 \times 10^{-16}$
I	126	36	9	
II	244	165	62	
III	14	22	28	
IV	7	7	4	
<b>Pathological stage</b>				$< 2.2 \times 10^{-16}$
I	5	2	0	
II	591	296	97	
III	48	67	66	
IV	14	17	30	
<b>Recurrence</b>				$5.0 \times 10^{-15}$
Local	74	53	27	
Regional nodes	58	40	23	
Distant	195	167	115	
None	398	181	49	

Staging according to Fifth American Joint Commission on Cancer

Recurrences were counted for each category, some patients had a combination of recurrences (double counting)

The effects of supraclavicular and axillary radiotherapy (SART) on time to first recurrence, 10 year overall survival (OS) and 10 year cause specific survival (CSS) compared with no SART are shown in the following table and categorized by nodal ratios. The effects of SART were significant in improving outcomes at medium and high node ratios but not at low node ratios.

OUTCOME	LNR	MNR	HNR
Median time to first recurrence (months)			
With SART	191	130	33
Without SART	193	61	24
	P=0.29	P=0.0009	P=0.12
Overall survival (OS) (10 year)			
With SART	57%	48%	19%
Without SART	58%	34%	10%
	P=0.18	P=0.007	P=0.005
Cause Specific Survival (10 year)			
With SART	68%	57%	26%
Without SART	71%	43%	14%
	P=0.32	P=0.002	P=0.005

SART = supraclavicular and axillary RT

A multivariate analysis of data from the 1,255 patients showed that SART ( $p < 0.0001$ ), age ( $p < 0.0001$ ), NR ( $p = 0.002$ ), clinical stage ( $p = 0.01$ ) and pathological stage ( $p = 0.0004$ ) were significant factors for OS. Whilst SART ( $p < 0.0001$ ), Nodal Ratio ( $p = 0.005$ ), clinical stage ( $p = 0.02$ ), pathological stage ( $p = 0.0009$ ), tumour grade ( $p = 0.017$ ) and performance status ( $p = 0.03$ ) were significant factors for CSS.

Radiotherapy to the Internal Mammary Chain field was not significant for OS or CSS ( $p = 0.42$ ,  $p = 0.47$  respectively) on multivariate analysis. Similarly RT to the breast or chest wall was also not significant for OS or CSS ( $p = 0.79$ ,  $p = 0.69$  respectively) on multivariate analysis.

*Effect of regional RT on Cause Specific Survival*

For 1,255 patients with  $\geq 10$  nodes examined from the axilla, supraclavicular fossa and axillary regional RT did not significantly improve cause-specific survival for the LNR group ( $p = 0.32$ ); but was significant for the MNR ( $p = 0.002$ ) and HNR groups ( $p = 0.005$ ).

*Effect of regional RT on Overall Survival*

For 1,255 patients with  $\geq 10$  nodes examined from the axilla, supraclavicular fossa and axillary regional RT did not significantly improve overall survival for the LNR group ( $p = 0.18$ ); but was significant for the MNR ( $p = 0.007$ ) and HNR groups ( $p = 0.005$ ).

**Author conclusions**

Node Ratio is a useful prognostic factor. The study demonstrates that for patients with 10 or more nodes resected, regional RT significantly improves survival for the MNR and HNR groups, but not for the LNR group.

**General comments -**

Grills, I. S., Kestin, L. L., Goldstein, N., Mitchell, C., Martinez, A., Ingold, J., & Vicini, F. A. 2003, "Risk factors for regional nodal failure after breast-conserving therapy: Regional nodal irradiation reduces rate of axillary failure in patients with four or more positive lymph nodes", *International Journal of Radiation Oncology Biology Physics*, vol. 56, no. 3, pp. 658-670

Design: NRS Cohort (1980-2000) Level 3  
 Country: USA, setting: Single hospital  
 Aim: To determine the incidence of, and risk factors for, regional nodal failure (RNF) and to evaluate the effectiveness of, and indications for, regional nodal irradiation (RNI) in patients with Stage I-II breast cancer treated with breast-conserving therapy.

**Inclusion criteria**

Women with Stage I or II breast cancer

**Exclusion criteria**

None reported

**Population** number of patients = 1550

Median age 59 yrs (range 25-92)

40% (604) of patients had complete data available on tumour pathology

1411 (94%) of patients had at least a level I-II axillary lymph node dissection

Median nodes excised for all patients = 14

More than 10 nodes excised in 70% (982) patients

*Node status*

Nx 89 cases

N0 1076 cases

Pathologically involved lymph nodes in 335 (22%) of patients:

N1-3 in 255/335 (76%) of cases

N4+ in 80/335 (24%) of cases

*% positive nodes:*

≤ 33% in 83% of cases

34-66% in 11% of cases

≥ 67% in 6% of cases

*Size of node metastasis:*

< 1.0cm in 116 cases

1.0-1.9cm in 41 cases

> 2.0cm in 18 cases

(Note – size of node metastasis available only in 175 cases)

Extracapsular extension (ECE) in 35% with pathologically positive lymph nodes

*Characteristics of patients with 1-3 positive nodes by regional nodal irradiation treatment*

There were statistically significant differences for several characteristics between the group receiving regional node irradiation (RNI) (n=67) and the group with no RNI (n=188). These are shown in the table below. There were no significant differences between RNI and no RNI groups for tumour size, oestrogen receptor status, margin status, presence of angiolymphatic invasion, age, menopausal status, or systemic chemotherapy.

In this group of patients with 1-3 positive nodes a smaller proportion with > 10 positive nodes received RNI than no RNI; a larger proportion with > 34% of positive lymph nodes received RNI than no RNI; a larger proportion of ECE positive cases received RNI than no RNI; a larger proportion with large metastases > 1.0 cm received RNI than no RNI.

Characteristic	No RNI (%) (n=188)	RNI (%) (n=67)	p
----------------	-----------------------	-------------------	---

<b>Lymph nodes excised (n)</b>			
<6	6 (3)	2 (3)	0.002
6-10	30 (16)	25 (37)	
>10	152 (81)	30 (60)

Mean	11	18	0.001
<b>ECE</b>			
LN (+) ECE (-)	146 (82)	40 (61)	<0.001
LN (+) ECE (+)	34 (18)	26 (39)	
<b>Maximal size of LN metastasis (cm)</b>			
<1.0	82 (80)	15 (56)	0.015
1.0-1.9	15 (15)	7 (26)	
≥2.0	5 (5)	5 (18)	
Mean	0.6	1.2	0.002

#### *Characteristics of patients with ≥4 positive nodes by regional nodal irradiation treatment*

Statistically significant differences for characteristics between the group receiving regional node irradiation (RNI) (n=59) and the group with no RNI (n=21) were reported for percentage of positive lymph nodes, age and systemic chemotherapy. The other characteristics shown in the previous table and tumour size, oestrogen receptor status, margin status, presence of angiolymphatic invasion and menopausal status were not statistically significantly different between treatment groups.

Characteristic	No RNI (%) (n=21)	RNI (%) (n=59)	p
<b>Lymph node positive (%)</b>			
≤ 33	16 (76)	21 (36)	0.006
34-66	3 (14)	23 (39)	
≥ 67	2 (10)	15 (25)	
Mean	32	48	0.011
<b>Age (years)</b>			
≤ 45	11 (52)	16 (27)	0.036
<b>Systemic chemotherapy</b>	19 (95)	38 (67)	0.016

In this group of patients with ≥ 4 positive nodes a larger proportion of those with > 33 % of positive lymph nodes received RNI than no RNI; larger proportions of patients < 45 years and those receiving chemotherapy did not receive RNI than did receive RNI.

#### **Interventions**

Breast Conserving Therapy (BCT)

1411 (94%) had at least Level I or II ipsilateral axillary lymph node dissection. (Level III dissections were not routinely performed).

All patients had external beam RT of photons to the whole breast with tangential fields at a dose of 45 Gy. A tumour bed boost of 61Gy with electrons (19 had photons) was also given.

The breast alone, breast plus supraclavicular nodes and Level III nodes, or breast plus full axilla were treated at the discretion of the radiation oncologist

RT to breast alone n=1309 (87%)

RT to breast and regional nodes n = 191 (13%)

RNI was delivered by a three field technique to the breast and supraclavicular fossa/ axilla. Twenty three percent (n=44) also had a posterior axillary boost. Eight percent (n=16) also received RT to the IMC at a median dose of 50Gy.

#### **Outcomes**

Regional Node Failure (RNF) -detection of cancer in the regional site before, or simultaneously with, the diagnosis of local recurrence (LR) or distant metastasis (DM)

Cause-specific survival

Overall survival

DM-free survival

**Follow up**

Median follow-up 8.1 years

**Results**

35 patients developed RNF: 12 (6%) received RNI, 23 (2%) had no RNI.

Median time to failure 3.1 years.

Sites of failure are shown in the following table:

*Sites of regional nodal failure*

Site	Failure (n)				
	Any node	Nx	N0	N 1-3 (+)	N ≥ 4 (+)
Supraclavicular fossa	16	1	8	5	2
Axilla	11	1	3	6	1
Supraclavicular fossa and axilla	2	0	1	0	1
Internal mammary lymph nodes	6	0	3	3	0
<b>Total</b>	35	2	15	14	4

The 5 and 10 year actuarial failure rates by node site are reported in the following table.

Site of relapse	5 Year actuarial rate	10 Year actuarial rate
Any regional nodal failure	1.9%	2.8%
Axillary failure (AF)	0.6%	1.0%
Supraclavicular failure (SCF)	0.9%	1.6%
Internal mammary failure	0.4%	0.4%

*RNF and axillary node status*

When the 10 year actuarial regional nodal failure rates were related to nodal status and regional node irradiation statistically significant differences between rates with and without RNI were reported for any RNF in patients with 1-3 positive nodes (15% with RNI, 4% without RNI; p=0.003); and patients with ≥ 4 positive nodes (2% with RNI, 11% without RNI; p=0.041). 10 year actuarial failure rates in the axilla were reported as significant in patients with ≥ 4 positive nodes only (0% with RNI, 5% without RNI; p=0.027). However for supraclavicular fossa failure a significant difference was reported in patients with 1-3 positive nodes (8% with RNI, <1% without RNI; p=0.004). No statistically significant differences were reported between patients receiving RNI and no RNI in patients with no positive nodes (N0), unknown node status (Nx) or all N+ patients.

Failure rates by node status and regional node irradiation in subsets of patients are reported in the following table.

Node status	N of patients	+ RNI	-RNI	Site of failure	Characteristics of patients receiving RNI
NX	89 No AXD	42 (47%)	47 (53%)	1 SCF 1AF Both had RNI Not significant	Larger tumours >1cm (69% vs 43%, p=0.02) Angiolymphatic invasion (27% vs 5%, p=0.05)
pN0	1076	23 (2%)	1053 (98%)	15 RNFs SC 8 AF 3 SC+AF 1 IMC 3 1 received RNI 14 did not receive RNI No significant difference between RNI vs no RNI failure	Negative or unknown ER status (p=0.007) Close or positive surgical margins (p=0.004)
N Irradiation (1-3 +ve nodes)	255	67 (26%)	188 (74%)	14 RNFs 8 received RNI: (1 AF, 4 SCF, 3 IMC) 6 no RNI: (5 AF, 1 SCF)	< 6 or < 10 lymph nodes excised Greater % of positive nodes, ECE, or nodal metastasis >1-2cm

N Irradiation (≥ 4 +ve nodes)	80	59 (74%)	21 (26%)	4 RNFs 1 received RNI (2 SCF, 1 AF, 1 AF+SCF)	Higher percentage positive nodes (p=0.006) Age >45 years (p=0.036) Systemic chemotherapy (p=0.008)
----------------------------------	----	----------	----------	---	--

In patients with Nx status RNI was more likely to be delivered to patients with tumour sizes > 1cm or angiolymphatic invasion. Both failures occurred in the RNI group.

In patients with N0 status RNI was more likely to be delivered to patients with negative or unknown oestrogen receptor status or close/positive surgical margins. The rates of RNF, AF, or SCF according to regional nodal treatment were not statistically significant, however the RNI group was very small in comparison to the no RNI group, and this is reflected in the findings (14 failures had no RNI vs. 1 failure had RNI).

In patients with N1-3 positive nodes RNI was more likely to be delivered to patients with <6 or <10 lymph nodes excised, a greater percentage of positive nodes, ECE, or a nodal metastasis >1-2cm. Patients were more likely to develop RNF if they received RNI (15% vs. 3%, p=0.002). SCF was more likely if they received RNI (8% vs. 1%, p=0.005). The rates of AF were similar between groups (2% vs. 4%, p=0.68). Although the number of RNFs was similar between RNI and no RNI groups, again the RNI group was smaller than the no RNI group.

In patients with more than 4 positive nodes RNI was more likely to be delivered to patients with a higher percentage of positive nodes (p=0.006), aged over 45 years (p=0.036), and had received systemic chemotherapy (p=0.008). Three of four RNFs occurred in the no RNI group. In these patients RNI reduced the 10 year actuarial rate of any RNF from 11% to 2% (p=0.041) and the rate of AF from 5% to 0% (p=0.027).

A Cox multiple regression analysis of data from these patients found that RNI was the only significant independent factor predicting a reduced rate of RNF ( $p = 0.03$ , hazard ratio 0.046). Factors included in the analysis were the percentage of positive nodes, size of lymph node metastasis, age, and angiolymphatic invasion. Independent predictors of AF or SCF were not determined because of the small number of failures.

#### *Extracapsular extension (ECE)*

116 (35%) of patients with pathologically involved nodes had ECE.

When ECE-positive patients were stratified by regional nodal treatment, RNI had no impact on the 10-year rate of RNF (6% vs. 7%,  $p = 0.690$ ) or SCF (4% vs. 4%,  $p = 0.765$ ). The rate of AF was lower for RNI patients (0% vs. 4%), but this difference was not statistically significant ( $p = 0.109$ ).

#### *Effect of axillary lymph node dissection*

Node negative (N0) patients with <6 nodes excised had a significantly higher rate of RNF. The 10 year rates for patients with <6, 6-10 and >10 nodes excised were 5%, 4% and 1% respectively (p=0.04). The rates of failure were higher in node positive patients (N1) but the differences were not statistically significant ( $p = 0.427$ ).

#### *Univariate analysis of RNF*

RNI did not affect the rates of regional failure in patients with negative or 1-3 positive nodes. In node-negative patients, the rate of RNF was significantly greater if <6 nodes were removed at the time of axillary dissection. In patients with more than 4 positive lymph nodes RNI significantly reduced RNF. Multiple clinical, pathological, and treatment-related factors were analyzed for association with RNF. On univariate analysis, RNF was associated with the number of nodes excised, number of positive nodes, percentage of positive nodes, size of nodal metastasis, presence of angiolymphatic invasion, oestrogen receptor status, age, systemic chemotherapy, and RNI.

Three subsets of patients had unusually high rates of RNF at 10 years, those with  $\geq 67\%$  nodes positive (16%), nodal metastasis  $\geq 2.0$  cm (44%), or age  $\leq 35$  years (14%). RNI did not improve the overall survival for any of these subsets.

*Multivariate analysis of RNF*

A further multivariate analysis of all patients found that the only significant independent predictor of RNF was the maximal size of the nodal metastasis ( $p = 0.013$ ).

*Survival analysis*

*All patients*

Data on survival rates are reported in the table below for all 1500 patients (note this figure may be a misprint as 1550 were included in total).

Outcome	5 year rate	10 year rate
Overall survival	90%	78%
Disease Free Survival	84%	70%
Cause-Specific Survival	94%	87%

Rates of survival (DFS and OS) and distant metastases (DM) in relation to regional node treatment are reported in the following table.

Rate	Breast +RNI (%)		Breast alone (%)		p
	5 year	10 year	5 year	10 year	
DFS	68	52	87	73	<0.001
OS	79	61	91	80	<0.001
Distant metastases	13	30	7	11	<0.001

The authors suggest that the poorer survival statistics for RNI patients may be due to the high risk characteristics of these patients (selection bias).

*Node status*

The number of lymph nodes excised had an impact on overall survival in node-positive patients only. 10-year survival rates were 33%, 65%, and 69% in patients with <6, 6-10, and >10 nodes excised, respectively ( $P = 0.05$ ). Actuarial survival rates at 10 years were not significantly different by number of nodes excised in node negative patients.

The 10 year actuarial rates of DM-free survival, overall survival, and cause-specific survival related to nodal status and RNI are shown in the following table.

Nodal status	Distant metastasis free survival (%)			Overall survival (%)			Cause specific survival (%)		
	RNI	No RNI	P	RNI	No RNI	P	RNI	No RNI	p
N0	82	90	<b>0.042</b>	70	84	<b>0.015</b>	77	92	<b>0.006</b>
Nx	80	89	0.057	51	50	0.234	91	93	0.081
All N+	64	82	<b>0.002</b>	61	70	<b>0.005</b>	69	77	<b>0.039</b>
N+ (1-3)	68	84	<b>0.011</b>	62	72	<b>0.008</b>	71	79	<b>0.040</b>
N+ ( $\geq 4$ )	59	64	0.889	58	56	0.941	67	62	0.639

P values in bold font were statistically significant

Node-negative and N1 patients with 1–3 positive nodes receiving RNI had statistically significantly lower survival rates across all three parameters.

NX patients and N1 patients with  $\geq 4$  positive nodes receiving RNI had survival rates equivalent to those of patients treated to the breast only.

*Toxicity*

Brachial plexopathy 2/1342 (0.1%), occurred in 2/64 (1.2%) patients treated with RNI.

Pneumonitis 5/1250 (0.4%) (1 patient had RNI, 4 had no RNI)

Arm oedema: mild 6.8% in RNI patients, and 5.8% those not irradiated.

Moderate 3.1% in RNI patients, and 1.4% those not irradiated

3 patients had severe arm oedema, none received RNI.

Breast oedema: 27% with RNI, 42% no RNI

**Author conclusions**

Failure within the regional lymph nodes as an isolated site of first relapse is uncommon in patients with Stage I–II breast cancer treated with BCT. RNI can significantly reduce the rate of RNF (AF) in patients with  $\geq 4$  positive lymph nodes. The maximal size of the lymph node metastasis was found to be the only significant independent predictor of RNF, with nodal metastases  $\geq 2.0$  cm associated with extremely high regional failure rates. Despite this, young age and extent of axillary dissection (particularly as related to the number of positive nodes) also appear to be important and should be considered when evaluating patients for RNI. Inadequate axillary dissection was not only associated with increased regional failure, but also reduced survival.

**General comments –**

94% of patients received Level I-II axillary dissection as well as node irradiation. The majority of patients with no node irradiation had received axillary surgery only. Extensive subgroup analyses were conducted in this paper. Not all of these analyses are reported in the table since some subgroups were very small (less than 20 patients).

## Treatment of the Internal Mammary Node Chain (Dissection or Radiotherapy)

Arriagada, R., Lê, M. G., Mouriessse, H., Fontaine, F., Dewar, J., Rochard, F., Spielmann, M., Lacour, J., Tubiana, M., & Sarrazin, D. 1988, "Long-term effect of internal mammary chain treatment. Results of a multivariate analysis of 1195 patients with operable breast cancer and positive axillary nodes", *Radiotherapy and oncology : journal of the European Society for Therapeutic Radiology and Oncology*, vol. 11, no. 3, pp. 213-222.

Design: NRS Cohort (1958-1978) Level 3

Country: France, setting: Single centre

Aim: To evaluate in a large series of N+ patients the long term effects of treatment of the IMC by IMC dissection (IMCD) or RT on the risk of death or metastasis; and to confirm the beneficial long-term effect of post-operative RT on risk of locoregional recurrence.

### Inclusion criteria

Women under 70 years with a primary unilateral infiltrating breast carcinoma (UICC stage T1a, T2a or T3a, N0 or N1 and M0, < 7cm in diameter and histologically invaded axillary nodes.

**Exclusion criteria** Not reported

**Population** number of patients = 1195

### Interventions

Mastectomy and axillary dissection (Halsted or Patey operation).

From 1958-1963 when axillary nodes were positive IMCD and postoperative RT was administered.

When axillary nodes were negative only patients with medial tumours were treated by IMCD and RT.

When axillary nodes were positive on pathological examination RT was given (standard protocol)

From 1963-1968 IMCD was performed on randomized patients (152 N+ patients did not receive postoperative RT).

From 1968-1972 standard protocol was followed.

From 1972-1978 Patey mastectomy was compared with lumpectomy, axillary dissection and RT to the breast on randomized patients with tumours up to 2cm.

N+ patients were further randomised to postoperative lymph node RT or no further treatment.

For irradiated patients 45Gy in 16 fractions over 32 days was delivered to the chest wall, supraclavicular and axillary nodes and to homolateral IMC.

### Outcomes

Mortality

Metastasis

### Follow up

### Results

Treatment groups are described in the following table.

Characteristics	Group 0 No IMCD	Group 1 IMCD	Group 2 No IMCD	Group 3 IMCD
-----------------	--------------------	-----------------	--------------------	-----------------

	No RT N=135	No RT N=102	RT N=523	RT N=435
Age -years (SD)	53 (9)	52 (10)	52 (10)	50 (9)
Tumour size cm(SD)	34 (13)	39 (12)	33 (13)	37 (13)
% patients with:				
Medial tumour	44	51	38	64
N≥4 +ve axillary nodes	27	40	41	53
Grade 3	39	43	34	36

The risks of death and metastases were similar for groups 1, 2 and 3 indicating that IMCD alone and RT alone have similar effects. These findings are reported in the following table.

Relative risk (adjusted)	Group 1 IMCD no RT	Group 2 No IMCD RT	Group 3 IMCD RT
RR Death	1.0	1.0	1 (ref)
RR Metastasis	1.1	1.1	1 (ref)
10 year rates (Cox):			
Mortality	48%	42%	42%
Metastasis	44%	42%	40%

When pooling the groups (1-3) where treatment was given and comparing to group 0 where no treatment was given, the difference between deaths and metastases was not significant. A significant difference was observed between the subgroups with medial tumours, but not those with lateral tumours. These findings are reported in the following table.

Relative risk (adjusted) of 10 year rates	All patients Gp 0 (n=135) (ref) vs Gp 1-3 (n=1060)	Medial tumours Gp 0 (n=60) (ref) vs Gp 1-3 (n=528)	Lateral tumours Gp 0 (n=75) (ref) vs Gp 1-3 (n=532)
Deaths	1.3 p=0.06	1.6 p=0.01	1.1 NS
Metastases	1.2 NS	1.5 p=0.05	0.9 NS
Mortality %	50 vs 42	52 vs 42	50 vs 42
Metastases %	46 vs 42	56 vs 44	40 vs 40

#### Multivariate analysis

The long term risk of death at 15 years was assessed in relation to clinical and pathological factors and IMC treatment for the 270 patients still alive:

Characteristic	RR of death	P value
Age (each year)	1.1	0.01
Clinical size (each 2cm)	1.4	NS
Histological grading(each class)	1.2	NS
Positive axillary nodes	0.9	NS
Size of tumour	1.1	NS
Group 0 (n=31)	1 (ref)	
Group 1 (n=43)	1.0	NS
Group 2 (n=75)	0.8	NS
Group 3 (n=121)	0.9	NS

There was no adverse effect of IMC RT or IMCD on long term survival. Age at initial treatment was related to risk of death.

#### Author conclusions

A beneficial effect of treatment of the internal mammary chain (IMC) on the risks of death and distant metastasis for the patients with medial tumours was found. For these patients, surgical IMC dissection and post-operative irradiation have similar effects on both the risk of death and of distant metastasis. For patients with lateral tumours, no beneficial effect of treatment of the IMC on these two risks was observed. Postoperative irradiation to the IMC, axilla, chest wall and supraclavicular nodes significantly decreases the risk of locoregional recurrences independent of the tumour site and surgical management of the lymph nodes.

#### General comments –

A recent systematic review by Vinod & Pendlebury (1999) and included earlier in the table commented on the limitations of this study where findings have been based on a subgroup analysis of a retrospective study, and different treatment policies were adopted over sequential time periods, so the possibility exists for staging biases.

Obedian, E. & Haffty, B. G. 1999, "Internal mammary nodal irradiation in conservatively-managed breast cancer patients: Is there a benefit?", *International Journal of Radiation Oncology Biology Physics*, vol. 44, no. 5, pp. 997-1003.

Design: NRS Cohort (1970-1990) Level 3

Country: USA, setting: Single institution

Aim: To evaluate outcome as a function of Internal Mammary Nodal Radiation (IMNR) in a cohort of breast cancer patients treated with CS + RT

**Inclusion criteria**

Early stage breast cancer with conservative management.

**Exclusion criteria** None reported.

**Population** number of patients = 984

Median age 57 years (range 20-86)

T1 690 (73%)

T2 249 (26%)

T3 7 (1%)

Pathologically-negative lymph nodes n= 399 (42%)

Pathologically-involved lymph nodes n=166 (18%):

N1-3 n=113 (12%)

N>4 n=53 (6%)

No lymph node dissection n=381 (40%)

**Interventions**

All had wide local excision with or without axillary nodal dissection, followed by radiation therapy to the intact breast and regional nodes.

Node-positive patients received adjuvant systemic therapy (94%) and were treated with tangential fields matched to a separate supraclavicular field (95%) with or without IMNR.

Treatment techniques are shown in the following table.

Treatment technique	All patients	IMNR	No IMNR
N	946 (100%)	535 (100%)	411 (100%)
Tangents alone	221 (23%)	1 (0.2%)	220 (54%)
Tangents + supraclavicular	106 (11%)	9 (1.7%)	97 (24%)
Tangents + supraclavicular + axilla	128 (13%)	41 (7.7%)	87 (21%)
Tangents + supraclavicular + IMN	229 (24%)	229 (43%)	0
Tangents + supraclavicular + axilla + IMN	225 (24%)	225 (48%)	0
<b>Median dose (Range, Gy):</b>			
Intact breast	64 (40-96)	64 (40-96)	64 (46-82)
Tangents	50 (20-70)	48 (20-70)	52 (32-64)
Supraclavicular nodal region	46 (0-62)	46 (0-55)	44 (0-62)
Internal mammary nodal region	46 (0-62)	46 (20-54)	0

**Outcomes**

OS (Overall Survival)

BRFS (Breast Relapse-Free survival)

DMRFS (Distant Metastasis-Free Survival)

**Follow up** Median follow-up 13 years

**Results**

At 10 years:

OS=76%

BRFS =88%

DMRFS =81%

Clinical outcomes of node positive patients are shown below:

	Total	IMNR	No IMNR	p-value
<b>Clinical status</b>				P<0.001

Alive with disease	42	27 (5%)	15 (4%)	
Alive, no evidence of disease	693	345 (64%)	348 (85%)	
Dead with disease	123	96 (18%)	27 (7%)	
Dead, no evidence of disease	88	67 (13%)	21 (5%)	
<b>Site of recurrence</b>				P<0.001
None	724	366 (68%)	358 (87%)	
Breast only	82	65 (12%)	17 (4%)	
Nodes only	12	9 (2%)	3 (0.7%)	
Distant only	119	86 (16%)	33 (8%)	
Breast and nodes	1	1 (0.2%)	0 (0%)	
Breast and distant	5	5 (1%)	0 (0%)	
Nodes and distant	3	3 (0.6%)	0 (0%)	

There were no significant differences between the IMC+RT and IMC-noRT groups at 10 years for all patients:

	IMC+RT vs IMC noRT	
OS	72% vs. 84%	p=NS
DMFS	77% vs. 87%	p=NS

Patients in the IMC-noRT group had significantly higher Breast-relapse Free Survival (BRFS) rates at 10 years than patients in the IMC+RT group (84% IMC+RT vs. 94% IMC-noRT,  $p < 0.001$ ).

The authors suggest that the difference in breast relapse rate may be due to increased attention to the status of the surgical margins and increased use of systemic therapy in later years, when internal mammary radiation was less likely to be utilized.

A further subgroup analysis of node positive patients found a trend towards better outcomes in the IMC-noRT group, although there were no significant differences between the IMC+RT and IMC-noRT groups of node positive patients at 10 years for:

OS	68% IMC+RT vs. 76% IMC-noRT	$p > 0.5$
BRFS	85% IMC+RT vs. 96% IMC-noRT	
DMFS	64% IMC+RT vs. 82% IMC-noRT	$p = 0.2$

No benefit of IMC RT was found in further subgroup analyses comparing:

Age <50 vs. >50 years  
Number of +ve nodes (1-3 vs. 4 or more)  
Location medial vs. lateral  
Right vs. left breast

A final subset analysis comparing IMC treatment by a separate field vs. IMC treatment by deep tangent also found no benefit of IMC irradiation.

#### Author conclusions

No benefit could be attributed to IMNR in conservatively-treated breast cancer patients, even if node-positive or medial in location. Until results of an ongoing EORTC randomized trial addressing this issue are available, these data suggest that it is acceptable to continue to treat node-positive conservatively-managed patients to tangential fields usually matched to a supraclavicular field, but without a separate internal mammary field.

#### General comments -

## Abstracts of other relevant non-randomized studies that were weaker in design or analysis

### No node irradiation

Strom, E. A., Woodward, W. A., Katz, A., Buchholz, T. A., Perkins, G. H., Jhingran, A., Theriault, R., Singletary, E., Sahin, A., & McNeese, M. D. 2005, "Clinical investigation: regional nodal failure patterns in breast cancer patients treated with mastectomy without radiotherapy", *International Journal of Radiation Oncology, Biology, Physics*, vol. 63, no. 5, pp. 1508-1513.

**Abstract: PURPOSE:** The purpose of this study was to describe regional nodal failure patterns in patients who had undergone mastectomy with axillary dissection to define subgroups of patients who might benefit from supplemental regional nodal radiation to the axilla or supraclavicular fossa/axillary apex.

**METHODS AND MATERIALS:** The cohort consisted of 1031 patients treated with mastectomy (including a level I-II axillary dissection) and doxorubicin-based systemic therapy without radiation on five clinical trials at M.D. Anderson Cancer Center. Patient records, including pathology reports, were retrospectively reviewed. All regional recurrences (with or without distant metastasis) were recorded. Median follow-up was 116 months (range, 6-262 months).

**RESULTS:** Twenty-one patients recurred within the low-mid axilla (10-year actuarial rate 3%). Of these, 16 were isolated regional failures (no chest wall failure). The risk of failure in the low-mid axilla was not significantly higher for patients with increasing numbers of involved nodes, increasing percentage of involved nodes, larger nodal size or gross extranodal extension. Only 3 of 100 patients with <10 nodes examined recurred in the low-mid axilla. Seventy-seven patients had a recurrence in the supraclavicular fossa/axillary apex (10-year actuarial rate 8%). Forty-nine were isolated regional recurrences. Significant predictors of failures in this region included > or = 4 involved axillary lymph nodes, >20% involved axillary nodes, and the presence of gross extranodal extension (10-year actuarial rates 15%, 14%, and 19%, respectively,  $p < 0.0005$ ). The extent of axillary dissection and the size of the largest involved node were not predictive of failure within the supraclavicular fossa/axillary apex.

**CONCLUSIONS:** These results suggest that failure in the level I-II axilla is an uncommon occurrence after modified radical mastectomy and chemotherapy. Therefore, supplemental radiotherapy to the dissected axilla is not warranted for most patients. However, patients with > or = 4 involved axillary lymph nodes, >20% involved axillary nodes, or gross extranodal extension are at increased risk of failure in the supraclavicular fossa/axillary apex and should receive radiation to undissected regions in addition to the chest wall

(Similar study to Livi *et al* (2006) but with fewer patients and stage II-IIIa. Intervention was radical mastectomy or modified radical mastectomy with a Level I and II axillary dissection. No RT was administered after surgery. A crude univariate analysis was performed).

Stranzl, H., Peintinger, F., Ofner, P., Prettenhofer, U., Mayer, R., & Hackl, A. 2004, "Regional nodal recurrence in the management of breast cancer patients with one to three positive axillary lymph nodes - Outcome of patients following tangential irradiation without a separate nodal field", *Strahlentherapie und Onkologie*, vol. 180, no. 10, pp. 623-628.

**Abstract: Purpose:** To examine the prognosis of breast cancer patients (T1-3, one to three positive axillary Lymph nodes) and loco regional failure rate after breast-conserving therapy/modified radical mastectomy and adequate axillary dissection following tangential radiotherapy without irradiation of the regional lymph nodes.

**Patients and Methods:** From 1994 to 2002, the medical records of 183 breast cancer patients (T1-3, one to three involved axillary lymph nodes) were examined in order to identify those experiencing regional nodal recurrence, with or without Local recurrence. The median age of the patient population was 58 years (range, 28-86 years). All patients underwent surgical treatment, either breast-conserving therapy ( $n = 146$ ) or modified radical mastectomy ( $n = 37$ ). The median number of Lymph nodes removed was twelve (range, seven to 26 nodes). Irradiation was given to the breast through tangential fields. Chemotherapy was administered to 101 patients (55%), hormonal therapy to 124 (60%), and combined systemic treatment to 47 (26%).

**Results:** The median observation time was 44.4 months (range, 11-102 months). Of the 14 patients (7.7%) with a relapse, six (3.3%) had a Local recurrence, five (2.8%) a regional relapse, and three (1.6%) a simultaneous recurrence. Nine out of 14 patients with locoregional relapse developed distant failure subsequently and seven of them (78%) died of the disease.

**Conclusion:** Regional recurrence is uncommon among patients with one to three positive axillary Lymph nodes treated with surgery, adequate axillary dissection, and tangential field irradiation only. The authors conclude that

regional nodal irradiation should not routinely be given following adequate axillary dissection when only one to three Lymph nodes are positive.

(This was a small study of patients treated mainly with BCS (80%) and axillary dissection (the extent varied by individual surgeon) which supports the findings of larger studies for women with N1-3 positive nodes).

### Limited node irradiation

Vicini, F. A., Horwitz, E. M., Lacerna, M. D., Brown, D. M., White, J., Dmuchowski, C. F., Kini, V. R., & Martinez, A. 1997, "The role of regional nodal irradiation in the management of patients with early-stage breast cancer treated with breast-conserving therapy", *International Journal of Radiation Oncology Biology Physics*, vol. 39, no. 5, pp. 1069-1076.

**Abstract: Purpose:** To determine the incidence of regional nodal failure (RNF) and indications for regional nodal irradiation (RNI) in patients with Stage I and II breast cancer treated with breast-conserving therapy (BCT),  
**Methods and Materials:** Four hundred fifty-six patients with Stage I/II breast cancer were treated with BCT at William Beaumont Hospital. All patients underwent excisional biopsy and 288 (63%) were reexcised, A Level VII ipsilateral axillary lymph node dissection was performed on 431 patients (95%), Pathologically involved nodes were found in 106 (23%) cases (69 with one to three nodes and 37 with greater than or equal to four nodes involved), All patients received whole breast irradiation (median dose 50 Gy) and 415 (91%) were boosted to the tumor bed (median total dose 60.4 Gy), Three hundred and sixty (79%) patients received breast alone irradiation and 96 (21%) also received RNI, The median axilla/supraclavicular fossa dose was 50 Gy,

**Results:** With a median follow-up of 83 months, 15 patients developed a RNF for a 5- and 8-year actuarial rate of 3 and 4%, respectively, The 5- and 8-year actuarial rates of axillary failure (AF) were 0.7 and 1.0%, respectively, The incidence of RNF or AF was not affected by the use of RNI in NO or N1 patients with one to three positive nodes, Only in patients with four or more positive nodes was there a trend towards improved regional control with RNI ( $p = 0.09$ ), However, patient numbers were extremely small, and this improvement was limited to a reduction in the rate of failure in the supraclavicular fossa (SCF) (20 vs, 0%,  $p = 0.04$ ), Multiple clinical, pathologic, and treatment related factors were analyzed for an association with AF, On univariate analysis, AF was associated with the number of lymph nodes excised ( $p < 0.0001$ ) estrogen receptor status ( $p = 0.0016$ ), and pathologic node status ( $p = 0.0021$ ),

**Conclusions:** Regional nodal failure as the first site of failure is uncommon in patients with early-stage breast cancer treated with BCT with less than or equal to three positive lymph nodes and appears unaffected by RNI, For patients with four or more positive lymph nodes, a trend towards improved RNF was noted with RNI, primarily in the SCF, However, patient numbers were extremely small in all subsets analyzed. Additional studies are needed to further define the need for RNI in these patients and help determine other factors associated with RNF.

(Small number of patients had regional node irradiation, the authors' state that conclusions should not be drawn from these findings)

Livsey, J. E., Magee, B., Stewart, A. L., & Swindell, R. 2000, "Axillary recurrence following conservative surgery and radiotherapy in early breast cancer", *Clinical Oncology*, vol. 12, no. 5, pp. 309-314.

**Abstract:** At the institute, since the late 1980s, there has been a uniform treatment protocol for the management of the regional lymph nodes in patients referred for radiotherapy following breast-conserving surgery. An analysis of 2277 consecutive patients referred for radiotherapy between 1989 and 1992, with particular reference to regional lymph node management, has been undertaken. Axillary surgery alone was used in 517 patients (23%); 1191 (52%) patients had no axillary surgery but had radiotherapy to the axilla, and infraclavicular and supraclavicular fossae by a single anterior field, delivering 40 Gy in 15 daily fractions over 3 weeks; and 474 patients (21%) had axillary surgery followed by radiotherapy. Ninety-five patients (4%) underwent no axillary treatment. There was a total of 155 axillary recurrences with a median follow-up of 5.9 years, giving an actuarial nodal control rate of 94% at 5 years (95% confidence interval (CI) 93.1-95.1). The overall survival at 5 years was 86% (95% CI 84.6-87.5). There was a trend towards improved axillary control with surgery alone compared with radiotherapy alone (4.5% versus 5.9% actuarial axillary failure rate at 5 years). An extremely low incidence of brachial plexus neuropathy secondary to radiotherapy was reported. The multidisciplinary treatment protocol used gave a high rate of regional node control, with minimal recorded morbidity.

(A large study comparing axillary surgery to axillary irradiation including the supraclavicular nodes. The type of axillary surgery was varied and the node status of patients not clear. The independently significant prognostic

factors for nodal recurrence from a univariate Cox's regression analysis were screen-detected referral, grade, age and clinical stage.)

Pierce, L. J., Oberman, H. A., Strawderman, M. H., & Lichter, A. S. 1995, "Microscopic Extracapsular Extension in the Axilla - Is This An Indication for Axillary Radiotherapy", *International Journal of Radiation Oncology Biology Physics*, vol. 33, no. 2, pp. 253-259.

**Abstract:** Purpose: Although the axilla is often treated with radiotherapy (RT) postoperatively when microscopic extracapsular extension (ECE) of lymph nodal metastases is present, little data are available to assess axillary failure in the absence of such treatment. As it has been the practice at this institution to withhold axillary irradiation in the presence of microscopic extracapsular spread, we retrospectively analyzed our results for axillary recurrence, disease-free survival (DFS), and overall survival (OS).

**Methods and Materials:** Clinical records were reviewed of 82 women with Stage II node positive breast cancer treated with lumpectomy, axillary dissection, and RT in addition to systemic chemo/hormonal therapy. Axillary surgery consisted of a level I, II, +/-III dissection, with a median of 16.5 nodes removed. Tangential radiotherapy fields were used to treat the breast. All patients were also treated with an abbreviated supraclavicular field with the lateral border medial to the humeral head. Pathological sections were available for review in 72 of the 82 women.

**Results:** Twenty-seven of 72 (37.5%) had evidence of ECE; 45 of 72 (62.5%) had metastatic carcinoma confined within the nodal capsule. Clinical characteristics were comparable between the patients with and without ECE with the exception of (a) pathologic subtype, with a greater percentage of infiltrating ductal tumors associated with ECE ( $p = 0.044$ ), and (b) number of positive lymph nodes, with 93% of patients without ECE having one to three positive nodes vs. only 56% among patients with ECE ( $p < 0.001$ ). With a median follow-up of 40 months, 1 of 27 patients (4%) with ECE experienced an axillary failure as a component of first failure compared to 0 of 45 patients without ECE ( $p = 0.4$ ). There were no isolated axillary failures. Five-year disease-free survival (72% without ECE vs. 57% with ECE,  $p = 0.12$ ) and overall survival (83% vs. 53%, respectively,  $p = 0.068$ ) suggested a less favorable outcome for patients with ECE.

**Conclusions:** Microscopic ECE appears to be associated with increased axillary involvement and decreased survival rather than subsequent axillary failure. Our data suggest that radiotherapy to a dissected axilla may be omitted for the sole indication of microscopic extracapsular disease.

[A small study of 82 patients who received BCS and axillary dissection (level I and II, some level III) with tangential irradiation to the breast and a limited supraclavicular field to those with positive nodes. 93% of women had 1-3 positive nodes. A Cox multiple regression analysis of clinical factors was performed for DFS and overall survival. No factors were significant independent predictors (5% level). Trends were observed for each end point, indicating a shorter duration for patients with ECE.

Hazard ratio for survival was 3.3 (95% CI 0.9 to 11.3,  $p = 0.06$ , adjusted for the number of positive nodes [ $> 3$  vs. 1-3]). The probability of death for patients with ECE was three times that of patients without ECE. Similarly for DFS, the HR was estimated to be 2.6 (95% CI 0.9 to 7.6,  $p = 0.07$ ).

## Guidelines

### SIGN 2005

The relevant section from the SIGN guideline for radiotherapy to the chest wall and supraclavicular fossa, axilla, and internal mammary node chain is reported below:

#### RADIOTHERAPY TO THE CHEST WALL AND SUPRACLAVICULAR FOSSA

Recht et al (2001) addressed the question of whether adjuvant radiotherapy should be given to the chest wall and supraclavicular fossa the American Society of Clinical Oncology guideline. Fewer data are available addressing the benefit of PMRT in subgroups of patients with specific numbers of positive axillary nodes. Supraclavicular nodal failures are more common in unirradiated patients with four or more positive axillary nodes.

##### Level 3

In one series, supraclavicular nodal failure appeared in 17% of unirradiated patients (17/102) compared with 2% of 56 irradiated patients (Kuske 1996 et al abstr). In another series the risk of supraclavicular failure was 13% (6/46) among unirradiated patients with four or more positive nodes, compared with 4% (2/52) for those irradiated (Ewers et al 1992).

##### Level 1++

An RCT showed improvements in risk of loco-regional failure (LRF) in irradiated patients in the subgroups with either one to three or four or more positive nodes (Ragaz et al 1997). The difference in crude LRF rates for patients with 1-3 positive nodes was of borderline significance between arms (20% in control arm and 8% in the irradiated arm,  $p=0.066$ ), while the difference between arms for patients with 4 or more positive nodes remained highly significant (LRF rates of 51% and 17% respectively,  $p=0.004$ ).

##### Level 1+

In another trial, patients with one to three positive nodes and those with four or more positive nodes had statistically significant improvements in disease-free survival when given PMRT in addition to chemotherapy, but only patients with 4 or more involved nodes achieved a significant advantage in cancer-specific survival from the addition of PMRT (McArdle et al 1986).

#### Grade D

**The supraclavicular field should be irradiated in all patients with 4 or more positive axillary nodes.**

#### AXILLARY RADIOTHERAPY

The American Society of Clinical Oncology recommends that after adequate surgery by a complete or level I/II axillary dissection, routine adjuvant radiotherapy is not necessary and may add to morbidity (Recht et al 2001).

#### INTERNAL MAMMARY NODE CHAIN RADIOTHERAPY

There are studies addressing whether radiotherapy to the internal mammary node chain (IMC) is of benefit. The evidence for IMC is conflicting.

##### Level 1+

Two trials showed no improvement in survival in patients who underwent internal mammary node dissection in addition to standard radical mastectomy (Lacour et al 1983, Veronesi et al 1999).

A trial of 150 patients with internal mammary node involvement randomised individuals to either radical resection of the internal mammary supraclavicular chain, irradiation of the supraclavicular and internal mammary nodes, or no further surgery or deliberate irradiation of these areas. The 5 year disease-free survival rates were similar in the 3 arms (57%, 53% and 51% respectively), although the risk of supraclavicular and/or internal mammary recurrence was lowest in the irradiated group (12%, 0% and 16% respectively) (Yamashita et al 1996 abstr).

##### Level 4

One overview of case series and RCTs showed no benefit of IMC radiotherapy (Freedman et al 2000). Studies reviewed included patient data from 1938 onwards, raising the possibility that the side effects of antiquated treatments may have influenced the results against IMC irradiation. There is no evidence that IMC irradiation should be performed routinely in any patient group (Recht et al 2001, Freedman et al 2000). The number of screen-detected cancers is increasing and, together with the fact that fewer patients present with locally advanced cancers, should result in a reduction in IMC involvement.

**Fodor, J.,** Polgar, C., Peley, G., & Nemeth, G. 2001, "[Management of the axilla in breast cancer: evidences and unresolved issues]. [Review] [111 refs] [Hungarian]", *Orvosi Hetilap*, vol. 142, no. 36, pp. 1941-1950.

This paper is written in Hungarian so only data provided in the abstract has been reported here.

Computerized searches for publications on the specific treatment of the axilla in breast cancer were run in the MEDLINE database. The level of evidence was graded using standard criteria: 1. meta-analysis of randomized trials, 2. randomized trial, 3. prospective and retrospective studies, 4. reports and opinion of expert committees and working teams. The authors report that the probability of lymph node involvement is related directly to the size of the primary tumour, and even with small tumours (up to 10 mm), the risk of nodal metastases is in the order of 10-20%. The best strategy for determining complete lymph node status (qualitative and quantitative information) was considered to be axillary dissection. At least ten nodes have to be obtained for accurate staging. Formal axillary sampling does not provide all the quantitative data for patients with involved axilla, and sentinel node biopsy is a promising alternative to axillary dissection for staging but at the development stage. Axillary dissection should be omitted in patients with ductal carcinoma in situ since the probability of nodal involvement is less than 1%. In invasive breast cancer, the risk of axillary recurrence in the untreated axilla varies from 10% to 40%. For women with stage I-II breast cancer at least level I and II axillary node dissection should be offered as the standard procedure to reduce the risk of regional recurrence. Women at high risk of axillary recurrence ( $\geq 4$  involved nodes,  $< 6$  nodes obtained from a positive axilla) require axillary irradiation after axillary dissection. However, there is a lack of higher level evidence to support the benefit of post-dissection axillary irradiation. Evidence suggests that axillary irradiation is as effective as axillary dissection in preventing regional recurrence. The following factors have to be considered for decisions regarding dissection or irradiation: patient wishes, general condition, age, the necessity of pathological nodal status for systemic therapy and the risk of post-treatment morbidity. At this time, there is no well defined subgroup of patients in whom axillary intervention can be safely omitted. In selected patients with clinically negative axilla, the decision to observe the axilla rather than use surgery or irradiation should be made jointly between the women and her specialists (surgeon, radiation and medical oncologist). The benefits of axillary treatment in prolonging survival are unclear. Studies have reported different effects on survival. Whilst there is insufficient evidence, the risk of axillary recurrence has to be minimized, and more randomized clinical trials should be conducted. Patients should be fully informed about the benefits and the potential side effects of treatments. A combination of radiotherapy and axillary dissection increases the morbidity rate compared with each individual treatment.

**The Australian Clinical Practice Guidelines** for the Management of Early Breast Cancer (2001)  
NHMRC 2001 includes a section on the potential complication of irradiation to the axilla and supraclavicular fossa. The extracts are reported below:

## COMPLICATIONS

### **Acute radiation pneumonitis**

The risk of acute radiation pneumonitis is reported to range from 0.7–7 per cent. When the breast and axilla are irradiated, the risk will be at the upper end of the range because the risk increases with the amount of lung in the radiation field. It is, therefore, a rare complication. Small asymptomatic radiological changes, often referred to as fibrosis, may be noted on the chest X-rays. They may cause confusion and may be mistaken for metastases.

### **Brachial plexopathy**

This is a very rare complication and will only occur when the axilla and supraclavicular fossa are irradiated. The incidence is 0.3 per cent at five years with current doses and fractionation, but has exceeded 5 per cent when hypofractionated regimens have been used.

### **Second malignancy**

Six studies involving about 150,000 women treated with radiotherapy have reported on the development of a second malignancy. These studies have shown a relative risk of 1.17 which was not statistically significant. About half the series quote an increased incidence of colon, uterine and ovarian cancer in patients irradiated for breast cancer. These cancers are unlikely to have been caused by radiotherapy, as the host organ does not lie within the field irradiated. When site-specific associations such as colon, uterus and ovary are excluded, the risk of second malignancy becomes negligible in the clinical context (**Level III**).

In terms of post-radiation sarcoma, only 24 cases have been reported in seven series involving nearly 34,000 patients with follow-up of 5–18 years. The best estimate of risk is of two cases of post-radiation sarcoma per 10,000 women years of follow-up. In the case of breast conservation, perhaps half of these cases will be an angiosarcoma of the breast.

Recht, A., Edge, S. B., Solin, L. J., Robinson, D. S., Estabrook, A., Fine, R. E., Fleming, G. F., Formenti, S., Hudis, C., Kirshner, J. J., Krause, D. A., Kuske, R. R., Langer, A. S., Sledge, G. W., Jr., Whelan, T. J., & Pfister, D. G. 2001, "Postmastectomy radiotherapy: Clinical practice guidelines of the **American Society of Clinical Oncology**", *Journal of Clinical Oncology*, vol. 19, no. 5, pp. 1539-1569.

Extracts from the ASCO guideline are reproduced below:

*Axillary node irradiation*

*Guideline:* We suggest that full axillary radiotherapy *not* be given routinely to patients undergoing complete or level I/II axillary dissection. There is insufficient evidence to make suggestions or recommendations as to whether some patient subgroups might benefit from axillary irradiation.

*Level of Evidence:* III.

*Grade of Recommendation:* B.

*Supraclavicular Nodal Irradiation for patients with Four or more Positive Axillary Lymph Nodes*

*Guideline:* The incidence of clinical supraclavicular failure is sufficiently great in patients with four or more positive axillary nodes that we suggest a supraclavicular field should be irradiated in all such patients.

*Level of Evidence:* III.

*Grade of Recommendation:* A.

*Supraclavicular Nodal Irradiation for patients with One to Three Positive Axillary Lymph Nodes*

*Guideline:* There is insufficient evidence to state whether a supraclavicular field should or should not be used for patients with one to three positive axillary nodes.

*Internal Mammary Nodal Irradiation*

*Guideline:* There is insufficient evidence to make suggestions or recommendations on whether deliberate internal mammary nodal irradiation should or should not be used in any patient subgroup.

## Expert Overviews

Grabenbauer, G. G. 2004, "Internal mammary nodes in invasive breast carcinoma. To treat or not to treat? [Review] [37 refs]", *Strahlentherapie und Onkologie*, vol. 180, no. 11, pp. 690-694.

Design: Overview of selected (non-systematic) studies and cohort (1985-1996) Level 4  
 Country: Germany setting: Cohort: University Radiation Oncology Department  
 Aim: To determine the prognostic impact of radiation therapy (RT) to internal mammary nodes (IMNs) in early breast cancer patients with medial hemisphere tumour location.

### Inclusion criteria

Four large recent series of the literature reporting on > 50,000 patients with a special focus on the impact of tumour location, with no systematic RT to IMNs.

Patients with lateral or medial lesions in early breast cancer treated by surgery and RT with or without chemotherapy.

### Exclusion criteria

#### Population

4 recent retrospective studies:

Gaffney 2003 (SEER)

Hammer 2001

Lohrisch 2000

Zucali 1998

Cohort of 822 patients - 492 lateral and 330 medial lesions

T1 or T2 tumour

Primary unilateral breast cancer

Complete surgery with axillary dissection (no residual tumour)

Complete RT

Complete follow-up

Absence of distant metastases at diagnosis

### Interventions

Overview: Recent studies with no radiation to the IMN region. No information provided about type or extent of surgery.

Cohort: Surgery and postoperative RT with or without chemotherapy

All patients with medial lesions received RT to IMNs by a mixed-beam approach (50% photons, 50% electrons) with a total dose of 50 Gy.

Patients with lateral lesions received RT directed to the breast alone (50.4 Gy total dose, boost 12-16 Gy).

### Outcomes

Overall survival (OS)

Breast cancer specific survival (BCSS)

Disease-free survival (DFS)

Systemic Disease-free survival (SDFS)

### Follow up -

### Results

#### Overview

Findings reported in table below. All outcomes were significantly poorer for medial tumours.

Study details	Medial tumours (n)	Lateral tumours (n)	Outcomes (p values indicating lower survival in medial lesions)
Gaffney 2003 N=45880 (1988-1997) All stages M0	10 111	35 769	OS p=0.004 BCSS p= 0.001 DFS NA

Hammer 2001 N=644 (1984-1995) T1-2, N0-2, M0	220	429	OS p=0.0009 BCSS p= 0.009 DFS p= 0.001
Lohrisch 2000 N=5359 T1-3, N0-1, M0	1 511	3 848	OS NA BCSS p= 0.028 DFS p= 0.005 (high risk lesions only)
Zucali 1998 N=2396 (1973-1989) T1-2, N0-1, M0	777	1 619	OS p=0.03 BCSS NA DFS p= 0.0066

Other findings were:

Zucali: A subgroup of 777 women with medial tumours had an excess risk of 30% for distant metastases, and an excess mortality of 20%.

Hazard Ratio (HR) for distant metastases 1.29 with medial tumour vs. lateral tumours.

Lohrisch: in women with low risk cancer there was no effect of tumour location on outcome; in contrast women with high risk factors, e.g. tumour size > 2cm, nodal disease, negative receptors, or invasion of lymphatic or blood vessels, had an excess risk of 50% for both distant metastases and tumour associated death.

HR for BCSS 1.46 for medial tumour vs. lateral tumours.

Gaffney: Both node negative and positive patients, inner vs. outer quadrant tumour location were predictive for OS and breast cancer-specific survival rates. The 5 year BCSS for inner and outer tumour location was 78.9% vs. 82.2% (p=0.002), and the 5 year OS was 72.8% vs. 74.7% (p<0.001).

HR for BCSS 1.31 for medial tumour vs. lateral tumours.

#### *Erlangen Cohort*

The findings are reported in the table below.

	Overall survival (10 yrs) RT to IMN			Systemic disease-free survival (10 yrs) No IMN		
	Lateral	Medial	p	Lateral	Medial	p
All patients (n=822)	60.3%	64%	NS	65.5%	70.1%	NS
pT1 (n=458)	73.5%	73.9%	NS	75.8%	75.9%	NS
pT2 (n=364)	45.7%	49.6%	NS	53.0%	60.6%	NS
pN0 (n=432)	75.0%	75.7%	NS	78.4%	82.0%	NS
pN+ (n=390)	46.2%	49.5%	NS	51.9%	55.2%	NS
Premenopausal (n=317)	71.6%	73.4%	NS	70.7%	70.8%	NS
Postmenopausal (n=505)	52.0%	58.9%	0.05	61.6%	69.8%	0.07
Without chemotherapy (n=582)	61.7%	62.8%	NS	70.3%	70.9%	NS
With chemotherapy (n=240)	57.2%	68.9%	NS	54.5%	67.6%	0.02

10 year overall survival was significantly better in patients with medial than lateral tumours (58.9% vs. 52%; p=0.05) in postmenopausal women; and 10 year SDFS was better for those with medial than lateral tumours (67.6% vs. 54.5%; p=0.02) for patients on chemotherapy. These findings are based on non-randomized participants and the univariate statistical comparisons may be affected by confounders.

Kaplan-Meier curves for overall survival were 79.1% and 64% at 5 and 10 years for medial tumours (n=330) with RT to the IMN, and 76.2% and 60.3% for lateral tumours (n=492) (p=0.2) with no IMN irradiation.

SDFS from Kaplan-Meier curves were 72.6% and 70.1% at 5 and 10 years for medial tumours (n=330) with RT to the IMN, and 72.9% and 65.5% for lateral tumours (n=492) (p=0.3) with no IMN irradiation.

#### **Author conclusions**

Consistent literature data exist indicating a diminished survival in patients with inner versus

outer quadrant breast cancer. According to our data, RT with a total dose of 50 Gy to IMNs in breast cancer patients with medial lesions was associated with OS and SDFS rates comparable to patients with lateral tumours. RT to IMNs may represent a very effective means to improve survival in patients with medial tumours.

**General comments**

## Other Reviews

- **Freedman, G. M.**, Fowble, B. L., Nicolaou, N., Sigurdson, E. R., Torosian, M. H., Boraas, M. C., & Hoffman, J. P. 2000, "Should internal mammary lymph nodes in breast cancer be a target for the radiation oncologist?[see comment]. [Review] [61 refs]", *International Journal of Radiation Oncology, Biology, Physics*, vol. 46, no. 4, pp. 805-814.

The authors analyzed published randomized prospective trials testing the value of elective IMN dissection and/or radiation for patterns of failure for distant metastases and overall survival. Trials need to be carefully examined to draw conclusions that are relevant to present treatment regimes. The Danish and British Columbia trials included a separate internal mammary field in their technique, but attempts to attribute survival benefits to the IMN field is circumstantial. The survival benefit in these studies can be attributed to the reduction of the high rate (30%) of isolated locoregional failure to 10% or less by postmastectomy radiation of the chest wall, supraclavicular and axillary nodes alone. There have been many other postmastectomy trials that failed to show an overall survival benefit to radiation that included the IMN chain. These studies were not designed to assess the impact of IMN irradiation on disease-free or overall survival of patients. The NSABP B-02 trial found that distant metastases as a site of first failure were increased with regional radiation compared to no radiation, as well as other studies. A large reduction in isolated first local-regional (chest wall, supraclavicular or axillary) failures can be associated with a subsequent decrease in secondary late distant metastases and death.

In conclusion the historical reports of IMN positivity in over 25-30% of axillary node positive patients should not be extrapolated to breast cancer patients diagnosed and treated today.

A similar overview examined the postmastectomy RCTs that have been used for earlier topics in this guideline to separate out axillary and IMN metastases.

- **Noguchi, M.** 2002, "Does regional treatment improve the survival in patients with operable breast cancer?. [Review] [78 refs]", *Breast Cancer Research & Treatment*, vol. 76, no. 3, pp. 269-282.

Abstract: **BACKGROUND:** The impact of regional therapy on survival of patients with invasive breast cancer remains controversial. Regional therapies discussed include axillary lymph node dissection (ALND), internal mammary node dissection, and locoregional radiotherapy. **METHODS:** Prospective randomized clinical studies of regional therapy were reviewed using, as a source, Medline, main review articles on the related topic, and statements from consensus conference.

**RESULTS:** Although a number of randomized clinical studies have failed to demonstrate the benefits of regional treatment for survival, it is still a matter of debate whether ALND or regional radiotherapy alone can have a small but significant beneficial effect on the survival of breast cancer patients. However, recent studies have suggested that survival can be enhanced by interaction of postmastectomy locoregional radiotherapy with adjuvant systemic therapy.

**CONCLUSIONS:** Locoregional control is important for enhancing survival in the presence of adjuvant systemic therapy. Although only a few randomized controlled trials show conclusively the survival benefit of local therapies, it is expected that in clinical practice, the node-positive or other high-risk breast cancer patients given systemic treatment will be more frequently treated with postmastectomy radiation.

## Phase II study

A recent Phase II study of 30 patients (mainly T1-2; N0-N1) requiring a level II/III axillary dissection recommends a change in practice for the localisation of the supraclavicular fossa for radiation therapy.

- Wheatley, D., Adwani, A., Ebbs, S., Hanson, J., Ross, G., Sharma, A. K., Wells, P., & Yarnold, J. 2005, "Matching supraclavicular fields to the extent of axillary surgery in women prescribed radiotherapy for early stage carcinoma of the breast", *Clinical Oncology (Royal College of Radiologists)*, vol. 17, no. 1, pp. 32-38.

The conclusions were that the current standard radiation fields to the supraclavicular fossa, as applied in this study, leave apical axillary lymph nodes untreated in a high proportion of patients. Standard lung shielding, as

applied in this study to patients simulated for axillary radiotherapy, protects medial axillary lymph nodes in a few patients. A change in practice is recommended.

## Chapter 7 – Primary systemic therapy

### 7.1 What is the role of primary medical treatment in patients with early, invasive breast cancer?

#### Short Summary

The evidence that describes the role of primary systemic treatment in patients with early, invasive breast cancer has been drawn from three systematic reviews (Hind *et al.* 2006; Mieog *et al.* 2007; Trudeau *et al.* 2005) and a review providing updated results of two randomised trials (Rastogi *et al.* 2008). This research question lists two comparisons of interest; the first comparison is related to primary endocrine therapy versus primary surgery in elderly patients while the second comparison relates to primary chemotherapy versus surgery as primary treatment for patients with breast cancer.

#### Primary Endocrine Therapy

A systematic review of randomised controlled trials provides the most applicable data for the use of endocrine therapy as initial treatment in patients >70 years and reported no significant difference in overall survival between surgery and primary endocrine treatment (Hind *et al.* 2006). There was evidence of a non-significant trend in favour of surgery plus endocrine therapy over primary endocrine therapy (Hind *et al.* 2006). There is a statistically significant effect in favour of surgery plus endocrine therapy over endocrine therapy for breast cancer specific survival (Hind *et al.* 2006).

#### Primary Chemotherapy

A systematic review (Mieog *et al.* 2007) and a subsequently published review (Rastogi *et al.* 2008) reported no significant difference in overall survival or disease free survival between preoperative and postoperative chemotherapy. A statistically significant difference in rate of mastectomy in favour of preoperative chemotherapy was observed based on pooled estimates from good quality RCTs (Mieog *et al.* 2007).

#### PICO

Population	Intervention	Comparison	Outcome
Elderly patients: unfit for surgery or who decide not to receive surgery	Primary medical therapy: Endocrine therapy Chemotherapy	No primary medical therapy / surgery  Mastectomy	Breast conservation rate Recurrence Survival Cosmesis Patient acceptability Quality of life
Patients who receive primary medical therapy with the aim of breast conserving surgery			

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

## Evidence Summary

There is a moderate volume of published evidence for the use of primary chemotherapy or primary hormone therapy in patients with breast cancer. A Cochrane Review of RCTs addresses directly the comparison of primary hormone treatment vs. primary surgery in elderly patients; while a second Cochrane Review has good applicability to the second comparison; namely primary chemotherapy vs. primary surgery. A third systematic review focussed on primary chemotherapy using taxane-containing regimens. A review providing updated results of two randomised trials and an RCT comparing chemotherapy regimens were also identified during update searches.

There are four areas where treatment regimens in the trials do not necessarily coincide with modern clinical practice. Therefore, the appropriateness of the following should be questioned:

- (1) endocrine therapy for women with ER negative tumours;
- (2) surgery without adjuvant endocrine therapy;
- (3) primary endocrine therapy where the individual is fit for and agreeable to surgery;
- (4) new endocrine therapies.

The three systematic reviews reported heterogeneity between the primary randomised studies.

There is no significant difference in overall survival rates when comparing surgery and primary hormone treatment.

There is no significant difference in overall survival or disease free survival between preoperative and postoperative chemotherapy.

## Taxane-based primary chemotherapy

In the systematic review of RCTs of taxane-based primary chemotherapy by Trudeau *et al.* 2005, data were reported but have not been cited in this summary for:

- primary taxane regimens versus non-taxane regimens as primary chemotherapy;
- comparisons of different doses/schedules of taxane primary chemotherapy.

However these data are cited in the associated evidence table, but are not the prime concern of topic 26. Data are cited in this summary from Trudeau *et al.* 2005 for primary taxane-based chemotherapy versus adjuvant taxane-based chemotherapy.

In addition to the limitations of study applicability and heterogeneity reported above, the Cochrane Review by Hind *et al.* 2006 reported the following limitations of the data from its included RCTs:

## Competing risks

Competing risks apply to outcomes such as local failure in Kaplan-Meier analyses. Censoring patients in whom a competing risk occurs (e.g. death) is not appropriate as it gives an underestimate of the probability of local failure by treating those cases who haven't failed locally and are alive the same as those who have not failed locally but have died (Hind *et al.* 2006).

## Informative censoring

Re: time to local or distant recurrence: in one trial patients were censored at the time of their last clinical examination. Assuming that those who have progressed are more likely to attend follow-up clinics and that those who are disease or metastases-free are less likely to attend

clinics, the latter group will be censored earlier, and will stop contributing information to the study. Thus the censoring is potentially dependent on the likelihood of disease progression (that is, related to the outcome). This is another source of potential bias as the rate of censoring does not leave a representative sample of those at risk (Hind *et al.* 2006).

## **PART 1: PRIMARY HORMONE THERAPY**

The Cochrane systematic review of randomised trials by Hind *et al.* (2006) provides the most applicable data for the use of hormone therapy as initial therapy in patients with breast cancer of age >70 years.

### **1. Primary hormone therapy versus surgery in patients aged over 70 years**

#### **Overall survival**

The pooled result in the Cochrane Review of three trials based upon a total 495 women demonstrated no statistically significant difference in overall survival between surgery versus primary hormone therapy: hazard ratio (HR) 0.98, 95% CI 0.74 to 1.30,  $p=0.9$  (Hind *et al.* 2006).

#### **Progression-free survival**

One RCT included in the Cochrane Review provided data on progression-free survival and favoured surgery over primary hormone therapy: HR 0.55, 95% CI 0.39 to 0.77,  $p=0.0006$  (Hind *et al.* 2006).

#### **Adverse effects**

There were insufficient data for a quantitative analysis of adverse effects. In 1 RCT no patient discontinued treatment with primary endocrine therapy. Eight patients had a total of ten side effects, including hot flushes, skin rash, vaginal discharge, indigestion, breast pain and sleepiness (Hind *et al.* 2006).

#### **Local disease control**

No data on local disease control were acceptable for citing due to biases introduced by competing risks, heterogeneity of interventions and informative censoring (Hind *et al.* 2006).

#### **Distant metastasis-free survival**

Data from 1 RCT included in the Cochrane Review based upon 164 women demonstrated no statistically significant difference between surgery and primary hormone therapy: HR 0.77, 95% CI 0.37 to 1.58,  $p=0.47$  (Hind *et al.* 2006). NB due to the method of calculation, this hazard ratio incorporates distant metastases recorded both as a first event and following or simultaneously with a local progression.

#### **Quality of life**

No trials in the Cochrane Review reported any data for quality of life (Hind *et al.* 2006).

### **2. Surgery plus adjuvant endocrine therapy versus primary endocrine therapy**

#### **Overall survival**

The pooled overall survival result of three trials in the Cochrane review by Hind *et al.* 2006 based upon 1076 women demonstrated a trend in favour of surgery plus endocrine therapy over primary endocrine therapy, that was not statistically significant: HR 0.86, 95% CI 0.73 to 1.00,  $p=0.06$ .

### **Overall survival by ER status**

One trial included in the Cochrane Review by Hind *et al.* 2006 provided data based on 147 women, all of whom had ER-positive tumours. There was no significant difference in overall survival arising from surgery plus adjuvant hormone therapy versus primary hormone therapy: HR 0.80, 95% CI 0.28 to 2.32,  $p=0.68$ .

### **Overall survival by age**

Age-related subgroup analysis in the Cochrane Review was not possible on the basis of published data (Hind *et al.* 2006). In a conference abstract authors reported analyses of combined individual patient data from both trials. They reported that patient age was the most important determinant of survival in patients of age 75 years or more. In patients of age between 70 and 75 years, initial surgery (rather than primary endocrine therapy) was found to determine survival.

### **Breast cancer specific survival**

A published meta-analysis of individual patient data from two RCTs cited by Hind *et al.* 2006 found a statistically significant effect in favour of surgery plus endocrine therapy over primary endocrine therapy: HR 0.7, 95% CI 0.51 to 0.95.

### **Progression-free survival**

Data from 1 RCT cited by Hind *et al.* 2006 found a statistically significant effect in favour of surgery plus endocrine therapy over primary endocrine therapy: HR 0.65, 95% CI 0.53 to 0.81,  $p = 0.0001$ ).

### **Adverse effects**

There were insufficient data to justify any quantitative analysis of adverse effects (Hind *et al.* 2006).

### **Local disease control**

A pooled estimate based on data from 2 RCTs (929 women) included in the Cochrane Review by Hind *et al.* 2006 demonstrated a statistically significant difference in favour of surgery plus endocrine therapy over primary endocrine therapy: HR 0.28, 95% CI 0.23 to 0.35,  $p < 0.00001$ . There were insufficient data to justify any quantitative analysis of prospectively identified subsets. However, one trial which recruited only patients with ER-positive tumours reported better local control in the surgery plus endocrine arm.

One trial which contributed data to the hazard ratio quoted above reported this outcome by type of surgery, comparing both mastectomy (52 of 225 women) and breast-conserving surgery (159 of 225) against the same population of primary endocrine therapy (230 women). The trialists reported better local disease control for both mastectomy and breast-conserving surgery than primary endocrine therapy.

### **Distant metastasis-free interval**

Although data were available from one trial they were not used by the review authors because data quality was suspect (Hind *et al.* 2006).

### **Quality of life**

There were insufficient data to justify any quantitative analysis of this outcome (Hind *et al.* 2006). However, in one published trial included in the Cochrane Review by Hind *et al.* 2006

authors used the General Health Questionnaire 28, designed to detect psychiatric morbidity, and a socio-demographic questionnaire, which investigated levels of domestic support and social isolation. At three months after start of treatment the surgery group had more psychosocial morbidity than the primary hormone therapy group (p value 0.03). However, there was no difference between the surgery and primary hormone therapy groups at two years.

### **3. Main results of randomised trials not included in the cited systematic reviews**

Three additional RCTs evaluate primary hormone therapy in patients with breast cancer either compared to primary chemotherapy (Tan *et al.* 2001) or in combination with primary chemotherapy (Cocconi *et al.* 1990; Von *et al.* 2001b).

The small (n=49) and possibly underpowered RCT by Cocconi *et al.* 1990 compared primary CMF chemotherapy followed mastectomy and adjuvant CMF chemotherapy, versus primary chemoendocrine therapy (CMF plus tamoxifen) followed by mastectomy and the same chemoendocrine combination as adjuvant treatment in patients with locally advanced breast cancer. There was no statistically significant difference in median time to progression or recurrence in the CMF group (58.3 months) compared to the CMF plus tamoxifen group (29.1 months; p=0.38, Cox-Mantel test). Respective values of median overall survival were 79.7 months and 41.5 months; this difference was of borderline statistical significance (p=0.05, Cox-Mantel test).

The RCT by Von *et al.* 2001 also evaluated the addition of tamoxifen to a primary chemotherapy regimen (docorubicin-docetaxel), versus primary chemotherapy alone, studying short-term outcomes. There was no evidence of a difference in the rate of pathological complete response between the randomised arms: 10.3% in the primary chemotherapy arm versus 9.1 in the primary chemotherapy plus tamoxifen arm (difference - 1.2%; 95% CI -8.6 to +6.2) There was little difference in toxicity between the two groups (numerous variables tabulated; no statistical testing of differences performed). There was a higher incidence of severe infections associated with the higher rate of grade 3/4 neutropenia in the primary chemotherapy plus tamoxifen arm. However, the incidences of febrile neutropenia were similar, at 8.3% in the primary chemotherapy plus tamoxifen arm and 8.7% in the primary chemotherapy group. The most common severe forms of toxicity, apart from alopecia, were fatigue and loss of appetite. All other toxicities occurred in less than 5% of the cycles. The rate of breast-conserving surgery did not vary significantly between randomised arms, at 68.6% in the primary chemotherapy plus tamoxifen arm and 69.0% in the primary chemotherapy arm (difference -0.4; 95% CI -12.0% to +11.1%) (Von *et al.* 2001a).

The RCT by Tan *et al.* 2001 compared primary hormone therapy versus primary chemotherapy as initial therapies in patients with locally advanced breast cancer. The time to first locoregional failure was significantly shorter in the initial hormone therapy group when compared with the multimodal therapy group (P<0.01). There was no difference in the number of patients who developed distant metastases (n=29 and n=30 for those treated with initial hormone therapy and multimodal therapy, respectively), nor in the time to distant metastases between the two groups (p=0.84). There was no statistically significant difference in overall survival between the randomised groups (p=0.22) (Tan *et al.* 2001).

An RCT by Eirmann *et al.* 2001 evaluated preoperative treatment of postmenopausal breast cancer patients with letrozole compared to tamoxifen.

## **PART 2: PRIMARY CHEMOTHERAPY**

### **1. Primary chemotherapy versus adjuvant (following surgery) chemotherapy**

NB: In The Cochrane Review by Mieog *et al.* 2007 which is the best quality source of data for primary chemotherapy, median follow-up in each of the 14 included RCTs had range 18-124 months.

#### **Overall survival**

The Cochrane Review by Mieog *et al.* 2007 provided a pooled estimate of overall survival based on data from 10 RCTs (4620 women). There was no statistically significant difference in overall survival between preoperative and postoperative chemotherapy: HR 0.98 (95% CI, 0.87 to 1.09;  $p=0.67$ ).

#### **Disease-free survival**

The Cochrane Review by Mieog *et al.* 2007 provided a pooled estimate of disease-free survival based on data from 10 RCTs (4510 women). There was no statistically significant difference between preoperative and postoperative chemotherapy: HR 0.97 (95% CI, 0.89 to 1.07;  $p=0.58$ ).

#### **Time to loco-regional recurrence**

The Cochrane Review by Mieog *et al.* 2007 provided a pooled estimate of time to loco-regional recurrence based on data from 11 RCTs (5041 women). There was a statistically significant difference in favour of postoperative chemotherapy: HR 1.21 (95% CI, 1.02 to 1.43;  $p=0.03$ ).

#### **Rate of loco-regional recurrence reported in Cochrane Review by Mieog *et al.* 2007 (preoperative versus postoperative chemotherapy) by subgroup for loco-regional treatment**

1. Breast conserving surgery (4 RCTs, 1830 women): relative risk (RR), 1.13; 95% CI, 0.82 to 1.54;  $p=0.5$
2. Mastectomy (4 RCTs, 1427 women, 82 recurrences): RR, 1.14; 95% CI, 0.74 to 1.75;  $p=0.6$
3. Exclusive RT: no data
4. Total (3257 women, 225 recurrences): HR 1.13; 95% CI, 0.88 to 1.46;  $p=0.35$ ; risk difference, 2.3; 95% CI, 0.9 to 3.6; control group risk, 5.9%;  $p=0.3$ .

There was no statistically significant difference in loco-regional recurrence between women treated with BCT and those treated with mastectomy ( $\text{Chi}^2$  for difference, 0.01;  $p, 0.92$ ).

#### **Nodal involvement revealed by surgery**

The systematic review by Trudeau *et al.* 2005 reported data from one RCT in which there were significantly different rates of nodal involvement at surgery; 61% of patients who received primary chemotherapy with paclitaxel and doxorubicin were node-negative at surgery compared with 38% of patients who received no primary chemotherapy ( $p=0.0001$ ).

### **2. Tumour response to preoperative chemotherapy**

Tumour response to primary chemotherapy is described below and summarised in the table below.

In the Cochrane Review by Mieog *et al.* 2007, eleven studies reported a complete clinical response rate in the preoperative chemotherapy arm for 1761 assessable patients. The complete clinical response rate ranged from 0 to 64.7%.

Twelve studies reported an overall clinical response rate in the preoperative chemotherapy arm for 2032 assessable patients. The overall clinical response rate ranged from 11.1 to 83.3% (Mieog *et al.* 2007).

Seven studies reported a pathological complete response rate in the preoperative chemotherapy arm for 1972 assessable women. The pathological complete response rate ranged from 4.0 to 29.2% (Mieog *et al.* 2007).

In the systematic review of primary taxane chemotherapy by Trudeau *et al.* 2005 the proportion of cases in which a tumour pathological complete response (pCR) was achieved was reported for 36 randomised arms across 18 RCTs. This value had mean 15.6%, median 15.0% and range 0% to 31%.

In the same systematic review eight randomised arms provided data for the proportion of cases in which a tumour pathological partial response (pPR) was achieved. This value had mean 28%, median 28.5% and range 0% to 57% (Trudeau *et al.* 2005).

21 randomised arms provided data for the proportion of cases in which a tumour clinical complete response (cCR) was achieved. This value had mean 24%, median 20% and range 0% to 84% (Trudeau *et al.* 2005).

25 randomised arms provided data for the proportion of cases in which a tumour clinical partial response (cPR) was achieved. This value had mean 53.8%, median 56% and range 3% to 96% (Trudeau *et al.* 2005).

**Table: summary of tumour responses to primary chemotherapy**

<b>Study</b>	<b>(Mieog <i>et al.</i> 2007)</b>	<b>(Trudeau <i>et al.</i> 2005)</b>
Overall clinical response (%)		
mean		
median		
range	11.1-83.3	
Partial clinical response (%)		
mean		53.8
median		56
range		3-96
Complete clinical response (%)		
mean		24
median		20
range	0-64	0-84
Pathological partial response (%)		
mean		28
median		28.5
range		0-57

Pathological complete response (%)		
mean		15.6
median		15
range	4-29.2	0-31

### Association of pathological complete response with clinical outcome

The Cochrane Review by Mieog *et al.* 2007 compared overall and disease-free survival between patients with a pathological complete response and those who had residual disease at pathological examination.

Four RCTs reported overall survival data for 1290 assessable patients involving 381 estimated deaths. There was a statistically significant difference in favour of pathological complete response: HR (pCR versus residual disease) 0.48 (95% CI 0.33 to 0.69) (Mieog *et al.* 2007).

Five studies reported disease-free survival data for 1741 assessable patients. There was a statistically significant difference in favour of pathological complete response: HR (pCR versus residual disease) 0.48 (95% CI 0.37 to 0.63) (Mieog *et al.* 2007).

### 3. Primary chemotherapy and rates of breast conserving treatment

The Cochrane Review by Mieog *et al.* 2007 provided a pooled estimate of the rate of mastectomy following preoperative versus postoperative chemotherapy based upon 10 RCTs (5292 women, of which 2395 underwent mastectomy<sup>17</sup>). There was a statistically significant difference in rate of mastectomy in favour of preoperative chemotherapy: RR 0.71 (95% CI, 0.67 to 0.75;  $p < 10^{-5}$ ), representing a risk difference of 16.6% (95% CI, 15.1 to 18.1; control group risk, 52.9%; NNT = 6). For this result there was considerable heterogeneity between studies.

Sensitivity analysis did not account for the study heterogeneity relating to this pooled estimate. The authors excluded two studies from the analysis due to clinical heterogeneity<sup>18</sup> and re-analysed using data from 8 RCTs (3709 women, of which 1452 underwent mastectomy). There was a statistically significant difference in rate of mastectomy in favour of preoperative chemotherapy: RR 0.82 (95% CI, 0.76-0.89;  $p < 10^{-5}$ ), representing a risk difference of 8.0% (95% CI, 6.3-9.7; control group risk, 43.1%; NNT = 13); with moderate heterogeneity across studies (Mieog *et al.* 2007).

---

<sup>17</sup> In three of these studies the reported conservative treatment rate was that achieved after subsequent follow-up i.e. taking account of mastectomy as a second operation to treat local recurrence (Bordeaux 1991, Institut Curie 1994; Royal Marsden 1998).

<sup>18</sup> One study involved an intensive chemotherapy regimen including taxane and anthracycline drugs and reached a high pCR rate, allowing <sup>more</sup> conservative treatment (ECTO 2005). The second study treated all patients in the control arm with mastectomy since one of the inclusion criteria was patients with tumours not suitable for conservative treatment (Bordeaux 1991).

In the systematic review of taxane primary chemotherapy by Trudeau *et al.* 2005, the proportion of patients who received breast conserving surgery was reported for 21 randomised arms in 14 RCTs. This proportion had mean 54%, median 56% and range 20% to 85%.

#### **Changes to originally planned locoregional treatment (5 RCTs)**

In the Cochrane Review by Mieog *et al.* 2007 five studies reported changes of loco-regional treatment to those planned originally in the preoperative chemotherapy arm (1549 assessable women). Across studies, 397 women had their originally planned surgical treatment altered due to down staging (25.6%; 95% CI, 23.5 to 27.8), 1086 women had no change to planned treatment (70.1%; 95% CI, 67.8 to 72.4), and 66 women required more radical surgery than originally planned (4.3%; 95% CI, 3.3 to 5.3).

In the same review two RCTs compared outcomes between patients who received down staged breast conserving therapy compared to those who received planned breast conserving therapy in the preoperative chemotherapy arm. There was no statistical significant difference in either overall survival (odds ratio (OR) 1.33; 95% CI 0.67-2.63) or loco-regional recurrence (RR 1.34; 95% CI 0.85-2.13). However the review authors concluded that direct evidence concerning long-term prognosis and risk of local recurrence after downstaging of surgical treatment following preoperative chemotherapy is still lacking (Mieog *et al.* 2007).

#### **4. Adverse events**

In the Cochrane Review by Mieog *et al.* 2007, seven RCTs provided data on adverse effects. There was no statistically significant difference between preoperative and postoperative chemotherapy for postoperative complications, nausea/ vomiting, and alopecia. Events of cardiotoxicity were less frequent in women receiving preoperative chemotherapy, but not statistically significantly so (RR 0.74; 95% CI, 0.53-1.04;  $p=0.08$ ). The four studies reporting on leucopenia/ neutropenia/ infections involving 2799 women demonstrated a statistically significant difference in favour of preoperative chemotherapy: RR 0.69 (95% CI, 0.56 to 0.84;  $p=0.0003$ ); risk difference 4.2% (95% CI, 2.3 to 5.6; control group risk, 13.8%; NNT, 24).

The systematic review of taxane primary chemotherapy by Trudeau *et al.* 2005 reported a large amount of data on adverse effects: haematologic toxicity, cardiotoxicity, neurotoxicity, gastrointestinal toxicity and other toxicities. The authors concluded that general, haematologic toxicity, in particular neutropenia and febrile neutropenia, was more common with a taxane-containing regimen compared to non taxane-comparing regimens. Neurotoxicity may be associated with primary paclitaxel and hand-foot syndrome may be associated with primary docetaxel. There was little evidence to suggest that other adverse events occur more frequently with a primary taxane (Trudeau *et al.* 2005).

#### **5. Quality of life**

In the Cochrane Review by Mieog *et al.* 2007, no data were available for this outcome.

#### **6. Main results of randomised trials not included in the cited systematic reviews**

The RCT by Avril *et al.* 1998 compared primary chemotherapy (followed by locoregional treatment) with mastectomy (followed by adjuvant chemotherapy). At 10 years follow-up, estimated overall survival was 60% both in the primary chemotherapy group and in the mastectomy group. Also at 10 years follow-up, estimated recurrence-free survival was 50% in the primary chemotherapy group and 57% in the mastectomy group.

The RCT by Ragaz *et al.* 1986 reported on an early step towards primary chemotherapy, comparing a regimen in which one cycle of CMF chemotherapy was given before surgery followed by eight further cycles adjuvant to surgery, versus all nine cycles of CMF adjuvant to surgery. There was no statistically significant difference between randomised arms in disease-free survival at 2 years follow up ( $p > 0.1$ ).

The RCT by Scholl *et al.* 1991 compared primary chemotherapy versus multimodal therapy based mostly on RT, but also involving surgery and adjuvant chemotherapy. Over the entire follow-up period (median 54 months) there was no statistically significant difference in disease-free survival between randomised groups (primary versus adjuvant chemotherapy);  $p = 0.4$ . Over the same follow-up period there was no statistically significant difference in overall survival between randomised groups (primary versus adjuvant chemotherapy);  $p = \text{NS}$ ; log-rank test. The rate of local recurrence between randomised groups was similar: 18% for the primary chemotherapy group and 20% for the adjuvant chemotherapy group (no  $p$  value reported). The rate of breast conserving surgery was 56% in the primary chemotherapy group versus 35% in the adjuvant chemotherapy group.

Update evidence:

- From an RCT (von Minckwitz *et al.* 2008) that compared 6 cycles of doxorubicin, docetaxel and cyclophosphamide (two 3-week cycles of docetaxel at 75 mg/m<sup>2</sup>, doxorubicin at 50 mg/m<sup>2</sup>, and cyclophosphamide at 500 mg/m<sup>2</sup>)(TAC) with 8 cycles of TAC in patients with previously untreated unilateral or bilateral primary breast cancer.
- The rates of pathological complete response were not statistically significantly different between the arms.
- The clinical complete responses at surgery were not statistically different with 8 TAC cycles than with 6 TAC cycles.
- The sonographic complete responses at surgery were statistically more with 8 TAC cycles than with 6 TAC cycles.
- There was no statistical significant difference in the rate of breast-conserving surgery in both arms.
- Grade 3 or 4 leukopenia and edema and various grade 1 or 2 adverse events were more frequent in patients receiving 8 TAC cycles than in those receiving 6 cycles.
- There were statistically more treatment discontinuations were due to adverse reactions reported in the 8 cycle arm than in the 6-cycle arm.
- Negative hormonal receptor status; nonlobular histology; undifferentiated grade; age younger than 50 years were statistically significantly independently associated with pathological complete response.

A review by Rastogi 2008, provided updated results from two randomised controlled trials, B-18 and B-27; trial B-18 compared preoperative chemotherapy with doxorubicin and cyclophosphamide with postoperative chemotherapy. Trial B-27 compared 3 groups; 4 cycles of preoperative AC plus docetaxel vs. 4 cycles of preoperative AC chemotherapy and postoperative docetaxel vs. 4 cycles of preoperative AC chemotherapy alone.

The updated results provide evidence that there is no statistically significant difference in overall survival (OS) or disease free survival (DFS) when comparing preoperative chemotherapy with post-operative chemotherapy in either trial.

		<b>Hazard Ratio, 95% CI (p)</b>
<b>B-18</b>	<b>Overall Survival</b>	HR=0.99, 95% CI, 0.85 to 1.16 (p=0.90)
	<b>Disease Free Survival</b>	HR=0.93, 95% CI, 0.81 to 1.06 (p=0.27)
<b>B-27</b>	<b>Overall Survival</b>	No HR or CI given (p=0.76)
	<b>Disease Free Survival</b>	No figures given

In trial B-18, individuals who achieved a pathological complete response (pCR) had superior DFS and OS outcomes when compared with patients not achieving a pCR (DFS HR =0.47, p<0.0001; OS HR =0.32, p<0.0001).

In trial B-27 pCR was a significant predictor of improved DFS (HR=0.49, p<0.0001) and OS (HR=0.36, p<0.0001).

Updated 2018

## Evidence Tables

### Systematic reviews of RCTs

<b>Citation</b>
Hind, Wyld, Beverley & Reed . Surgery versus primary endocrine therapy for operable primary breast cancer in elderly women (70 years plus). [Review] [43 refs]. Cochrane.Database.of Systematic.Reviews. [1], CD004272. 2006.
<b>Design</b>
Systematic review of RCTs, evidence level: 1 + Country: Various
<b>Inclusion criteria</b>
Aim: to systematically review the evidence for the clinical effectiveness of surgery (with or without adjuvant endocrine therapy) in comparison to primary endocrine therapy in the treatment of operable breast cancer in women aged 70 years and over, both in terms of local progression and mortality.  Eligible studies: RCTs
<b>Exclusion criteria</b>
No eligible studies were excluded.
<b>Population</b>
Women aged 70 years or over with clinically-defined operable primary breast cancer, that is, primary tumour not fixed to underlying structures (including the TNM classification T1-3 and T4b where there is only minor skin involvement, N0-1, mobile lymph nodes (UICC 1987)). The following age-based subgroups were planned: 70 to 79 years; 80 years and over.
<b>Interventions</b>
1) Surgery alone versus primary endocrine therapy. 2) Surgery plus adjuvant endocrine therapy versus primary endocrine therapy.
<b>Outcomes</b>
Primary outcome measures 1) Survival - overall (interval between start of treatment and patient's death; cause of death where available). 2) Progression-free survival (interval between start of treatment and need for second-line treatment/palliative treatment/recurrence/death from any cause).  Secondary outcome measures 1) Adverse effects (number of surgical complications/primary endocrine therapy related side effects, including hot flushes, nausea, vomiting, vaginal discharge, vaginal bleeding, thrombosis, endometrial carcinoma, visual

problems, skin rashes).

2) Local disease control (interval between start of treatment and need for second-line treatment/palliative treatment/recurrence; specified whether local disease has recurred in the breast/mastectomy scar or axilla).

3) Distant metastasis-free interval (interval between start of treatment and the development of metastatic disease).

4) Quality of life (however measured).

### **Follow up**

Variable across primary studies but adequate; commonly approximately 10 years.

### **Results**

Ratios of treatment effects are reported so that HRs less than 1.0 favour surgery or surgery plus adjuvant endocrine therapy and values greater than 1.0 favour primary endocrine therapy.

7 RCTs were eligible of which 6 provided usable data. In each trial the endocrine therapy used was tamoxifen

#### **1. Surgery versus primary endocrine therapy**

Overall survival

Pooled result of three trials (495 women). There was no statistically significant difference between interventions (HR 0.98, 95% CI 0.74 to 1.30,  $p=0.9$ ).

#### **Progression-free survival**

Data from 1 RCT favours surgery (HR 0.55, 95% CI 0.39 to 0.77,  $p=0.0006$ ).

#### **Adverse effects**

There were insufficient data for a quantitative analysis. In 1 RCT no patient discontinued treatment with primary endocrine therapy. Eight patients had a total of ten side effects, including hot flushes, skin rash, vaginal discharge, indigestion, breast pain and sleepiness.

#### **Local disease control**

No data were acceptable for citing due to biases introduced by competing risks, heterogeneity of interventions and informative censoring.

#### **Distant metastasis-free survival**

Data from 1 RCT (164 women) shows no statistically significant difference between interventions (HR 0.77, 95% CI 0.37 to 1.58,  $p=0.47$ ). NB due to the method of calculation, this hazard ratio incorporates distant metastases recorded both as a first event and following or simultaneously with a local progression.

#### **Quality of life**

No trials reported any data for this outcome.

## **2. Surgery plus adjuvant endocrine therapy versus primary endocrine therapy**

### **Overall survival**

Pooled result of three trials (1076 women): There was a trend in favour of surgery plus endocrine therapy that was not statistically significant (HR 0.86, 95% CI 0.73 to 1.00,  $p=0.06$ ).

### **Overall survival by ER status**

One trial provided data based on 147 women, all of whom had ER+ tumours. There was no significant difference between the interventions (HR 0.80, 95% CI 0.28 to 2.32,  $p=0.68$ ).

### **Overall survival by age**

Age-related subgroup analysis was not possible on the basis of published data. In a conference abstract authors from two trials reported analyses of combined individual patient data from both trials. They reported that patient age was the most important determinant of survival in later years (75 years plus). In those between 70 and 75 years, initial surgery (rather than primary endocrine therapy) determined survival.

### **Breast cancer specific survival**

A published meta-analysis of individual patient data from two RCTs found a statistically significant effect in favour of surgery plus endocrine therapy (HR 0.7, 95% CI 0.51 to 0.95).

### **Progression-free survival**

Data from 1 RCT found a statistically significant effect in favour of surgery plus endocrine therapy (HR 0.65, 95% CI 0.53 to 0.81,  $P$  value 0.0001).

### **Adverse effects**

There were insufficient data to justify any quantitative analysis of this outcome.

### **Local disease control**

Pooled estimate based on data from 2 RCTs (929 women): this analysis showed a statistically significant difference in favour of surgery plus endocrine therapy (HR 0.28, 95% CI 0.23 to 0.35,  $p < 0.00001$ ). There were insufficient data to justify any quantitative analysis of prospectively identified subsets. However, one trial which recruited only patients with ER+ tumours reported better local control in the surgery plus endocrine arm.

One trial which contributed data to the hazard ratio quoted above reported this outcome by type of surgery, comparing both mastectomy (52 of 225 women) and breast-conserving surgery (159 of 225) against the same population of

primary endocrine therapy (230 women). The trialists reported better local disease control for both mastectomy and breast-conserving surgery than primary endocrine therapy.

### **Distant metastasis-free interval**

Although data were available from one trial they were not used by the review authors because data quality was suspect.

### **Quality of life**

There were insufficient data to justify any quantitative analysis of this outcome. However, in one published trial authors used the General Health Questionnaire 28, which detects psychiatric morbidity, and a socio-demographic questionnaire, which investigated levels of domestic support and social isolation. At three months after start of treatment the surgery group had more psychosocial morbidity (p value 0.03). However, there was no difference between the surgery and PET groups at two years.

### **Authors' summary and conclusions**

This study has demonstrated that primary endocrine therapy is inferior to surgery with endocrine therapy for the local control of breast cancer in medically fit older women who are not selected on the basis of ER status. This is independent of the type of surgery, with both mastectomy and wide excision (without adjuvant radiotherapy) achieving superior local control. However, the surgery does not result in significantly better overall survival.

Primary endocrine therapy should only be offered to women with oestrogen receptor (ER) positive tumours who are unfit for or who refuse surgery. In women with significant co-morbid disease and ER positive tumours it is possible that primary endocrine therapy may be a superior option to surgery. Trials are needed to evaluate the clinical effectiveness of aromatase inhibitors as primary therapy for an infirm older population with ER positive tumours.

### **General comments**

In some cases the strength of evidence was affected by competing risks, informative censoring and study heterogeneity between trials, in terms of interventions and outcome assessment. Therefore only reliable data were used. The authors describe these limitations as follows:

#### **Competing risks**

Applies to outcomes such as local failure in Kaplan-Meier analyses: censoring patients in whom a competing risk occurs (e.g. death) is not appropriate as it gives an under-estimate of the probability of local failure by treating those cases who haven't failed locally and are alive the same as those who have not failed locally but have died.

#### **Informative censoring**

Re: time to local or distant recurrence: in one trial patients were censored at

the time of their last clinical examination. Assuming that those who have progressed are more likely to attend follow-up clinics and that those who are disease or metastases-free are less likely to attend clinics, the latter group will be censored earlier, and will stop contributing information to the study. Thus the censoring is potentially dependent on the likelihood of disease progression (that is, related to the outcome). This is another source of potential bias as the rate of censoring does not leave a representative sample of those at risk.

### **Heterogeneity of populations and interventions**

Whilst all studies met the inclusion criteria for the review, there was heterogeneity between studies in terms of tumour size, and use of either breast conserving surgery or mastectomy.

### **Heterogeneity of outcome assessments**

Studies differed with regard to classification of distant metastatic events either as those occurring after local events or as those occurring as first events.

### **Applicability of results**

The authors report that the results of their review need to be read bearing in mind that they are derived from a small number of individually underpowered studies. Additionally, there are four areas where treatment regimens in the trials do not necessarily coincide with modern clinical practice. Therefore, the appropriateness of the following should be questioned:

- (1) endocrine therapy for women with ER negative tumours;
- (2) surgery without adjuvant endocrine therapy;
- (3) primary endocrine therapy where the individual is fit for and agreeable to surgery;
- (4) new endocrine therapies.

### **Literature search strategy**

The Cochrane Breast Cancer Group Specialised Register was searched on 21st August 2003. Details of the search strategy applied by the Group to create the register, and the procedure used to code references, are described in the Group's module on The Cochrane Library. Studies coded as "EARLY BREAST CANCER", "ENDOCRINE THERAPY", "PSYCHOSOCIAL" or "SURGERY" on the specialised register were extracted for consideration.

### **Assessment of primary study quality**

This is evident and considers randomisation method, concealment and intention-to-treat analysis. It was not possible to accurately assess the quality of all studies (including the quality of the randomisation process) due to lack of information in the published articles. The quality of three trials was graded as A (CRC; EORTC 10851; GRETA) with the rest being graded as B (Naples; Nottingham 1; Nottingham 2; St Georges).

<b>Citation</b>
Mieog, van der Hage & van d . Preoperative chemotherapy for women with operable breast cancer. Cochrane Database of Systematic Reviews. [2], CD005002. 2007.
<b>Design</b>
Systematic review of RCTs (therapy), evidence level: 1 ++ Country: Various, setting: Tertiary care
<b>Inclusion criteria</b>
RCTs of primary (preoperative) chemotherapy in women with operable breast cancer: TNM stage T1c, T2, T3, N0 to 2, and M0 (AJCC stage I-IIIa).
<b>Exclusion criteria</b>
5 RCTs were excluded for the following reasons: 1. Randomised controlled trial consisting of 101 women with operable locally advanced disease (T4b, N0-2, M0) 2. Abstract of conference proceeding. Reported a subset of patients part of NSABP B-18 study. 3. Abstract of conference proceeding. No data available. Publication pending. 4. Randomised controlled trial comparing preoperative with postoperative chemotherapy. Relevant data stratified to apoptotic index. No response from authors. 5. Abstract of conference proceeding. Not properly randomised (of the 98 analysed patients only 87 were included in a randomised prospective fashion)
<b>Population</b>
Number of patients = 5500.
<b>Interventions</b>
Aim: to systematically identify and assess all of the available evidence from RCTs as to the effectiveness of preoperative chemotherapy on treatment-related outcomes in women with operable breast cancer.
<b>Eligible comparisons</b>
i) Preoperative chemotherapy versus postoperative chemotherapy. ii) Preoperative and postoperative chemotherapy versus postoperative chemotherapy.
All included trials compared preoperative chemotherapy with a postoperative regimen (see also Appendix AAtable). In six trials patients in the preoperative arm received all cycles prior to loco-regional treatment. In the remaining eight trials, patients in the preoperative arm received some of the cycles after loco-regional treatment. A variety of chemotherapeutic regimens were administered to patients across the included trials; all regimens were made up

of multiple chemotherapeutic agents.

### **Hormone therapy in eligible studies**

Endocrine treatment was administered instead of chemotherapy to patients with tumours expressing high estrogen receptor levels in two studies (Edinburgh 1995, London 2001). Non-responders to endocrine treatment in the preoperative arm of London 2001 crossed over to an anthracycline containing chemotherapeutic regimen after loco-regional treatment. Tamoxifen was administered to eligible patients in seven studies (ECTO 2005, EORTC 2001, Japan 1998; Lithuania 1998; NSABP 1998, Royal Marsden 1998; USA 2003) and was mostly started after loco-regional treatment; in one study patients in the preoperative arm started tamoxifen treatment along with chemotherapy and thus before surgery (Royal Marsden 1998).

### **Loco-regional therapy**

Loco-regional treatment varied across studies. Five studies applied the same local treatment to all included patients (Edinburgh 1995, Japan 1998; Lithuania 1998, St. Petersburg 1994). In other studies treatment varied according to patients' individual requirements (e.g. tumour size, nodal involvement). Three studies administered radiotherapy before surgery (Institut Curie 1991; Institut Curie 1994, St. Petersburg 1994). Three studies treated some of the participants exclusively with radiotherapy (Bordeaux 1991; Institut Curie 1991; Institut Curie 1994).

## **Outcomes**

### **Primary outcomes:**

1. Overall survival
2. Disease-free survival
3. Loco-regional recurrence as first event

### **Secondary outcomes:**

1. Tumour response rate to primary chemotherapy as follows:
  - i) Clinical complete response (cCR): complete disappearance of all clinically detectable malignant disease at the time of surgery
  - ii) Overall clinical response (OR): defined as  $\geq 50\%$  decrease in total tumour size after chemotherapy compared to the pre-treatment size
  - iii) Pathological complete response (pCR): defined as the complete disappearance of invasive carcinoma on histological examination
2. Association of pathological complete response with clinical outcome
3. Type of loco-regional treatment
4. Changes of originally planned loco-regional treatment
5. Adverse effects (WHO grades III and IV events of postoperative complications, cardiotoxicity, leukopenia or neutropenia or infection, nausea and vomiting, and alopecia).
6. Quality of life

<b>Follow up</b>
In 14 RCTs median follow-up had range 18-124 months
<b>Results</b>
<p>14 RCTs met the inclusion criteria.</p> <p>Unless stated otherwise, ratios of treatment effects are reported so that values less than 1.0 favour primary chemotherapy and values greater than 1.0 favour adjuvant chemotherapy.</p> <p><b>Overall survival</b>  10 RCTs, 4620 randomised women, 1139 estimated deaths. See appended table below for survival rates of the research and control arm for each study after 5 and 10 years median follow-up. There was no statistically significant difference in overall survival between preoperative and postoperative chemotherapy: HR 0.98 (95% CI, 0.87 to 1.09; p=0.67); without heterogeneity.</p> <p><b>Disease-free survival</b>  10 RCTs, 4510 randomised women, 1596 estimated events. There was no statistically significant difference between preoperative and postoperative chemotherapy: HR 0.97 (95% CI, 0.89 to 1.07; p=0.58); moderate heterogeneity.</p> <p><b>Time to loco-regional recurrence</b>  11 RCTs, 5041 randomised women, 558 estimated recurrences. There was a statistically significant difference in favour of postoperative chemotherapy: HR 1.21 (95% CI, 1.02 to 1.43; p=0.03), without heterogeneity.</p> <p><b>Rate of loco-regional recurrence (preoperative versus postoperative chemotherapy) by subgroup for loco-regional treatment</b></p> <ol style="list-style-type: none"> <li>1. Breast conserving surgery (4 RCTs, 1830 women, 143 recurrences): RR, 1.13; 95% CI, 0.82 to 1.54; p=0.5</li> <li>2. Mastectomy (4 RCTs, 1427 women, 82 recurrences): RR, 1.14; 95% CI, 0.74 to 1.75; p=0.6</li> <li>3. Exclusive RT: no data</li> <li>4. Total (3257 women, 225 recurrences): HR 1.13; 95% CI, 0.88 to 1.46; p=0.35; risk difference, 2.3; 95% CI, 0.9 to 3.6; control group risk, 5.9%; p=0.3.</li> </ol> <p>There was no statistically significant difference in loco-regional recurrence between women treated with BCT and those treated with mastectomy (Chi<sup>2</sup> for difference, 0.01; p, 0.92).</p> <p><b>Tumour response to preoperative chemotherapy</b>  Eleven studies reported a complete clinical response rate in the preoperative chemotherapy arm for 1761 assessable patients involving 653 complete</p>

clinical responses. The complete clinical response rate ranged from 0 to 64.7%.

Twelve studies reported an overall clinical response rate in the preoperative chemotherapy arm for 2032 assessable patients involving 1384 overall clinical responses. The overall clinical response rate ranged from 11.1 to 83.3%.

Seven studies reported a pathological complete response rate in the preoperative chemotherapy arm for 1972 assessable women involving 278 pathological complete responses. The pathological complete response rate ranged from 4.0 to 29.2%.

### **Association of pathological complete response with clinical outcome**

The authors compared overall and disease-free survival between patients with a pathological complete response and those who had residual disease at pathological examination.

Four studies reported overall survival data for 1290 assessable patients involving 381 estimated deaths. There was a statistically significant difference in favour of pathological complete response: HR (pCR versus residual disease) 0.48 (95% CI 0.33 to 0.69).

Five studies reported disease-free survival data for 1741 assessable patients involving 606 estimated events. There was a statistically significant difference in favour of pathological complete response: HR (pCR versus residual disease) 0.48 (95% CI 0.37 to 0.63).

### **Primary chemotherapy and rates of breast conserving treatment**

10 RCTs, 5292 randomised women, of which 2395 underwent mastectomy<sup>19</sup>. There was a statistically significant difference in rate of mastectomy in favour of preoperative chemotherapy: RR 0.71 (95% CI, 0.67 to 0.75;  $p < 10^{-5}$ ), representing a risk difference of 16.6% (95% CI, 15.1 to 18.1; control group risk, 52.9%; NNT, 6) and with substantial heterogeneity across studies.

Sensitivity analysis did not account for the study heterogeneity relating to this pooled estimate. The authors excluded two studies from the analysis due to clinical heterogeneity<sup>20</sup> and re-analysed with the following result:

---

<sup>19</sup> In three of these studies the reported conservative treatment rate was that achieved after subsequent follow-up i.e. taking account of mastectomy as a second operation to treat local recurrence (Bordeaux 1991, Institut Curie 1994; Royal Marsden 1998).

<sup>20</sup> One study involved an intensive chemotherapy regimen including taxane and anthracycline drugs and reached a high pCR rate, allowing <sup>more</sup> conservative treatment (ECTO 2005). The second study treated all patients in the control arm with mastectomy since one of the inclusion criteria was patients with tumours not suitable for conservative treatment (Bordeaux 1991).

8 RCTs, 3709 randomised women, of which 1452 underwent mastectomy. There was a statistically significant difference in rate of mastectomy in favour of preoperative chemotherapy: RR 0.82 (95% CI, 0.76-0.89;  $p < 10^{-5}$ ), representing a risk difference of 8.0% (95% CI, 6.3-9.7; control group risk, 43.1%; NNT, 13) and with moderate heterogeneity across studies.

### Changes to originally planned locoregional treatment (5 RCTs)

Five studies reported changes of loco-regional treatment that had been originally planned in the preoperative chemotherapy arm (1549 assessable women; see appendix: table). Across studies, 397 women had their originally planned surgical treatment altered due to down staging (25.6%; 95% CI, 23.5 to 27.8), 1086 women had no change to planned treatment (70.1%; 95% CI, 67.8 to 72.4), and 66 women required more radical surgery than originally planned (4.3%; 95% CI, 3.3 to 5.3).

**Table: relationship between treatment intended and treatment performed**

Study	BCT - BCT	MAST - MAST	MAST - BCT	MAST - RT	BCT - RT	BCT - MAST	Total
Bordeaux 1991	-	49	40	44	-	-	133
EORTC 2001	60	190	60	-	-	14	324
Institut Curie 1994	-	36	62	102	-	-	200
NSABP 1998	435	187	69	-	-	52	743
Royal Marsen 1998	113	16	19	-	1	-	149
Total	608	478	250	146	1	66	1549

Two RCTs compared outcomes between patients who received down staged breast conserving therapy compared to those who received planned breast conserving therapy in the preoperative chemotherapy arm. There was no statistical significant difference in loco-regional recurrence or overall survival between these groups:

**Table: Effect on outcome of downstaging: ratio outcomes for downstaged vs planned breast conserving surgery in primary chemotherapy arms of two RCTs**

Outcome	No. of studies	No. of participants	Statistical method	Effect size
Overall	1	120	Peto Odds Ratio	1.33 [0.67,

survival			[95% CI]	2.63]
Loco-regional recurrence	2	623	Relative Risk (Fixed) [95% CI]	1.34 [0.85, 2.13]

Authors conclude that direct evidence concerning long-term prognosis and risk of local recurrence after downstaging of surgical treatment following preoperative chemotherapy is still lacking. Indirectly derived data suggest no intrinsic risk amplification associated with downstaged breast-conserving surgery. However, evidence from direct comparison is needed to draw valid conclusions.

### Adverse events

7 RCTs provided data. There was no statistically significant difference between preoperative and postoperative chemotherapy for postoperative complications, nausea/ vomiting, and alopecia. Events of cardiotoxicity were less frequent in women receiving preoperative chemotherapy (RR 0.74; 95% CI, 0.53-1.04; p=0.08); without heterogeneity. The four studies reporting on leucopenia/ neutropenia/ infections involving 2799 women and 327 events demonstrated a statistically significant difference in favour of preoperative chemotherapy: RR 0.69 (95% CI, 0.56 to 0.84; p=0.0003); with low heterogeneity; risk difference 4.2% (95% CI, 2.3 to 5.6; control group risk, 13.8%; NNT, 24).

### Quality of life

No data were available for this outcome.

### General comments

Most outcomes are reported as hazard ratios for primary (preoperative) versus postoperative chemotherapy arms.

The studies vary in their primary chemotherapy regimens, use of axillary surgery, hormone therapy and, in primary chemotherapy arms, whether adjuvant chemotherapy was also given.

### Literature search:

Cochrane Breast Cancer Group Specialist Register of RCTs searched on 4.8.05; includes published and unpublished trials; no language restrictions. Keywords: 'early' and 'chemo' and 'locally advanced' and 'chemo'. In addition the authors searched reference lists of related literature reviews.

### Study selection:

Two review authors independently applied the selection criteria on the methods sections of the selected trials. The review authors were blinded to all but the methods section. Any disagreements were resolved by consensus.

**Quality assessment:**

Two review authors independently reviewed each included study based on:

- concealment of the allocation sequence
- generation of the allocation sequence
- comparability between groups at the baseline
- inclusion of all randomised participants in the analysis (Intention to treat)
- loss to follow-up

Allocation concealment was graded as follows:

- Grade A - clearly adequate
- Grade B - possibly adequate,
- Grade C - clearly inadequate
- Grade D - not used.

**Data extraction:**

At least two individuals independently extracted data from the studies identified for inclusion. Any disagreements were resolved by consensus.

Updated 2018

**Appendix: table of eligible RCTs of primary chemotherapy; from Cochrane Review, including survival data where reported**

NB estimated 5-year and 10-year survival values read from bar graph

RCT	Population (stage)	Randomised comparison	Surgery/other treatment	5-year survival (%)		10-year survival (%)	
				Pre-op	Post-op	Pre-op	Post-op
ABCSG 2001	Receptor -ve tumours (n=301); receptor +ve tumours, size >3cm (n=122)	Preop and postop vs postop CMF/EC  Arm A: 3 cycles of preoperative Cyclophosphamide, Methotrexate, Fluorouracil. Followed by 3 cycles of postoperative CMF (same as above) for node-negative pts or 3 cycles of Epirubicin, Cyclophosphamide for node-positive pts.  Arm B: idem as for A, all postoperative.	Surgery given (including breast conservation; otherwise not specified)	-	-		
Bordeaux 1991	T2>3cm, T3, N0-1, M0	Preop vs postop EVM + MTV  Arm A: 3 cycles of preoperative Epirubicin -Vincristine - Methotrexate every 3 weeks followed by 3 cycles of preoperative Mitomycin C - Thiotepa - Vindesine every 3 weeks.  Arm B: mastectomy then adjuvant chemotherapy as for arm A if histological axillary node involvement or negative ER/PR, otherwise no adjuvant chemotherapy.	Arm A i) Complete regression: exclusive RT of breast (50 Gy + 20-24 Gy boost) and axilla, internal mammary, supraclavicular node areas (50 Gy + 10 Gy boost on axilla if positive prechemotherapy). ii) Residual < 2cm: lumpectomy + breast irradiation (50 Gy + 10 Gy boost). iii) Residual > 2cm: modified radical mastectomy (Patey) without RT.  Arm B mastectomy	80	80	62	59
ECTO 2005	T size >2cm; (20%>4cm)	3 Arms: Preop AT-CMF vs postop AT-CMF vs postop A-CMF  Arm A: 4 cycles of preoperative Doxorubicin - Paclitaxel every 3 weeks followed by 4 cycles of Cyclophosphamide - Methotrexate -Fluorouracil on days 1 and 8 every 4 weeks.  Arm B: idem as for A, all postoperative.  Arm C: 4 cycles of postoperative Doxorubicin 75 mg/m <sup>2</sup> IV every 3 weeks followed by 4 cycles of CMF IV on days 1 and 8 every 3 weeks.	Mastectomy or BCT + radiotherapy RT for mastectomy-treated patients with pT4 tumours.	87	90	-	-
EORTC 2001	T1c-T3, T4b, N0-1, M0	Preop vs postop FEC  Arm A: 4 cycles of preoperative Fluorouracil - Epirubicin - Cyclophosphamide every 3 weeks.  Arm B: idem as for A, all postoperative	Mastectomy or BCS + RT (50 Gy in 5 weeks). Chest wall/parasternal: pts with initial tumour of 5 cm or more. Infra and supraclavicular fossa: pts with positive infraclavicular node after LN dissection. Tamoxifen: pts >50 yrs (regardless of ER/nodal status) received 20 mg daily for at least 2 yrs.	77	82	64	66

RCT	Population (stage)	Randomised comparison	Surgery/other treatment	5-year survival (%)		10-year survival (%)	
				Pre-op	Post-op	Pre-op	Post-op
Edinburgh 1995	Operable tumours >4cm in size; no metastases.	<p>Arm A: ER -ve pts and non-responding ER+ve pts: 4 cycles of preoperative Cyclophosphamide, Doxorubicin, Prednisolone every 3 weeks. Followed by 2 cycles of postoperative cycles of CAP. Responding ER+ve pts: endocrine treatment: * Premenopausal: Goserelin monthly for 12 weeks. Followed by oophorectomy. * Postmenopausal: Tamoxifen for 12 weeks and continued postoperatively.</p> <p>Arm B: appropriate adjuvant therapy: NFS.</p>	Modified radical mastectomy with level III axillary clearance for all pts within 3 weeks after last cycle of chemotherapy or after study entry.	-	-		
Institut Curie 1991	T2-3, N0, 1b, M0	<p>Preop and postop vs postop FAC/AMVT</p> <p>Arm A: 2 cycles of preoperative 5-Fluorouracil, Doxorubicin and Cyclophosphamide every 4 wks. Good responders received a following 4 cycles of FAC as above after loco regional treatment. Non-responders received 4 cycles of Doxorubicin, Methotrexate, Vindesine and Thiotepa.</p> <p>Arm B: 6 cycles of postoperative FAC as above.</p>	<p>Primary radiation therapy: 55 Gy in 6 weeks to breast and inferior axillary nodes + 45 Gy to supraclavicular nodes and internal mammary chain. A boost to tumour bed (totalling 75-80 Gy) was given to pts who had a regression of the tumour at 55 Gy.</p> <p>Surgery (mastectomy or lumpectomy) was limited to pts presenting with a persisting mass after RT.</p>	-	-		
Institut Curie 1994	T2-3, N0-1, M0 (T size 3-7cm)	<p>Preop vs postop FAC</p> <p>Arm A: 2 cycles of preoperative 5-Fluorouracil on days 1, 3, 5, 8, Doxorubicin and Cyclophosphamide on day 1 and 8 every 4 wks. Followed by response assessment: Good responders: 2 additional cycles of preoperative FAC. Non-responders: loco-regional treatment</p> <p>Arm B: 4 cycles of adjuvant FAC within 2 weeks of ending loco-regional treatment.</p>	<p>Primary RT: 54 Gy in 6 weeks to breast and axillary nodes + 45 Gy to supraclavicular nodes and internal mammary chain. Patients with CR or near CR received a boost to tumour bed (totalling 75-80 Gy) and had no surgery. N+ patients received a 10-15 Gy boost to inferior axilla if no surgery was performed.</p> <p>Surgery (mastectomy or lumpectomy) was limited to patients presenting with a persisting mass after 54 Gy. A total of 24 patients underwent mastectomy without RT.</p>	84	77	64	60
Japan 1998	Stage II with tumour size >4cm and stage III.	<p>Preop and post op vs postop EC and UFT</p> <p>Arm A: 2 cycles of preoperative Epirubicin, Cyclophosphamide every 3 weeks followed by 3 cycles of postoperative EC. Daily administration of 400 mg UFT.</p> <p>Arm B: idem as for A, all postoperative.</p>	Surgery: mastectomy for all patients. Tamoxifen for 2 yrs.	-	-		

RCT	Population (stage)	Randomised comparison	Surgery/other treatment	5-year survival (%)		10-year survival (%)	
				Pre-op	Post-op	Pre-op	Post-op
Lithuania 1998	Stage II (T2, N0-1)	Preop and postop vs postop CMF  Arm A: 2 cycles of preoperative Cyclophosphamide, Methotrexate, Fluorouracil: NFS.  Arm B: idem as for A, all postoperative.	Conservative surgery (plastic quadraneotomy), RT, adjuvant chemo/hormonotherapy (NFS).	-	-		
London 2001	T1-4, N0-1, M0 (24% T3-4)	Preop and postop vs postop treatment. Either chemo- or endocrine therapy based on ER-status:  Arm A: ER+ pts (47): endocrine treatment Premenopausal: Goserelin monthly for 12 weeks. Postmenopausal: Formestane every 2 weeks for 12 weeks. ER - pts: 4 cycles in 12 weeks of preoperative Mitozantrone every 3 weeks, Mitomycin C every 6 weeks, Methotrexate every 3 weeks with fonic acid rescue 4 times for 24 hours, starting 24 hrs after chemotherapy. After clinically assessing tumour response and surgery/radiotherapy: Responders: received a total of 8 cycles MMM or 18 months Goserelin or Formestane (doses as above). Non-responders: ER + pts: 8 cycles of MMM (as above) ER - pts: 8 cycles of 5-Fluorouracil - Epirubicin - Cyclophosphamide every 3 weeks.  Arm B: ER+ pts: endocrine therapy Premenopausal: Goserelin as above for 18 months. Postmenopausal: Formestane as above for 18 months. ER - pts: 8 cycles of MMM as above.	Primary surgery (mastectomy or BCS + RT to breast + boost to scar) or primary RT. Pts with involved axillary nodes: RT to axilla and supraclavicular fossa. Pts with tumours in medial half of breast: RT to ipsilateral mammary chain. When primary RT did not produce a response, a mastectomy was performed.	77	87	-	-
NSABP 1998	T1-3, N0-1, M0 (no locally advanced disease)	Preop vs postop AC  Arm A: 4 cycles of preoperative Doxorubicin - Cyclophosphamide every 3 weeks. Women with progressive disease before completion of all 4 courses received the remaining courses after surgery.  Arm B: idem as for A, all postoperative.	Mastectomy or BCS + RT. Tamoxifen: pts >50 yrs (regardless of ER/nodal status) received 10 mg twice daily for 5 yrs	80	82	68	70

RCT	Population (stage)	Randomised comparison	Surgery/other treatment	5-year survival (%)		10-year survival (%)	
				Pre-op	Post-op	Pre-op	Post-op
Royal Marsden 1998	T1-4, N0-1, M0 (7% T3-4)	Preop and postop vs postop MM(M)  Arm A: 4 cycles of preoperative Mitomycin C every 6 weeks, Mitoxantrone every 3 weeks, Methotrexate every 3 weeks or 2M (same as 3M, with the exclusion of Mitomycin C and increased dose of Mitoxantrone) followed by 4 cycles postoperative of 3M or 2M.  Arm B: idem as for A, all postoperative.	Mastectomy or BCT + RT (54 Gy to breast + 10 Gy boost to scar). Clinically involved lymph nodes: Level II axillary lymph node dissection. No axillary dissection for clinically node negative pts. RT to axilla and supraclavicular fossa was only given to those pts with palpable nodes at presentation, who did not have axillary dissection. Tamoxifen: 20 mg daily for 5 years simultaneously started with chemotherapy.	77	77	70	64
St Petersburg 1994	Stage IIb-IIIa: T3, N0-1; T2, N1; T1-2, N2, M0	Preop and postop vs postop TMF  Arm A: 1 or 2 cycle(s) of preoperative Thiotepa on days 1,3,5,7,9,11, Methotrexate - 5-Fluorouracil on days 1 and 8 every 4 weeks. Followed, starting during mastectomy, by 4-5 cycles of TMF.  Arm B: 6 cycles of postoperative TMF.	Preoperative RT: 60 Gy (2 Gy daily) to breast + 40 Gy to axillary area, supra- and subclavicular areas followed after 3-4 weeks by modified radical mastectomy.	87	78	-	-
USA 2003	Stage II: T1, N1; T2, N0; T2, N1	Preop vs postop FLAC + G(M)-CSF  Arm A: 5 cycles of preoperative 5-Fluorouracil - Leucovorin - Doxorubicin on days 1,2,3 and Cyclophosphamide on day 1 every 3 wks + Granulocyte-macrophage colony stimulation factor  Arm B: idem as for A, all postoperative (2-3 wks after surgery)	Mastectomy or BCS + RT. RT 50.4 Gy to the breast and, in cases with N stage disease, axilla. Patients with extranodal extension received 50.4 Gy to the posterior axillary field. All pts received an additional 10-Gy boost to the surgical bed. Tamoxifen for ER+/PR+ pts: 10 mg twice daily for 5 yrs.	93	84	87	72

Trudeau, Sinclair & Clemons . Neoadjuvant taxanes in the treatment of non-metastatic breast cancer: A systematic review. Cancer Treat.Rev. 31[4], 283-302. 2005.
<b>Design</b>
Systematic review of RCTs (therapy), evidence level: 1 - Country: Various, setting: Secondary care
<b>Inclusion criteria</b>
For eligible studies: <ul style="list-style-type: none"> <li>• A primary taxane-containing regimen was evaluated using any of the publication types listed in the search strategy (randomised controlled trials or systematic reviews/metaanalyses).</li> <li>• Reported outcomes included rates of clinical response, pathologic response, breast conservation, DFS, or overall survival.</li> <li>• Clinical trial results were reported in either full papers or abstracts.</li> </ul>
<b>Exclusion criteria</b>
Non English language papers
<b>Population</b>
Number of patients = 6225.
<b>Interventions</b>
Aim: to review RCT evidence on the role of primary taxane chemotherapy in patients with non-metastatic breast cancer.  All patients underwent primary chemotherapy; at least one arm receiving primary taxane chemotherapy. All randomised arms planned surgery in addition, and some, radiotherapy and hormone therapy in addition.
<b>Outcomes</b>
Response to primary chemotherapy (tumour and lymph nodes) Proportion of patients who underwent breast conserving surgery Disease-free survival (DFS) Overall survival (OS)
<b>Follow up</b>
See table below
<b>Results</b>
17 RCTs were included, presented in 18 papers, one of which provided further analysis between subgroups for different primary taxane doses/schedules. In all trials the randomised comparison is either primary taxane chemotherapy versus non-taxane primary chemotherapy, primary taxane versus adjuvant taxane, or different

doses/schedules of primary taxane chemotherapy.

Of 17 included RCTs only four provide data on DFS or OS (appendicised table 2). Due to heterogeneity in terms of follow-up extent for assessing survival, no concise summary statement is possible.

The majority (12) of studies were available only in abstract at the time of completion of the literature search (September 2004), suggesting that follow-up is immature.

### **Locoregional treatment**

Of 17 RCTs, nine omitted radiotherapy altogether and eight used radiotherapy in all randomised arms. In contrast all RCTs used surgery in all of their randomised arms. Some studies report the proportion of patients in whom breast conserving surgery was performed; the complement of this proportion represents patients who received mastectomy.

### **Primary tumour response to primary chemotherapy**

Across the 18 included trials, the proportion of cases in which a tumour pathological complete response (pCR) was achieved was reported for 36 randomised arms. This value had mean 15.6%, median 15.0% and range 0% to 31%.

Eight randomised arms provided data for the proportion of cases in which a tumour pathological partial response (pPR) was achieved. This value had mean 28%, median 28.5% and range 0% to 57%.

21 randomised arms provided data for the proportion of cases in which a tumour clinical complete response (cCR) was achieved. This value had mean 24%, median 20% and range 0% to 84%.

25 randomised arms provided data for the proportion of cases in which a tumour clinical partial response (cPR) was achieved. This value had mean 53.8%, median 56% and range 3% to 96%.

### **Breast conserving surgery after primary chemotherapy**

In all 17 RCTs surgery was performed in every randomised arm. In total the proportion of patients who received breast conserving surgery was reported for 21 randomised arms in 14 RCTs. This proportion had mean 54%, median 56% and range 20% to 85%.

NB See Appendix A below for table of primary study details reported in systematic review.

### **1. Primary taxane regimens vs. other primary regimens**

The smallest paclitaxel trial (n = 30, accrual ongoing) reported a statistically significant improvement in pathologic complete response (pCR) with paclitaxel and epirubicin

therapy compared to 5-fluorouracil, epirubicin, and cyclophosphamide (FEC) therapy (25% vs. 0%; p-value not reported) but no difference in pathologic partial response (pPR) (Malamos et al. 1998).

Two trials reported rates of breast-conserving surgery that appeared to favour primary paclitaxel; however, p-values for the differences were not reported (Budzar et al. 1999, Pouillart 1999). DFS was assessed in one trial; no significant difference between paclitaxel alone or 5-fluorouracil, doxorubicin, and cyclophosphamide (FAC) was detected. (Budzar et al. 1999) Overall survival was not reported in any of the paclitaxel trials.

While not quite significant at the 5% level, the Aberdeen trial results (n = 97) suggested improved pCR with CVAPr followed by docetaxel vs. CVAPr followed by CVAPr (31% vs. 15%; p=0.06). Overall clinical response was also higher in the first arm (85% vs. 64%; p = 0.001) (Hutcheon et al. 2003).

The ACCOG trial detected a trend towards improved clinical overall response with doxorubicin and docetaxel vs. doxorubicin and cyclophosphamide (AC) (71% vs. 61%; p = 0.06), but equivocal rates of pCR (Evans et al. 2004).

In the NSABP B-27 trial (n = 2,411), a pCR occurred in 26% of patients who received primary docetaxel in addition to AC (arm i) compared to 15% in the AC followed by surgery and adjuvant docetaxel group (arm ii) and 13% in the AC followed by surgery alone group (arm iii) (p < 0.001 for arm i vs. arms ii and iii) (Bear et al. 2003). Clinical overall response followed the same pattern, with improved rates in the primary docetaxel arm (p < 0.001 for arm i vs. arms ii and iii).

Of the docetaxel trials that measured and reported axillary lymph node involvement, only the NSABP B-27 trial reported significant differences. Women who received primary docetaxel after AC were more likely to be node negative at the time of surgery compared with women who received AC alone (58% vs. 51%; p < 0.001) (Bear et al. 2003).

In the Aberdeen trial, patients with tumours that responded to four cycles of CVAPr and who were randomised to docetaxel were more likely to undergo breast conservation compared with patients who were randomised to receive further CVAPr (67% vs. 48%; p < 0.01) (Smith et al. 2002).

Two of the four remaining trials reported rates of breast conservation that appeared to favour the docetaxel treatment arm; however, p-values were not reported (GEPAR-TRIO: von Minckwitz et al. 2003, Luporsi et al. 2000).

At 38 months, the Aberdeen trial detected higher overall survival rates in CVAPr-responders who received docetaxel compared with those who received further CVAPr (97% vs. 84%; p=0.02) (Hutcheon et al. 2001). At a median follow-up of 65 months, the difference was still statistically significant (93% vs. 78%; p = 0.04) (Hutcheon et al. 2003). DFS was also significantly higher among CVAPr-responding women who received primary docetaxel (90% vs. 77%; p=0.03) (Hutcheon et al. 2001).

At a median follow-up of 32 months, the ACCOG trial detected no significant differences in DFS (75% vs. 69%,  $p = \text{NS}$ ) or overall survival (86% vs. 84%,  $p = \text{NS}$ ) with docetaxel and doxorubicin vs. AC, respectively (Evans et al. 2004). Similarly, Bouzid et al. 2001 reported no significant difference between the median number of months progression free in the doxorubicin and docetaxel arm compared with the FAC arm (8.3 months vs. 6.9 months;  $p$ -value not reported).

## **2. Primary taxane regimens vs. adjuvant taxane regimens**

The ECTO trial ( $n = 892$ ) found significantly different rates of nodal involvement at surgery; 61% of patients who received primary paclitaxel and doxorubicin were node-negative at surgery compared with 38% of patients who received no primary chemotherapy ( $p=0.0001$ ) (ECTO; Gianni et al. 2002). Breast conservation was more likely in women who received primary paclitaxel and doxorubicin compared with no primary chemotherapy (71% vs. 35%;  $p < 0.0001$ ) (ECTO; Gianni et al. 2002).

## **3. Taxane dose and/or schedule comparisons**

The SICOG 9908 trial ( $n = 130$ ) reported significantly higher rates of pCR (16% vs. 4%,  $p=0.03$ ) and cCR (29% vs. 15%,  $p = 0.05$ ) with 12 cycles of lower-dose weekly cisplatin, epirubicin, and paclitaxel combination therapy vs. four cycles of higher-dose three-weekly epirubicin and paclitaxel (Cormella et al. 2004). Similarly, the M.D. Anderson trial by Green et al. 2002 ( $n = 118$ ) found significantly improved pCR rates, defined according to the Chevallier classification system, in weekly vs. three-weekly paclitaxel followed by FAC (29% vs. 14%,  $p<0.01$ ).

The AGO trial ( $n = 475$ ; accrual ongoing) detected significantly higher rates of pCR in the dose-dense sequential docetaxel therapy arm compared to the standard therapy arm (18% and 10%, respectively;  $p = 0.03$ ) (Untch 2002). Romieu et al. 2002 ( $n = 232$ ) reported pCR rates of 17% vs. 24% (Sataloff classification) and 11% vs. 16% (Chevallier classification) in patients who received four and six cycles of doxorubicin and paclitaxel, respectively ( $p$ -values not reported). Clinical response was 32% vs. 20% in the six-cycle group and four cycle groups, respectively ( $p$ -value not reported).

Node response was reported in two trials (Cormella et al. 2004, Untch et al. 2002). Untch et al. 2002 reported rates of 51% and 42% at the time of surgery in their dose-dense sequential and standard dose arms, respectively ( $p = 0.098$ ).

Two trials reported comparative breast conservation data. The AGO trial detected a higher rate in women who received dose-dense sequential epirubicin and paclitaxel compared with standard-dose epirubicin and docetaxel (66% vs. 55%;  $p = 0.016$ ) (Untch et al. 2002).

In the ABCSG-14 trial ( $n = 288$ ), the rate of pCR was higher in the six-cycle epirubicin–docetaxel arm vs. the three-cycle arm (19% vs. 8%;  $p = 0.0045$ ). More women in the six vs. three three-weekly cycles of epirubicin and docetaxel were node-negative at the time of surgery (57% vs. 43%;  $p = 0.02$ ) (Steger et al. 2004).

In the Miller et al. 1999 trial, 19% of women who received combination therapy were node negative at surgery compared with 53% of women who received sequential therapy (p-value not reported). On average, 2.17 vs. 4.81 nodes were positive in the combination and sequential groups, respectively ( $p = 0.037$ ).

While there was a slight trend towards improved rates of breast conservation in the ABCSG-14 trial, the rates of breast conservation in the six- and three-cycle groups were not significantly different at the 5% level (76% vs. 67%;  $p = 0.1$ ) (Steger et al. 2004). In the Miller et al. 1999 trial, 19% of women who received doxorubicin and docetaxel in combination underwent breast conservation compared with 37% of women who received sequential therapy ( $p = \text{NS}$ ).

#### **4. Adverse effects associated with primary taxanes**

##### **Hematologic toxicity**

Primary paclitaxel therapy appeared to be associated with higher rates of grade 3 and/or 4 febrile neutropenia in two trials; however, p-values were not reported (Budzar et al. 1999, Gianni et al. 2002). In the M.D. Anderson trial (Budzar et al. 2002), 53% of women receiving paclitaxel ( $250 \text{ mg/ m}^2 \text{ q3wx4}$ ) vs. 21% of those receiving FAC experienced neutropenic fever. Granulocyte colony-stimulating factor (G-CSF) was administered if patients had neutropenic fever in a previous cycle or was used prophylactically. Women receiving paclitaxel were more likely than those receiving FAC to receive G-CSF (56% vs. 25%; p-value not reported).

In the ECTO trial, 9% of women receiving doxorubicin and paclitaxel ( $200 \text{ mg/ m}^2 \text{ q3wx4}$ ) followed by CMF experienced febrile neutropenia compared with 5% in those receiving doxorubicin alone followed by CMF (Gianni et al. 2002).

Six of nine docetaxel trials reported differential rates of neutropenia. Lee et al. 2004 detected less grade 3 or 4 neutropenia in the docetaxel ( $75 \text{ mg/ m}^2$ ) and capecitabine arm (77%) than in the AC arm (94%) p-values not reported.

In the NSABP B-27 trial, febrile neutropenia was significantly more frequent in the primary docetaxel and AC arm compared with the AC-only arm (21% vs. 7%, p-value not reported). Rates of G-CSF support were approximately the same (21 vs. 18% respectively, p-value not reported) (Bear et al. 2003).

In the Aberdeen trial, Grade 3 or 4 granulocytopenia ( $p = 0.006$ ) was more common in patients who received eight cycles of CVAPr compared with those who received CVAPr followed by four cycles of docetaxel ( $100 \text{ mg/ m}^2 \text{ q3wx4}$ ) (Smith et al. 2002).

In the GEPAR-TRIO trial, grade 3 or 4 neutropenia seemed to occur more frequently in the non-responders who received TAC followed by vinorelbine and capecitabine compared with non-responders who received vinorelbine and capecitabine alone (76% vs. 33%; p-value not reported) (Bouzid et al. 2001).

Bouzid et al. 2001 reported higher rates of grade 3 or 4 neutropenia (71% vs. 25%; p-value not reported) and febrile neutropenia (10% vs. 0%; p-value not reported) with doxorubicin and docetaxel (75 mg/ m<sup>2</sup> q3wx4) than with FAC.

Miller et al. 1999 reported significantly more granulocytopenia in their combination doxorubicin and docetaxel arm (100 mg/ m<sup>2</sup>) than in their sequential doxorubicin and docetaxel arm (75 mg/ m<sup>2</sup>) (grade 3: 10% vs. 37% and grade 4: 76% vs. 37%, respectively; p < 0.05 for grade 3 and 4 events) In both arms, G-CSF was administered once daily on days 2–11 of both treatment cycles.

Anaemia data were reported in three paclitaxel trials: Only one trial reported a differential between arms: the SICOG 9908 trial reported “substantially more frequent” severe anemia in the lower dose cisplatin–epirubicin–paclitaxel (120 mg/ m<sup>2</sup> q1wx12) arm than in the higher-dose three-weekly epirubicin–paclitaxel (175 mg/ m<sup>2</sup> q3wx4) arm.

Two docetaxel trials reported leukopenia rates: the Aberdeen trial reported more grade 3 or 4 leukopenia in patients who received CVAPr for eight cycles compared with those who switched to docetaxel (100 mg/ m<sup>2</sup> q3wx4) after four cycles (p = 0.029) (Smith et al. 2002).

In the Miller et al. 1999 trial, leukopenia was more common with the combination arm (docetaxel 100 mg/ m<sup>2</sup> q3wx4) than with the sequential arm (docetaxel 75 mg/ m<sup>2</sup> q2wx3) (grade 3: 43% vs. 32% and grade 4: 38% vs. 11%, respectively; p < 0.05 for grade 3 and 4 events combined).

### **Cardiotoxicity**

One of four paclitaxel trials reporting cardiotoxicity data detected a slight trend towards more adverse cardiac events with primary taxane therapy. Pouillart et al. 1999 reported abnormal left ventricular fraction values in 8% and 5% of the women receiving a primary doxorubicin and paclitaxel (200 mg/ m<sup>2</sup> q3wx4) combination vs. those receiving AC, respectively. One patient in the doxorubicin–cyclophosphamide arm experienced congestive heart failure.

### **Neurotoxicity**

Three of six trials reported different rates of neurotoxicity between randomised arms (p-values not reported). The M.D. Anderson trial (Buzdar et al. 1999) reported grade 2 paresthesias in 46% of women receiving paclitaxel (250 mg/ m<sup>2</sup> qw3x4) vs. 8% of those receiving FAC. Severe neurotoxicity was less common, with only 5% and 1% experiencing grade 3 paresthesias, respectively.

Similar to the M.D. Anderson trial findings, grade 2 neurotoxicity occurred in 23% and 5% of women in the ECTO trial who received doxorubicin and paclitaxel (200 mg/ m<sup>2</sup> q3wx4) followed by CMF or doxorubicin alone followed by CMF therapy (Gianni et al. 2002). Grade 3 neurotoxicity rates were 2% and 0%, respectively.

Peripheral neuropathy was “substantially more frequent” in the SICOG 9908 lower-dose

weekly cisplatin–epirubicin–paclitaxel (120 mg/ m<sup>2</sup> q1wx12) arm than in the higher-dose three weekly epirubicin–paclitaxel (175 mg/ m<sup>2</sup> q3wx4) arm (Comella et al. 2004).

The NSABP B-27 was the only docetaxel trial to report rates of neurotoxicity (Bear et al. 2003). Grade 3 neurosensory and neuromotor events and grade 4 neuromotor and neurocortical events were very infrequent and not different among groups.

### **Gastrointestinal toxicity**

Two of three trials that reported on gastrointestinal toxicity noted differences in one or more of this class of adverse events. In the M.D. Anderson trial (Buzdar et al. 2002), rates of grade 3 stomatitis (16.9% vs. 13%), nausea (21% vs. 10%), vomiting (7% vs. 2%), and diarrhoea (16% vs. 3%) appeared to be higher in the FAC group than in the paclitaxel (250 mg/ m<sup>2</sup>, q3wx4) group, respectively.

Conversely, gastrointestinal toxicity was “substantially more frequent” in the SICOG 9908 cisplatin–epirubicin–paclitaxel (120 mg/ m<sup>2</sup> q1wx12) arm than in the higher-dose threeweekly epirubicin–paclitaxel (175 mg/ m<sup>2</sup>q3wx4) arm (Comella et al. 2004).

Four docetaxel trials reported gastrointestinal toxicity data (Lee et al. 2004, Bear et al. 2003, Smith et al. 2002, Bouzid et al. 2001). Nausea, vomiting, diarrhoea and stomatitis were infrequent, and toxicity rates were similar between groups in each trial.

### **Other toxicities**

The M.D. Anderson trial (Buzdar et al. 2002) reported grade 3 infection rates of 9% and 5% in the paclitaxel (250 mg/ m<sup>2</sup>, q3wx4) and FAC arms, respectively. The M.D. Anderson trial found lower rates of overall toxicity in the 80 mg/ m<sup>2</sup> weekly arm compared with the 150 mg/ m<sup>2</sup> weekly arm (personal communication: Green et al. 2002). No trials reported any incidents of death due to toxicity.

Lee et al.2004 reported the occurrence of hand–foot syndrome in 8% of women receiving docetaxel and capecitabine. No women receiving AC experienced hand–foot syndrome. Miller et al. 1999 reported a trend towards more grade 3 and 4 hand–foot syndrome (21% vs. 0%, p-value not reported) with sequential doxorubicin and docetaxel (75 mg/ m<sup>2</sup> q2wx3) than in their combination doxorubicin and docetaxel arm (75 mg/ m<sup>2</sup> q3wx4), respectively.

In the NSABP B-27 trial, more women receiving primary docetaxel in addition to AC required more dose reductions (19%) compared with those receiving AC alone (2%) (Bear et al. 2003). Deaths were more frequent in the primary docetaxel arm (0.4% vs. 0.1%; p-value not reported).

In the Aberdeen trial, two women in the CVAPr followed by docetaxel arm died of neutropenic sepsis. Women who switched to docetaxel after CVAPr were more likely to receive a higher percentage of the total intended drug dose than were patients who continued to receive CVAPr (p = 0.002) (Smith et al. 2002).

## Authors' conclusions

The RCTs reviewed suggest that primary taxane chemotherapy is both efficacious and safe. The addition of a taxane (paclitaxel or docetaxel) to standard primary FAC or AC chemotherapy regimen has been shown to be superior in terms of clinical response, pathologic response, and disease free and overall survival to the anthracycline-based regimen alone.

There is no evidence at this time to suggest that one taxane is superior to the other in the primary setting.

In general, haematologic toxicity, in particular neutropenia and febrile neutropenia, was more common with a taxane-containing regimen. Neurotoxicity may be associated with primary paclitaxel and hand-foot syndrome may be associated with primary docetaxel. There was little evidence to suggest that other adverse events occur more frequently with a primary taxane.

## General comments

Well-conducted systematic review; sparse DFS/OS data. High clinical and methodological heterogeneity between studies; results presented with tabulated data/narrative. Evidence grade applied reflects these shortcomings, and also that the majority of primary data were available only in abstract form.

Study quality assessment evident e.g. considering publication as peer-reviewed paper or abstract, complexity of randomised comparison(s) method of randomisation and concealment, stratification for confounding variables, intention-to-treat analysis, power calculation.

Criticisms of the studies in general include failing to describe methods of randomisation, lack of blinding to allocation, not adjusting p values or 95% confidence intervals to account for the effects of multiple comparisons, lack of power calculations, exclusion of patients who did not complete chemotherapy.

Re: reporting of adverse effects, often trials administered supportive agents, such as antibiotics, antiemetics or G-CSF to prevent or alleviate adverse events due to chemotherapy.

Re: reporting of tumour response rates, the definitions of pathologic and clinical response of the primary tumour varied. Across the 18 trials, three different definitions of clinical response and two different definitions of pathologic response involving the primary tumour were used. This is likely to affect the validity of the results.

The authors also note that these results are preliminary since the evidence on taxanes as primary chemotherapy is evolving rapidly.

Literature search strategy:

MEDLINE and EMBASE databases to September 2004. Search terms reported e.g.

MEDLINE: Breast neoplasms[MeSH], Induction chemotherapy OR primary chemotherapy OR primary chemotherapy OR preoperative chemotherapy[Title/Abstract] Taxoids[MeSH] Meta-analysis[pt] OR randomised controlled trial[pt] OR practice guideline [pt]. <p>Mean tumour diameter: 43mm</p>														
<b>Exclusion criteria</b>														
<p>Age <math>&gt; 70</math> years, bilateral cancer, other associated cancer, Also patients were excluded from analysis due to refusal of treatment, or contraindication of treatment e.g. poor anaesthetic risk.</p>														
<b>Population</b>														
<p>N=270</p>														
<b>Interventions</b>														
<p>Aim: to evaluate the use of neo-adjuvant chemotherapy in patients with operable breast cancers of T size <math>&gt; 3</math> cm.</p> <p>Group A (n = 138): received mastectomy and axillary node dissection. Adjuvant chemotherapy (3 cycles of epirubicine, vincristine and methotrexate followed by 3 cycles of mitomycine, thiotepa and vindesine) was indicated for 104 patients with axillary node involvement (n = 82) or negative oestrogen and progesterone receptors (n = 22).</p> <p>Group B (n = 134): received primary chemotherapy (identical regimen as in group A) followed by locoregional treatment according to the response: RT alone in cases of complete tumour remission (n=44), BCS + RT in cases of residual tumour <math>\leq 2</math>cm in size (n=40) and mastectomy in cases of residual</p>														

tumour >2cm in size (n=49).

### Outcomes

Locoregional recurrence  
Recurrence-free survival  
Overall survival

### Follow up

Median 124 months (range 87-148 months)

### Results

In group B (primary chemotherapy), 49 patients (36.5%) were resistant to chemotherapy, warranting mastectomy. In the remaining 84 patients BCS was performed (62.6%). In this last subgroup, 19 (22.6%) needed a secondary mastectomy because of locoregional recurrence.

10-year crude data for recurrence:

Recurrence type	Group A (mastectomy; n=136)	Group B (primary chemotherapy; n=134)
Locoregional recurrence alone	1	14
Locoregional and distant recurrence	19	27
Distant recurrence alone	37	26

Estimated overall survival:

Analysis point	Group A (mastectomy; n=136)	Group B (primary chemotherapy; n=134)
5-year	80%	80%
10-year	60%	60%

Estimated recurrence-free survival:

Analysis point	Group A (mastectomy; n=136)	Group B (primary chemotherapy; n=134)
5-year	65%	58%
10-year	57%	50%

### General comments

Data extracted from English language abstract and French language paper. Study reports survival analysis by Kaplan-Meier, but reports no p values for differences in survival between randomised groups.

Randomisation was stratified by ER-PR status.

### General comments

Study evaluates a putative synergistic effect of primary/adjuvant CMF chemotherapy and tamoxifen, and not tamoxifen continued as long term hormone therapy.

Response to primary chemotherapy was assessed according to the UICC criteria reported in: Hayward JL, Carbone PP, Heuson JC, Kumaoka S, Segaloff A, Rubens RD. Assessment of response to therapy in advanced breast cancer: a project of the Programme on Clinical Oncology of the International Union Against Cancer, Geneva, Switzerland. *Cancer*. 1977 Mar;39(3):1289-94. No abstract available.

ER testing was not consistently available during this study; the authors report the limitation that they'd have preferred to exclude patients with ER- tumours. There were slightly more patients with ER- tumours in the CMF+T group.

Randomisation method: randomly permuted blocks of three with stratification for T stage (any T versus inflammatory breast cancer), node stage (N0-1b versus N2) and menopausal status (premenopausal versus postmenopausal <5 years versus post menopausal >=5 years)

Wording of paper is ambiguous on whether all patients underwent mastectomy, or only those who responded to primary chemotherapy. On balance it appears that all patients underwent mastectomy.

Analysis appears to be by intention-to-treat, but the study is neither blinded, nor placebo-controlled. The study is further limited by small size and may be underpowered to detect meaningful differences; the study was stopped prior to the target accrual point of 130 patients in total owing to less favourable outcome in the CMF+T arm.

<b>Inclusion criteria</b>
68 premenopausal patients with newly diagnosed breast cancer. 50% of patients in each arm had N0 nodal status and tumour size <2cm.
<b>Exclusion criteria</b>
Not reported
<b>Population</b>
N=68
<b>Interventions</b>
<p>Patients were randomised to two treatment groups:</p> <p>Primary chemotherapy group (n=34): received the first cycle of CMF chemotherapy before surgery, and where indicated, eight further cycles of CMF chemotherapy, adjuvant to surgery, where indicated (see below).</p> <p>Adjuvant chemotherapy group: (n=34): received surgery, then nine cycles of CMF chemotherapy where indicated (see below).</p> <p>Patients received modified radical mastectomy (42 patients) or lumpectomy (26 patients)</p> <p>RT was given to patients with disease-positive axillary nodes, those with tumours located in the medial and central quadrants and those who underwent lumpectomy. RT dose was 37.5 Gy in 15 fractions.</p>
<b>Outcomes</b>
Disease-free survival
<b>Follow up</b>
2 years
<b>Results</b>
There was no statistically significant difference in disease-free survival at 2 years follow up (p>0.1).
<b>General comments</b>
Study appears to evaluate an early regimen of primary chemotherapy, as a

small proportion of the total systemic therapy given.

Due to the date of the paper applicability may be limited because of factors such as whether these tumours were screen detected etc. Also for patients randomised to either arm, adjuvant chemotherapy was not necessarily indicated, but reserved for patients with disease-positive axillary nodes, or tumour LVI. In any event only one of nine cycles of chemotherapy was given prior to surgery in the primary chemotherapy arm.

Of all patients with nodal status N0, 100% of those randomised to primary chemotherapy received 1 cycle or more of chemotherapy, compared with 24% of those randomised to the adjuvant chemotherapy arm ( $p < 0.0001$ ); representing a bias for more systemic therapy in the primary chemotherapy arm.

<b>Design</b>				
Design: Randomized controlled trial, evidence level: 1 - Country: France				
<b>Inclusion criteria</b>				
196 patients with T2-3, N0-1b operable breast cancer treated within the period: November 1983 to March 1986.				
Table: disease stage				
Stage	Primary chemotherapy group (n=95)		Adjuvant chemotherapy group (n=86)	
	n	%	n	%
T2 N0	0	0%	3	3%
T2 N1b	43	45%	26	30%
T3 N0	24	23%	24	28%
T3 N1b	28	29%	33	38%
Total	95	100%	86	100%
Mean T size: Primary chemotherapy group: 5.4 cm Adjuvant chemotherapy group: 5.0 cm				
<b>Exclusion criteria</b>				
Prior cancer; Concomitant serious illness; Age >65 years.				
15 patients were excluded after randomisation due to randomisation errors, poor compliance or receipt of treatment in a non-participating centre.				
<b>Population</b>				
N=181				
<b>Interventions</b>				
Aim: to compare the effects of two treatment strategies: one based on primary				

chemotherapy and the other based on primary RT with adjuvant chemotherapy.

Primary chemotherapy group (n=100): received 2 cycles of doxorubicin, cyclophosphamide and fluorouracil (ACF), followed by assessment of tumour response and locoregional treatment (see below). Patients with a good initial response to primary chemotherapy received adjuvant chemotherapy consisting of 4 further cycles of ACF, whereas patients with a poor response received 4 cycles of doxorubicin, methotrexate, vindesine and thiotepa as adjuvant chemotherapy

Adjuvant chemotherapy group (n=96): received locoregional treatment (see below) followed by 6 cycles of ACF as adjuvant chemotherapy.

All patients received steroid drugs.

Table: locoregional treatment:

Treatment	Primary chemotherapy group (n=95)		Adjuvant chemotherapy group (n=86)	
	n	%	n	%
Mastectomy	22	23%	31	36%
Lumpectomy	32	34%	26	30%
No surgery	41	43%	29	34%
RT	95	100%	86	100%

RT consisted of 55Gy to the whole breast with boost to the tumour bed to make a total dose of 75-80Gy. 45-55Gy were applied to the node bearing tissues.

In the primary chemotherapy group, only patients with residual tumour after primary chemotherapy underwent surgery, with surgical procedure determined according to individual patients' needs.

### Outcomes

Local recurrence (defined as tumour presence at or after 9 months from the start of treatment, because not all patients underwent surgery)

Disease-free survival

### Follow up

Median 54 months (range 35-70 months).  
Two patients were lost to follow-up at 35 and 38 months

### Results

**Relationship between tumour response to primary chemotherapy and**

## dose received

In patients in the primary chemotherapy arm, there was a statistically significant relationship between tumour response and the total *dose* (dose/m<sup>2</sup> as an average for all drugs) received, as the proportion of the planned dose. This was true for the subgroup of patients who completed all planned *cycles* of primary chemotherapy (n=77; p=0.003; see tabulated data below) and also for all patients in the primary chemotherapy arm (n=95; p=0.002; no data shown).

**Table: tumour response by dose of chemotherapy as % of planned dose in 77 patients who completed all planned cycles of primary chemotherapy**

	Dose received as % of planned dose		
	<50%	50-75%	75-100%
CR	0	0	10
PR<50%	0	4	20
PR>50%	2	12	20
Stable disease	0	3	4
Progressive disease	0	1	0
Total	2	20	54

Chi<sup>2</sup> = 8.82; p=0.003

### Overall survival (all patients; intention-to-treat)

Over the entire follow-up period there was no statistically significant difference in overall survival between randomised groups (primary versus adjuvant chemotherapy); p=NS; log-rank test.

### Disease-free survival (all patients; intention-to-treat)

Over the entire follow-up period there was no statistically significant difference in disease-free survival between randomised groups (primary versus adjuvant chemotherapy); p=0.4; log-rank test.

### Disease-free survival in primary chemotherapy arm by subgroup for tumour response of regimen

In the subgroup of patients within the primary chemotherapy arm who completed all planned chemotherapy (n=77; 81% of the randomised arm) disease-free survival at 36 months follow-up was as follows:  
80% in patients with >50% tumour regression when assessed after 2 cycles of primary chemotherapy;  
68% in patients with ≤ 50% tumour regression when assessed after 2 cycles of primary chemotherapy (figures read from chart).  
This difference by tumour response was not statistically significant over the entire follow-up period (median 54 months; p=0.058; log-rank test).

The same analysis including the 18 patients randomised to primary chemotherapy, but who ceased treatment (e.g. due to stage N0 nodes, or toxicity) also indicated no significant difference in disease-free survival (median follow-up 54 months, n=95; p=0.3, log-rank test).

### **Overall survival in primary chemotherapy arm by subgroup for completion of regimen**

There was no statistically significant difference in overall survival in patients treated with primary chemotherapy and who completed all cycles (n=77) between the subgroup with >50% tumour regression and the subgroup with ≤50% tumour regression (median follow-up 54 months; p=0.07; log-rank test).

The same analysis including the 18 patients randomised to primary chemotherapy, but who ceased treatment (e.g. due to stage N0 nodes, or toxicity) also indicated no significant difference in overall survival (median follow-up 54 months, n=95; p=0.2, log-rank test).

### **Local recurrence**

For all randomised patients, the rate of local recurrence (defined as tumour presence at or after 9 months from the start of treatment) between randomised groups was similar: 18% for the primary chemotherapy group and 20% for the adjuvant chemotherapy group (no p value reported).

### **Rate of breast conserving surgery (all randomised patients)**

Primary chemotherapy group: 56%  
Adjuvant chemotherapy group: 35%

### **General comments**

In both randomised arms a subgroup arises of patients with N0 status revealed by surgery for whom chemotherapy (primary or adjuvant) was discontinued. This occurred in 18 patients in the primary chemotherapy group and 21 patients in the adjuvant chemotherapy group; these subgroups represent 'better prognosis' patients.

No mention of randomisation method. Blinding is unlikely to have been feasible. Not all analyses are by intention to treat.

<b>Design</b>		
Design: Randomized controlled trial (therapy), evidence level: 1 - Country: UK, setting: Tertiary care		
<b>Inclusion criteria</b>		
108 patients with locally advanced primary breast cancer (i.e. T size $\geq$ 5cm, inflammatory breast cancer and/or with skin involvement or chest wall/axillary node fixity but with no distant metastases), treated between January 1989 and December 1994.		
Table: patient characteristics		
Variable	Primary hormone therapy	Multimodal therapy
n	52	56
Median age (range) (years)	62 (36-73)	58 (32-71)
Mean T size	6.2 cm	6.5 cm
Inflammatory breast cancer	6 (12%)	5 (9%)
T2, N2 tumour	12 (23%)	7 (13%)
T3 tumour	34 (64%)	44 (79%)
Proportion of patients with ER+ tumours (NB: not assessed for all patients): Minimal therapy arm: 35/49 = 71% Multimodal therapy arm: 28/53 = 53% (Chi square=3.0; p=0.09)		
<b>Exclusion criteria</b>		
Not reported; defined by inclusion criteria		
<b>Population</b>		
N = 108, age range 32 to 73 years.		
<b>Interventions</b>		
Aim: to compare, in patients with locally advanced/inflammatory breast cancer, primary hormone therapy with multimodal therapy consisting of primary chemotherapy, Patey mastectomy, post-operative radiotherapy and adjuvant hormone therapy.		
Patients were randomised to two groups:		

**1. Primary hormone therapy group (n=52):** treated as follows:  
 Post-menopausal patients (n=45): tamoxifen i.e. sole hormone therapy  
 Pre-menopausal patients (n=7): tamoxifen plus goserelin i.e. sole hormone therapy  
 On discovery of progressive disease (PD): hormone therapy ceased; and either surgery, RT, or adjuvant chemotherapy given.  
 On discovery of further PD: the next appropriate therapy was given.  
 NB one treatment modality was given at a time

**2. Multimodal therapy group (n=56):** treated as follows:  
 Primary chemotherapy with mitoxantrone, methotrexate and mitomycin (n=55); followed by either breast RT (n=2) or Patey mastectomy (n=53) followed by RT: 40 Gy to the chest wall (n=50) and hormone therapy (n=53): tamoxifen for post-menopausal patients and tamoxifen plus goserelin for pre-menopausal patients.  
 On discovery of locoregional failure or distant metastases, the most appropriate treatment was given.

**Outcomes**

Initial response to primary chemotherapy:

- Complete response: resolution of tumour;
- Partial response: >50% reduction in bidimensional product of tumour;
- Static disease: <50% reduction, or <25% increase in bidimensional product of tumour;
- Progressive disease: >25% increase in bidimensional product of tumour.

Locoregional failure  
 Distant metastasis  
 Overall survival

**Follow up**

Median (range):  
 Primary hormone therapy: 45 (7-113) months  
 Multimodal therapy: 52 (6-120) months

**Results**

**Table: initial response to primary chemotherapy**

Response	Primary hormone therapy (n=52)	Multimodal therapy (n=56)
Complete response	2 (4%)	5 (9%)
Partial response	17 (33%)	26 (47%)
Stable disease	16 (31%)	22 (40%)
Progressive disease	17 (33%)	2 (4%)

## 1. Outcomes by randomised group

### Locoregional failure

The time to first locoregional failure was significantly shorter in the initial hormone therapy group when compared with the multimodal therapy group ( $P < 0.01$ ).

### Distant metastases

There was no difference in the number of patients who developed distant metastases ( $n=29$  and  $n=30$  for those treated with initial hormone therapy and multimodal therapy, respectively), nor in the time to distant metastases between the two groups ( $p=0.84$ ).

### Number of therapies

When compared with the multimodal therapy group, patients in the initial hormone therapy required fewer therapies to achieve disease control (mean 3.6 therapies) compared to patients in the multimodal therapy group (mean 4.9 therapies).

16 patients (31%) in the initial hormone therapy group eventually underwent mastectomy for locoregional control of their tumour, although over 80% required a 'local' therapy (i.e. either surgery (31%) or radiotherapy (52%)).

### Overall survival

There was no statistically significant difference in overall survival between the randomised groups ( $p=0.22$ ).

## 2. Outcomes by randomised group with subgroups based on tumour ER status

### Patients with ER+ tumours

In patients with ER+ tumours there was no statistically significant difference in time to distant metastasis ( $p=0.52$ ) nor overall survival ( $p=0.14$ ). However time to locoregional failure was statistically significantly shorter in the initial hormone therapy group ( $p=0.001$ ).

### Patients with ER- tumours

In patients with ER- tumours there was no statistically significant difference in time to distant metastasis ( $p=0.74$ ) nor overall survival ( $p=0.74$ ). However time to locoregional failure was statistically significantly shorter in the initial hormone therapy group ( $p=0.001$ ).

### General comments

1 patient in the multimodal therapy arm refused primary chemotherapy, surgery and RT and received Megestrol acetate.

Analysis appears to be by intention-to-treat; patients who refused particular

therapies are reported, and 100% of randomised patients completed the trial. The authors acknowledge that no prospective power calculation was performed, and that the sample size is small, and that the rates of late-occurring events are based on small numbers.

Patient/investigator blinding not reported, but unlikely to be feasible due to multimodal nature of therapy.

Patients were randomised irrespective of ER status, which was known for 103 patients.

**Interventions**

Aim: to determine whether the addition of tamoxifen to preoperative dose-dense doxorubicin and docetaxel combination chemotherapy improves the rate of pCRs.

Patients were randomly allocated to two groups:

1. Primary chemotherapy group (n=128): received doxorubicin and docetaxel every 14 days for four cycles (ADoc) as primary chemotherapy.
2. Primary chemoendocrine therapy group (n=122): received ADoc primary chemotherapy plus tamoxifen taken daily commencing on day 1 of the first cycle of ADoc and continued for 5 years for patients with a partial or complete tumour response, irrespective of ER status. Patients with no response or with progression were treated with other chemotherapy or endocrine therapy at the discretion of the treating clinicians but were followed up according to the protocol and all therapies received were documented. Patients in this group could receive black cohosh, clonidine or medroxyprogesterone acetate for symptoms of oestrogen withdrawal.

All patients received steroid, anti-emetic and G-CSF with primary chemotherapy. Patients in either group could receive antibiotic prophylaxis.

Therapy could be postponed for a maximum of 1 week only if severe hematologic or nonhematologic toxicities occurred (definition provided in paper). If toxicity did not improve during this period, chemotherapy had to be discontinued and surgery was recommended. No dose reduction was permitted.

**Locoregional treatment**

All patients underwent surgery between 14 and 28 days after the last chemotherapy cycle, as follows:

- i) modified radical mastectomy for large tumours; patients were offered autologous or heterologous reconstructive surgery.
- ii) breast-conserving surgery (BCS), in cases with clear ( $\geq 1$ mm) surgical margins where an adequate cosmetic result was anticipated; and where cosmetically acceptable, the whole previously involved area could be excised.

All patients who underwent BCS received radiotherapy. Radiotherapy to the chest wall or regional lymph nodes was performed according to local procedures at each participating center.

## Outcomes

Compliance with protocol (not cited)  
Toxicity  
pCR rate  
Rate of breast conserving surgery

## Follow up

Not reported; outcomes relate to peri-operative period.

## Results

### Pathological complete response rate

There was no evidence of a difference in rate of pCR between the randomised arms:

No. of pCRs:

ADoc + T: 11/121 = 9.1%

ADoc: 13/126 = 10.3% (difference -1.2%; 95% CI -8.6 to +6.2)

### Toxicity

Toxicity was analyzed according to the treatment actually given; 120 patients received ADocT and 128 received ADoc alone. There was little difference in toxicity between the two groups (numerous variables tabulated; no statistical testing of differences performed). There seemed to be a higher incidence of severe infections associated with the higher rate of grade 3/4 neutropenia in the ADoc + T group. However, the incidences of febrile neutropenia were similar, at 8.3% in the ADoc + T group and 8.7% in the ADoc group. The most common severe forms of toxicity, apart from alopecia, were fatigue and loss of appetite. All other toxicities occurred in less than 5% of the cycles.

### Rate of breast-conserving surgery.

Rate of BCS

ADoc + T: 68.6%

ADoc: 69.0% (difference -0.4; 95% CI -12.0% to +11.1%).

The chances of being able to conserve the breast in larger tumors were highly dependent on the clinical response to preoperative chemotherapy. Patients with tumors larger than 4 cm had a higher rate of breast conservations if they achieved a favorable remission.

Re-excisions had to be performed in 51 (20.6%) of 247 patients. A further three patients refused re-excision. The second operation consisted of mastectomy in 58.8% of cases and of BCS in 41.2% of cases.

## General comments

Non blinded study. Randomisation was carried out centrally with stratification for participating centre. Sample size is based upon a statistical power calculation. Analysis is by intention-to-treat.

Patient and tumour characteristics were evenly distributed between the randomised groups (statistically tested).

Toxicity was analyzed according to the treatment actually given; 120 patients received ADocT and 128 received ADoc alone (non ITT, but with only small likely impact on results).

Authors have not performed statistical testing of observed differences for the majority of variables.

## UPDATE EVIDENCE:

von Minckwitz, Kummel, S., Vogel, P., Hanusch, C., Eidtmann, H., Hilfrich, J., Gerber, B., Huober, J., Costa, S. D., Jackisch, C., Loibl, S., Mehta, K., Kaufmann, M. & German Breast Group. (2008) Intensified neoadjuvant chemotherapy in early-responding breast cancer: phase III randomized GeparTrio study. *Journal of the National Cancer Institute*, 100: 552-562.

**Design:** RCT, Evidence level 1-

**Country:** Germany

**Aim:** To evaluate the effect of extended chemotherapy on pathological complete response at surgery (the GeparTrio trial).

### **Inclusion criteria**

- Breast cancer diagnosis had to be confirmed histologically from a core biopsy specimen. Patients needed to have at least one of the following risk factors: age younger than 36 years, clinical tumour size > than 5 cm, estrogen receptor – and progesterone receptor – negative tumour, clinical involvement of axillary lymph nodes, or undifferentiated tumor grade.
- For bilateral disease, the investigator had to prospectively choose one side for evaluation (ie, the breast with the tumor that was most easily measured) on the registration form.
- Patients with locally advanced disease that included clinical involvement of skin and/or muscle, clinical evidence of inflammatory breast cancer (T4a – T4d), or N3 stage that included supraclavicular lymph nodes were eligible for this study but were randomly assigned to treatment in a separate stratum.
- For patients with inflammatory disease, the area of inflammation was used for evaluation and was measured clinically.
- For multifocal or multicentric disease, the lesion with the largest diameter was chosen for followup.
- Other inclusion criteria were age 18 years or older, Karnofsky performance status of at least 80%, normal left ventricular ejection fraction, and sufficient hematopoietic (neutrophil count of  $\geq 2.0 \times 10^9$  cells per liter, platelet count of  $\geq 100 \times 10^9$  platelets per liter, and hemoglobin of  $\geq 10$  g/dL), liver (total bilirubin of 1X upper normal limit; aspartate aminotransferase and alanine aminotransferase, each of  $\leq 2.5X$  upper normal limit; and alkaline phosphatase of  $\leq 5X$  upper normal limit), and renal (creatinine of  $\leq 175 \mu\text{mol/L}$ ) function.
- Patients were excluded if they had evidence of distant metastases, previous chemotherapy or radiation therapy, previous serious illnesses, concurrent treatment with sex hormones or experimental drugs, or a known hypersensitivity reaction to the study compounds or if they were male.

### **Exclusion criteria**

### **Population**

- Patients with previously untreated unilateral or bilateral primary breast cancer.

- 2090 eligible patients and 2072 were included in the GeparTrio trial: 1390 (66.5%) were randomly assigned as responders after 2 initial TAC cycles to receive an additional 4 (n = 704) or 6 (n = 686) TAC cycles.

**NOTE:** approx 88% of the included population fall into the EBC scope (tumour stage T1-3)

### Interventions

- Untreated breast cancer patients received two 3-week cycles of docetaxel at 75 mg/m<sup>2</sup>, doxorubicin at 50 mg/m<sup>2</sup>, and cyclophosphamide at 500 mg/m<sup>2</sup> (TAC).
- Those whose tumor size decreased by 50% or more by sonographic measurement (i.e. a reduction in the product of the two largest perpendicular diameters by at least 50%) were classified as responders and randomly assigned to receive 4 (for a total of 6 TAC cycles) or 6 more cycles of TAC (for a total of 8 TAC cycles)
- Only the TAC cycle outcomes are presented in this paper

### Outcomes

Sonographic response rates and rates of breast-conserving surgery and adverse effects

### Results

- Details of the early responders: 1390 (67.1%, or 66.5% of the 2090 patients enrolled) responded to treatment with a decrease in tumour size of 50% or more; 622 (30.0%) did not respond to treatment (ie, their tumours decreased in size by <50% or increased in size by <25%), and 60 (2.9%) terminated treatment early.
- Rates of pathological complete response were not statistically significantly different between the arms (21.0% with 6 TAC cycles and 23.5% with 8 TAC cycles; difference = 2.5%, 95% CI = -1.8% to 6.8%; P = 0.27).
- Assessment by physical examination: The clinical complete responses at surgery were not statistically different with 8 TAC cycles than with 6 TAC cycles (52.9% vs 48.2% respectively, difference = 4.7%; 95% CI = -0.55% to 9.95%; P = 0.08)
- Sonographic assessment showed a statistically different complete response to surgery with 6 TAC cycles than with 8 TAC cycles (22.6% vs 27.6%, difference = 5%; 95% CI = 0.45% to 9.55%; P = 0.033)
- The rate of breast-conserving surgery was similar in both arms, with no statistically significant difference (67.5% vs 68.5%, respectively, P = 0.68).
- Grade 3 or 4 leukopenia and edema and various grade 1 or 2 adverse events were more frequent in patients receiving 8 TAC cycles than in those receiving 6 cycles.
- Treatment discontinuations were due to adverse reactions were reported in 2.4% of the patients in the 6-cycle arm and 7.7% of the patients in the 8 cycle arm (P<0.001).
- In the multivariable model, negative hormonal receptor status (odds ratio [OR] = 5.5, 95% CI = 3.8 to 8.0), nonlobular histology (OR = 2.5, 95% CI = 1.2 to 5.4), undifferentiated grade (OR = 1.6, 95% CI = 1.1 to 2.4), and age younger than 50 years (OR = 1.5, 95% CI = 1.0 to 2.1) were statistically significantly independently associated with pathological complete response.

**General comments**

Authors' conclusions: Patients receiving 8 TAC cycles had statistically significantly higher sonographic response rates but not pathological complete response rates than those receiving 6 TAC cycles. However, they also had more toxic effects. So far, 8 cycles of TAC cannot be recommended for the whole group of patients responding to two initial cycles of TAC.

Limitations: The power of the study to detect a statistically significant difference between arms was reduced because of the small sample size. More patients in the 8-cycle arm than in the 6-cycle arm discontinued treatment. There was a high level of interobserver variability in the assessment of sonographic and clinical responses.

Rastogi, P. et al. (2008) Preoperative chemotherapy: Updates of National Surgical Adjuvant Breast and Bowel Project Protocols B-18 and B-27. *Journal of Clinical Oncology* 26;5:778-785

**Design:** Review of Randomised Controlled Trials B-18 and B-27

**Country:**

**Aim:** To provide and update of extended outcomes of two preoperative chemotherapy trials of NSABP through 16 years of follow-up for B-18 and 8.5 years of follow-up for B-27.

B-18: to determine whether preoperative chemotherapy with doxorubicin and cyclophosphamide would result in better OS and DFS when compared with post operative adjuvant chemotherapy. (This trial was reviewed as part of a Cochrane Review which was included in the original evidence (Mieog 2007)).

B-27: to determine whether adding docetaxel to preoperative AC would increase DFS and OS in patients with operable breast cancer (This trial was included in a systematic review which was included in the original evidence (Trudeau 2005)).

**Inclusion criteria**

Detailed eligibility and inclusion criteria were reported elsewhere.

B-18: Women with operable, palpable breast cancer diagnosed by core needle biopsy or FNA.

B-27: Women with primary operable breast cancer diagnosed by core biopsy or FNA.

**Exclusion criteria**

Reported in previous publications.

**Population**

B-18: N=1,523

B-27: N=2,411

### Interventions

B-18: surgery (lumpectomy or ALND) followed by four cycles of AC Chemotherapy (doxorubicin 60mg/m<sup>2</sup> and cyclophosphamide 600mg/m<sup>2</sup> every 21 days vs. AC Chemotherapy (doxorubicin 60mg/m<sup>2</sup> and cyclophosphamide 600mg/m<sup>2</sup> followed by surgery.

B-27: Four cycles of AC chemotherapy every 21 days before surgery followed by surgery, vs. Four cycles of AC chemotherapy every 21 days before surgery and preoperative docetaxel (T), followed by surgery vs. Four cycles of AC chemotherapy every 21 days before surgery followed by surgery and postoperative docetaxel.

### Outcomes

Tumour Response

Overall Survival (OS)

Disease Free Survival (DFS)

Relapse Free Interval (RFI)

### Results

*Overall Survival*

#### B-18:

No significant difference was observed between the two groups (HR=0.99; 95% CI, 0.85 to 1.16; p=0.90)

Survival estimates were as follows:

Estimated Survival	Preoperative	Postoperative
5 year	80%	81%
8 year	72%	72%
16 year	55%	55%

#### B-27:

No statistically significant differences in overall survival according to treatment (p=0.76).

Survival estimates were as follows:

Estimated Survival	Group 1	Group 2	Group 3
5 year	82%	83%	82%
8 year	74%	75%	75%

*Disease Free Survival*

#### B-18:

No significant difference in DFS between the two groups (HR=0.93; 95% CI, 0.81 to 1.06; p=0.27)

Survival estimates were as follows:

Estimated Survival	Preoperative	Postoperative
--------------------	--------------	---------------

<b>5 year</b>	80%	67%
<b>8 year</b>	72%	55%
<b>16 year</b>	55%	39%

**B-27:**

No statistically significant difference in DFS was observed according to treatment group.

Survival estimates were as follows:

<b>Estimated Survival</b>	<b>Group 1</b>	<b>Group 2</b>	<b>Group 3</b>
<b>5 year</b>	68%	71%	70%
<b>8 year</b>	59%	62%	62%

*Relapse Free Interval*

**B-18:**

No significant difference was observed between the two treatment groups (HR=0.98; 95% CI, 0.83 to 1.15; p=0.78)

**B-27:**

Survival estimates as follows:

<b>Estimated Survival</b>	<b>Group 1</b>	<b>Group 2</b>	<b>Group 3</b>
<b>5 year</b>	71%	76%	74%
<b>8 year</b>	66%	71%	69%

*Treatment by Covariate Interactions and Subset Analysis*

**B-18:**

There was a significant treatment-age interaction for OS (p=0.01).

There was no significant difference in DFS between treatment groups for women >50 years at entry.

**B-27:**

No significant effect of treatment heterogeneity was observed for age categories or other variables.

*Association between Pathological Response and Outcome*

**B-18:**

Individuals achieving a pCR have superior DFS and OS outcomes when compared with patients not achieving a pCR (DFR HR = 0.47, p<0.0001; OS HR = 0.32, p<0.0001).

**B-27:**

pCR was a significant predictor of improved DFS (HR = 0.49, p<0.0001)) and OS (HR = 0.36, p<0.0001).

**General comments**

Author's Conclusions:

These data demonstrate that the achievement of pCR in the breast and negative axillary nodes following preoperative therapy predict favourable outcomes. Although most patients

will not achieve pCR and significant heterogeneity exists in relation to outcomes among non pCR patients following preoperative therapy.

Preoperative Chemotherapy is equivalent to adjuvant chemotherapy with respect to OS and DFR; although it may be beneficial for patients who want breast conservation surgery but for whom this may not be an option on initial presentation.

Updated 2018

## 7.2 For patients with inflammatory of locally advanced breast cancer who are treated with primary cytotoxic chemotherapy, what is the role of surgery and/or radiotherapy?

### Short Summary

There is a considerable body of high quality evidence that has evaluated the role of primary chemotherapy in patients with locally advanced breast cancer, inflammatory breast cancer, or operable breast cancer. Patients also received loco-regional treatment, the effect of which was not the main focus of the study resulting in little direct evidence on the individual effects of surgery or radiotherapy following primary chemotherapy.

In patients with locally advanced breast cancer who receive primary chemotherapy, findings from a Cochrane review and two systematic reviews suggest that better tumour response is associated with better outcomes (Mieog *et al* 2007; Shenkier *et al* 2004; Pouillart *et al* 1981). The applicability of this evidence is limited however because the majority of patients had operable breast cancer of stage I-II.

No difference in overall survival was observed when comparing different radiotherapy regimens (Bucholz *et al.* 2006, Shenkier *et al.* 2004), however there was also evidence of a higher rate of loco-regional recurrence in patients who received radiotherapy without surgery after primary chemotherapy (Mieog *et al.* 2007, Mauri *et al.* 2005). Veyret *et al.* 2006 evaluated the outcomes after primary chemotherapy. Some patients underwent surgery or received radiotherapy. The univariate analysis conducted in this study showed the following factors were statistically significantly associated with recurrence: no surgery, no overall pathological complete response, no breast pathological complete response, no lymph node pathological complete response and diffuse inflammatory signs. However no variable remained statistically significant in multivariate analysis and the use of radiotherapy was not included in the model. A retrospective study by Huang *et al.* 2004 examined the effect of radiotherapy on outcomes in patients treated for locally advanced breast cancer with primary chemotherapy and mastectomy. Radiotherapy was found to reduce loco-regional recurrence and improve survival for patients. Another retrospective study by McGuire *et al.* (2007) investigated the role of post-mastectomy radiotherapy in women with breast cancer who achieved a pathologic complete response to neo-adjuvant chemotherapy. In patients initially presenting with stage III disease; those receiving radiotherapy had statistically significantly lower rates of locoregional response; higher distant metastatic survival rates; higher cause specific survival rates and higher overall survival rates.

### PICO

Population	Intervention	Comparison	Outcomes
Patients with <ul style="list-style-type: none"> <li>• inflammatory breast cancer</li> <li>• stage III/T3-4 (locally advanced breast cancer) who have received primary chemotherapy.</li> </ul>	<ul style="list-style-type: none"> <li>• Surgery</li> <li>• Radiotherapy</li> </ul>	<ul style="list-style-type: none"> <li>• Surgery</li> <li>• Radiotherapy</li> <li>• Surgery with WLE+XRT</li> <li>• Radiotherapy with WLE+XRT</li> <li>• Nothing</li> </ul>	<ul style="list-style-type: none"> <li>• Recurrence</li> <li>• Disease Free Survival</li> <li>• Overall Survival</li> <li>• Patient Acceptability</li> <li>• Quality of Life</li> <li>• Cost Effectiveness</li> </ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

### **Evidence Summary**

The evidence body for this question consisted of a Cochrane Review, a number of systematic reviews and RCTs and an observational study although there is little direct evidence from randomised studies on the individual effects of surgery or RT following treatment with primary chemotherapy.

Some of the included studies have limited applicability due to the majority of patients having operable breast cancer of stage I-II (Mieog *et al.* 2007; Trudeau *et al.* 2005; Mauri *et al.* 2005; Avril *et al.* 1998; Scholl *et al.* 1991).

There is evidence that in patients with locally advanced breast cancer that are treated with primary chemotherapy, better tumour response is associated with better outcomes (Mieog *et al.* 2007; Shenkier *et al.* 2004; Pouillart *et al.* 1981).

There is indirect evidence that 5 and 10 year overall survival is poorer in patients with locally advanced or inflammatory breast cancer whom are treated with primary chemotherapy and loco-regional therapy when compared with those with stage I-II disease ((Baldini *et al.* 2003; Tan *et al.* 2001; Veyret *et al.* 2006; Mieog *et al.* 2007).

There is evidence that radiation therapy was significantly associated with a higher 10 year overall survival in the irradiated group compared with the non-irradiated group (McGuire *et al.* 2007).

### **The effect of response to primary chemotherapy**

In a Cochrane Review of RCTs (Mieog *et al.* 2007) the rate of pathological complete response to primary chemotherapy in 7 trials ranged from 4.0% to 29.2%. From four RCTs a statistically significant difference in overall survival in patients with a pathological complete response was observed compared with those patients with residual disease (HR = 0.48; 95% CI, 0.33 to 0.69). From five RCTs there was a statistically significant difference in disease free survival in patients with a pathological complete response to primary chemotherapy compared to those with residual disease (HR = 0.48; 95% CI, 0.33 to 0.69).

### **Changes to intended loco-regional therapy and achievement of breast conserving surgery**

A Cochrane systematic review of RCTs (Mieog *et al.* 2007) estimated that in patients with operable breast cancer who are treated with primary chemotherapy, loco-regional treatment is changed to a less radical strategy due to down-staging in 25.6% (95% CI 23.5%-27.8%) of patients and in 4.3% (95% CI 3.3%-5.3%) of patients more radical loco-regional treatment was given. In the remaining 70.1% (95% CI 67.8%-72.4%) there was no change to planned treatment.

Two RCTs in the same review (Mieog *et al.* 2007) found that there was no significant difference in loco-regional recurrence (RR 1.34; 95% CI 0.85-2.13) or overall survival (OR 1.33; 95% CI 0.67-2.63) according to whether breast conserving surgery was planned from the outset or made feasible by the effect of primary chemotherapy.

From a systematic review of RCTs (Trudeau *et al.* 2005), the mean proportion of patients receiving breast conserving surgery was 54%, the median was 56% and the range was 20% to 85%.

The applicability of this evidence is limited due to the fact that the majority of patients were Stage I-II in both reviews.

### **The effect of loco-regional surgery of radiotherapy in patients with locally advanced or inflammatory breast cancer treated with primary chemotherapy**

Four RCTs provide randomised comparisons of loco-regional therapies in patients with locally advanced or inflammatory breast cancer who are treated with primary chemotherapy (Bucolz *et al.* 2006, Perloff *et al.* 1998, Murali *et al.* 1993 and DeLena *et al.* 1981).

An RCT (Bucolz *et al.* 2006) compared hyperfractionated RT with standard RT in patients with locally advanced breast cancer showing an acceptable response to primary chemotherapy and who had mastectomy and adjuvant chemotherapy. No significant difference was observed at 15 year follow-up between the hyperfractionated and standard arms for loco-regional recurrence free survival (12% and 7% respectively,  $p=0.36$ ), overall survival (33% and 45% respectively,  $p=0.54$ ), late toxicity (11% and 6% respectively,  $p=0.54$ ).

A systematic review (Shenkier *et al.* 2004) included three RCTs (Perloff *et al.* 1998, Murali *et al.* 1993 and DeLena *et al.* 1981) comparing mastectomy alone with loco-regional RT alone following primary chemotherapy in patients with locally advanced or inflammatory breast cancer. The results suggest that both treatments are equally effective in terms of recurrence and survival, after primary chemotherapy in inoperable disease.

In contrast the Cochrane Review (Mieog *et al.* 2007) and a systematic review (Mauri *et al.* 2005) suggest higher rates of loco-regional recurrence in patients who received RT without surgery after primary chemotherapy. Three RCTs included in the Cochrane Review (Mieog *et al.* 2007) a substantial number of patients received RT alone after primary chemotherapy; the combined rate of loco-regional recurrence for all patients was 19.3% as compared to a combined rate of 9.7% in the remaining RCTs in which all patients had surgery. A single RCT reported a rate of loco-regional recurrence of 29.5% in the subgroup of patients who received RT alone following primary chemotherapy.

A similar association was reported in a systematic review ((Mauri *et al.* 2005) based on the same three primary studies. Patients treated with primary systemic therapy were at 22% increased risk of loco-regional recurrence when compared with those who received adjuvant chemotherapy following primary loco-regional treatment (RR primary:adjuvant 1.22 (95% CI, 1.04-1.43),  $p=0.015$ ). This increased risk of loco-regional recurrence associated with primary systemic treatment was driven largely by three trials in which radiotherapy only was adopted more often in the primary systemic arm than in the adjuvant arms (RR primary:adjuvant 1.53; 95% CI 1.11 to 2.10;  $p=0.009$ ) whereas no association with loco-regional recurrences was found in other trials (RR 1.10; 95% CI 0.87 to 1.38;  $p=0.44$ ).

In one small RCT (Pouillart *et al.* 1981) of patients with inflammatory breast carcinoma treated with primary chemotherapy, subsequent loco-regional therapy was RT without surgery. The randomised comparison was live BCG vaccine in one arm and no vaccine in the other arm. In

all patients the mean overall survival was 34 months and mean disease-free survival was 26 months.

The high degree of heterogeneity of RCTs (Table 1) in terms of initial disease stage, distribution of loco-regional therapies, extent of follow-up (or time of assessment of outcome) and primary chemotherapeutic regimens does not permit a concise summary of their results.

Five year overall survival data are available for three randomised arms in 2 trials of patients with locally advanced or inflammatory breast cancer who are treated with primary chemotherapy followed by loco-regional therapy. The values are 52%, 54% and 50% (Baldini *et al.* 2003; Tan *et al.* 2001) (Table 1). This suggests that overall survival is poorer in patients with stage III or inflammatory disease, than in similarly treated patients with predominantly stage I-II disease: 5 year survival range 77%-93% (Mieog *et al.* 2007).

Similar data for 10 year overall survival in patients with inflammatory breast cancer comes from a single RCT in which patients received primary chemotherapy, surgery and RT (Veyret *et al.* 2006). 10 year overall survival was 41% (table 1), whereas 10-year survival in similarly treated patients with predominantly stage I-II disease reported in the Cochrane Review had range 62% to 87% (Mieog *et al.* 2007).

### **Multivariate analyses of factors to predict outcomes in patients with locally advanced breast cancer treated with primary chemotherapy**

The RCT by Veyret *et al.* 2006 (Table 2) evaluated in its randomised comparison, the addition of granulocyte colony stimulating factor to primary chemotherapy. After primary chemotherapy, 85% of patients underwent surgery and 95% received RT. At a median follow-up period of 120 months the rate of recurrence by subgroup for loco-regional therapy was: No surgery: 10 cases (55.6%), no mastectomy: 15 cases (33.3%), breast conserving surgery: 5 cases (18.5%) and RT as only adjuvant treatment: (12 cases) 84.6%. In univariate analysis the following factors were statistically significantly associated with recurrence: No surgery, no overall pathological complete response, no breast pathological complete response, no lymph node pathological complete response and diffuse inflammatory signs. However no variable remained statistically significant in multivariate analysis. The use of RT was not included in the model (Veyret *et al.* 2006).

A retrospective study by Huang *et al.* 2004 examined the effect of RT on outcomes in 676 patients treated for locally advanced breast cancer with primary chemotherapy and mastectomy. 542 patients received in addition, adjuvant RT and 134 patients did not. The 10-year rate of loco-regional recurrence was 11% in patients who received RT versus 22% in patients who did not receive RT ( $p=0.0001$ ; log-rank test). There were no statistically significant differences in 10-year overall survival (54% versus 47% respectively;  $p=0.063$ ; log-rank test) and in 10-year cause-specific survival (58% and 55% respectively,  $p=0.85$ ; log-rank test). In a multivariate analysis of factors, the following variables were statistically significantly associated with loco-regional recurrence: No RT,  $\geq 20\%$  sampled nodes positive, stage  $\geq$  IIIB, no tamoxifen, minimal (or less) clinical response to primary chemotherapy and ER negative tumour. Of these variables, the most strongly associated with local recurrence was not having RT (HR 4.68; 95% CI 2.70-8.13;  $p<0.0001$ ). Although this study was retrospective and excluded patients with recurrence within 2 months of surgery and those who received breast conserving surgery, the effect in favour of RT was observed despite patients who received RT

tending to have more advanced initial disease stage, a poorer response to primary chemotherapy and close or positive surgical margins (Huang *et al.* 2004).

On updating the evidence, a retrospective study by McGuire *et al.* (2007) investigated the role of post-mastectomy radiotherapy in women with breast cancer who achieved a pathologic complete response to neo-adjuvant chemotherapy. 106 patients without inflammatory breast cancer were included in the study (radiation therapy n=72; non-irradiated n=34). The 10 year actuarial rates of local regional recurrence (LRR) did not differ significantly between the two groups (p=0.40).

In patients initially presenting with stage III disease;

- Radiation therapy was significantly associated with a lower 10 year rate of LRR in the irradiated group compared with the non-irradiated group; 7.3% ± 3.5% vs. 33.3% ± 15.7% (p=0.040)
- 10 year distant metastasis survival rate was 87.9% ± 4.6% in the irradiated group and 40.7% ± 15.5% in the non-irradiated group (p = 0.0006)
- 10 year cause specific survival (CSS) rate was 87% ± 5% for the irradiated group and 40% ± 16% for the non-irradiated group (p=0.0014)
- 10 year overall survival (OS) rate was 77.3% ± 6% for the irradiated group and 33.3% ± 14% for the non-irradiated group (p=0.0016)

**Table 1: Recurrence and survival outcomes from trials that were not included in the Cochrane Review by Mieog et al. (2007): patients with locally advanced or inflammatory breast cancer treated with primary chemotherapy then loco-regional therapy**

RCT	n	Population (stage)	Loco-regional therapy (following primary chemotherapy); % of patients where applicable	Follow-up	Results	Notes
(Avril <i>et al.</i> 1998)	134	Stage T2-3/N0-1/M0	RT alone: 33% BCS + RT: 30% Mastectomy: 37%	5 years 10 years	DFS: 58% OS: 80% DFS: 50% OS: 60%	Included in SR by Mauri et al. (2005) Limited applicability (stage) 1 arm relevant (n=134)
(Baldini <i>et al.</i> 2003)	146	Stage III or IBC	Mastectomy: 125 (86%) BCS: 12 (8%) RT alone: 11 (8%)	5 years	DFS: 48%; 60% PFS: 52%; 56% OS: 52%; 54%	Two values for each outcome represent two randomised arms.
(Buchholz <i>et al.</i> 2006)	108	Stage II: 19.5% Stage III: 79% Other: 2%	Mastectomy, RT and adjuvant chemotherapy (all patients). Randomised comparison: hyperfractionated versus standard RT.	15 years	LRFS: 7%; 12% OS: 45%; 33% No difference in outcome by randomised RT regimen	Two values for each outcome represent two randomised arms. Applicable randomised comparison. Patients were also randomised to 1 of 2 adjuvant chemotherapy regimens and to 1 of 2 adjuvant RT regimens. The distribution of treatment arising from one randomisation relative to the other is not known.
(Cocconi <i>et al.</i> 1990)	49	LABC	Mastectomy + adjuvant chemotherapy + adjuvant RT (all patients)	Median 6 years	Median OS: 6.6 years; 3.5 years	50% of patients received tamoxifen as the randomised comparison (for the duration of primary and adjuvant chemotherapy). Two values for OS outcome represent two randomised arms

RCT	n	Population (stage)	Loco-regional therapy (following primary chemotherapy); % of patients where applicable	Follow-up	Results	Notes
(De Lena <i>et al.</i> 1981)	132	LABC	Randomised comparison: 1. Mastectomy + adjuvant chemotherapy 2. RT + adjuvant chemotherapy	Minimum 6 months	No difference in OS (percentages and p value not reported).  Median duration of remission 15 months in surgical group, 22 months in RT group (p=0.58).  Total incidence of loco-regional recurrence 29.6% in surgical group, 31.1% in RT group (no p value reported).  Total incidence of treatment failure in distant sites 43% in surgical group, 26.2% in RT group (p = 0.25). ## Evidence Tables

### Systematic reviews of RCTs

Mauri, Pavlidis & Ioannidis . Neoadjuvant versus adjuvant systemic treatment in breast cancer: a meta-analysis.[see comment]. J.Natl.Cancer Inst. 97[3], 188-194. 2005.

#### Design

Systematic review of RCTs (therapy), evidence level: 1 +  
Country: Various, setting: Secondary care

#### Inclusion criteria

1. RCTs that compared primary systemic with adjuvant systemic treatment (chemotherapy or endocrine therapy) for breast cancer, in which the same regimen was given preoperatively to one group and postoperatively to another group, regardless of what additional surgery or radiation treatment was used.
2. RCTs where one arm received exclusively postoperative therapy while the other arm received some cycles of the same regimen preoperatively and some other cycles postoperatively.

11 RCTs were included, of patients with disease stage as follows:

RCT	Stage
Avril et al. (1998) Mauriac et al. (1999)	T2-3 N0-1
Semiglazov et al. (1994)	IIB IIIA
Scholl et al. (1991)	T2-3 N0-1b
Scholl et al. (1994); Broet et al. (1999)	T2-3 N0-1b
Makris et al. (1998)	T0-4 N0-1
NSABP B-18 (1998; 2001)	T1-3 N0-1
Gazet et al. (2001)	T1-4 N0-2
van der Hage et al. (2001)	T1 c – 4 b N0-1
Danforth et al. (2003)	II

#### Exclusion criteria

Meeting abstracts, escalation dose studies, and pseudorandomised trials (e.g., those with alternate allocation of subjects). If other concomitant anticancer nonsurgical treatments were also used (e.g., hormone therapy and radiation therapy), these treatments should not have differed systematically between the two arms.

#### Population

number of patients = 3861.

#### Interventions

Aim: to review evidence from RCTs to assess whether primary systemic therapy is associated with any advantage compared with the same adjuvant systemic therapy for the treatment of breast cancer.

All patients underwent a chemotherapy regimen (and some regimens included hormone therapy); randomised comparisons were between primary systemic therapy and adjuvant systemic therapy.

Local treatment consisted of surgery and RT (full details not reported).

## **Outcomes**

Primary outcomes:

Death (from any cause), disease progression, loco-regional disease recurrence, and distant disease recurrence (metastasis). Disease progression was defined as locoregional or distant recurrence, occurrence of contralateral cancer, or death. Loco-regional recurrence was defined as recurrence in the ipsilateral breast or in the ipsilateral regional lymph nodes or chest wall.

Secondary outcomes:

Local clinical response to primary systemic treatment (three categories: complete versus partial versus none or progressive disease), the pathologic response (complete versus noncomplete) in the primary systemic arm, and the surgical approaches adopted (no surgery needed [radiotherapy only], breast-conserving surgery [e.g., lumpectomy or quadrantectomy], or mastectomy) in each arm. After preoperative chemotherapy, the absence of clinical evidence of tumor in the breast was defined as a clinically complete response and a reduction in the clinical tumor size of 50% or more was defined as a partial response. A complete pathologic response was defined as the absence of tumor in the surgical specimen (primary tumor and lymph node metastasis); this response was pertinent only for women who had surgery after primary systemic treatment.

## **Follow up**

Median follow-up in 9 RCTs had mean 80 months (range 53-124 months)

## **Results**

The pooled relative risks (RR) of death, disease progression and distant recurrence revealed no statistically significant difference in risk of event arising from primary systemic therapy compared to adjuvant systemic therapy. However primary systemic therapy was associated with a 22% increased risk of locoregional recurrence (RR primary:adjuvant 1.22 (95% CI 1.04-1.43),  $p=0.015$ ).

There was statistically significant heterogeneity across studies in the rates of conservative local treatment in the adjuvant arms (ranging from 0% to 92%;  $P$  for heterogeneity of  $<.001$ ) and in the primary systemic arms (ranging from 28% to 89%;  $P$  for heterogeneity of  $<.001$ ).

Overall, there was a statistically significant higher rate of conservative local treatment in the primary systemic arms than in the adjuvant arms of five studies, a borderline difference in another trial (  $P = .06$ ), and no difference between arms in three studies.

RT only, without surgery, was administered statistically significantly more often in the primary systemic arms than in the adjuvant arms in three trials.

Increased risk of loco-regional recurrence associated with primary systemic treatment was driven largely by the three trials in which radiotherapy only without surgery was adopted more often in the primary systemic than in the adjuvant arms (RR by random effects = 1.53, 95% CI = 1.11 to 2.10;  $P = .009$ ; and RR by fixed effects = 1.53, 95% CI = 1.17 to 2.00;  $P = .002$ ; no statistically significant between-study heterogeneity), whereas no association with loco-regional recurrences was found in other trials (RR by both fixed and random effects = 1.10, 95% CI = 0.87 to 1.38;  $P = .44$ ).

The strongest association between primary systemic treatment and increased risk of loco-regional recurrence was observed in the study in which the patients in the primary systemic arm with a complete clinical response received radiotherapy alone without any surgical treatment. Patients who were treated only with radiotherapy had statistically significantly higher rates of loco-regional recurrence (20 of 44 patients) than patients who were treated with breast-conserving surgery (nine of 40 patients).

### **General comments**

Patient population includes those with stage III disease, but also patients with less advanced disease; true applicability not known.

The authors warn that the principle subgroup data cited for this question (i.e. risk of locoregional recurrence following primary medical treatment with RT and no surgery) should be interpreted cautiously because of multiple comparisons.

#### Literature search:

MEDLINE and EMBASE databases. Keywords: breast cancer AND (neoadjuvant OR neo-adjuvant OR preoperative OR preoperative OR induction) AND (clinical trial OR randomised controlled trial OR double-blind OR single-blind OR random OR randomised OR placebo). Cochrane Central Register of Controlled Trials also searched for randomised trials that compared primary systemic with adjuvant systemic treatment for breast cancer.

No language restrictions.

Search cut-off date: October 2003.

Oncology journals hand-searched for the years 1995 through 2003

The reference list of retrieved papers was further screened for additional

publications, and several investigators were contacted and asked to provide clarifications and, potentially, additional data.

Study quality assessment:

Data were collected for each study based on the following: authors' names, journal and year of publication, country of origin of patients, inclusive dates of patient enrollment, number of centers involved, study design items (including whether there was a description of the mode of randomisation, allocation concealment, number of withdrawals per arm, and blinding).

Patient data were collected as follows: number of patients randomly assigned to treatment and analyzed per arm, their age, their tumor stage, their menopausal status, regimens used (including type of therapy [endocrine therapy and/or chemotherapy], timing, number of courses for each arm, and additional treatments given to both arms), and number of outcome events per arm.

Two individuals extracted and checked the data, checking discrepancies with the primary study authors.

Mieog, van der Hage & van, V . Preoperative chemotherapy for women with operable breast cancer. Cochrane.Database.of Systematic.Reviews. 2007.

## **Design**

Systematic review of RCTs (therapy), evidence level: 1 ++  
Country: Various, setting: Tertiary care

## **Inclusion criteria**

RCTs of primary (preoperative) chemotherapy in women with operable breast cancer: TNM stage T1c, T2, T3, N0 to 2, and M0 (AJCC stage I-IIIa).

## **Exclusion criteria**

5 RCTs were excluded for the following reasons:

1. Randomised controlled trial consisting of 101 women with operable locally advanced disease (T4b, N0-2, M0)
2. Abstract of conference proceeding. Reported a subset of patients part of NSABP B-18 study.
3. Abstract of conference proceeding. No data available. Publication pending.
4. Randomised controlled trial comparing preoperative with postoperative chemotherapy. Relevant data stratified to apoptotic index. No response from authors.
5. Abstract of conference proceeding. Not properly randomised (of the 98 analysed patients only 87 were included in a randomised prospective fashion)

## **Population**

number of patients = 5500.

## **Interventions**

Aim: to systematically identify and assess all of the available evidence from RCTs as to the effectiveness of preoperative chemotherapy on treatment-related outcomes in women with operable breast cancer.

Eligible comparisons:

- i) Preoperative chemotherapy versus postoperative chemotherapy.
- ii) Preoperative and postoperative chemotherapy versus postoperative chemotherapy.

(For details see Appendix ATable)

## **Outcomes**

Primary outcomes:

Overall survival

Disease-free survival

Loco-regional recurrence as first event

Secondary outcomes:

Tumour response rate

Association of pathological complete response with clinical outcome

Type of loco-regional treatment

Changes of originally planned loco-regional treatment

Adverse effects

Quality of life

## **Follow up**

In 14 RCTs median follow-up had range 18-124 months

## **Results**

Study characteristics

14 RCTs were included (5500 patients; 2748 of whom received preoperative chemotherapy and 2748 of whom received chemotherapy after locoregional treatment).

All included trials compared preoperative chemotherapy with a postoperative regimen (see also Appendix A table). In six trials patients in the preoperative arm received all cycles prior to loco-regional treatment. In the remaining eight trials, patients in the preoperative arm received some of the cycles after loco-regional treatment. A variety of chemotherapeutic regimens were administered to patients across the included trials; all regimens were made up of multiple chemotherapeutic agents.

Loco-regional treatment varied across studies. Five studies applied the same local treatment to all included patients (Edinburgh 1995, Japan 1998; Lithuania 1998, St. Petersburg 1994). In other studies treatment varied according to patients' individual requirements (e.g. tumour size, nodal involvement). Three studies administered radiotherapy before surgery (Institut Curie 1991; Institut Curie 1994, St. Petersburg 1994). Three studies treated some of the participants exclusively with radiotherapy (Bordeaux 1991; Institut Curie 1991; Institut Curie 1994).

## **Tumour response to preoperative chemotherapy**

Eleven studies reported a complete clinical response rate in the preoperative chemotherapy arm for 1761 assessable patients involving 653 complete clinical responses. The complete clinical response rate ranged from 0 to 64.7%.

Twelve studies reported an overall clinical response rate in the preoperative chemotherapy arm for 2032 assessable patients involving 1384 overall clinical responses. The overall clinical response rate ranged from 11.1 to 83.3%.

Seven studies reported a pathological complete response rate in the preoperative chemotherapy arm for 1972 assessable women involving 278

pathological complete responses. The pathological complete response rate ranged from 4.0 to 29.2%.

### **Association of pathological complete response with clinical outcome**

The authors compared overall and disease-free survival between patients with a pathological complete response and those who had residual disease at pathological examination.

Four studies reported overall survival data for 1290 assessable patients involving 381 estimated deaths. There was a statistically significant difference in favour of pathological complete response: HR (pCR versus residual disease) 0.48 (95% CI 0.33 to 0.69).

Five studies reported disease-free survival data for 1741 assessable patients involving 606 estimated events. There was a statistically significant difference in favour of pathological complete response: HR (pCR versus residual disease) 0.48 (95% CI 0.37 to 0.63).

### **Changes to originally planned locoregional treatment (5 RCTs)**

Five studies reported changes of loco-regional treatment that had been originally planned in the preoperative chemotherapy arm (1549 assessable women; see appendix: table). Across studies, 397 women had their originally planned surgical treatment altered due to down staging (25.6%; 95% CI, 23.5 to 27.8), 1086 women had no change to planned treatment (70.1%; 95% CI, 67.8 to 72.4), and 66 women required more radical surgery than originally planned (4.3%; 95% CI, 3.3 to 5.3).

**Table: relationship between treatment intended and treatment performed**

<b>Study</b>	<b>BCT - BCT</b>	<b>MAST - MAST</b>	<b>MAST - BCT</b>	<b>MAST - RT</b>	<b>BCT -RT</b>	<b>BCT - MAST</b>	<b>Total</b>
Bordeaux 1991	-	49	40	44	-	-	133
EORTC 2001	60	190	60	-	-	14	324
Institut Curie 1994	-	36	62	102	-	-	200
NSABP 1998	435	187	69	-	-	52	743
Royal Marsen 1998	113	16	19	-	1	-	149
<b>Total</b>	<b>608</b>	<b>478</b>	<b>250</b>	<b>146</b>	<b>1</b>	<b>66</b>	<b>1549</b>

Two RCTs compared outcomes between patients who received down staged breast conserving therapy compared to those who received planned breast

conserving therapy in the preoperative chemotherapy arm. There was no statistical significant difference in loco-regional recurrence or overall survival between these groups:

Table: Effect on outcome of downstaging: ratio outcomes for downstaged vs planned breast conserving surgery in primary chemotherapy arms of two RCTs

Outcome	No. of studies	No. of participants	Statistical method	Effect size
Overall survival	1	120	Peto Odds Ratio [95% CI]	1.33 [0.67, 2.63]
Loco-regional recurrence	2	623	Relative Risk (Fixed) [95% CI]	1.34 [0.85, 2.13]

Authors conclude that direct evidence concerning long-term prognosis and risk of local recurrence after downstaging of surgical treatment following preoperative chemotherapy is still lacking. Indirectly derived data suggest no intrinsic risk amplification associated with downstaged breast-conserving surgery. However, evidence from direct comparison is needed to draw valid conclusions.

Overall survival following primary chemotherapy and then locoregional treatment

Nine studies reported estimated overall survival at 5 years and six studies at 10 years in patients treated with primary chemotherapy and then locoregional therapy (RT alone, BCS plus RT, mastectomy, mastectomy plus RT; see Appendix A table).

Overall survival at 5 years had mean value 82.4%, median 80% and range 77% to 93%.

Overall survival at 10 years had mean value 69.2%, median 66% and range 62% to 87%.

### **Radiotherapy without surgery following primary chemotherapy**

In three studies, the loco-regional treatment for a substantial number of patients consisted of exclusive radiotherapy and no surgery. In Bordeaux 1991, 44 (33%) women in the primary chemotherapy arm received exclusive radiotherapy, and none in the control arm. In Institut Curie 1991, 41 (43%) women received exclusive radiotherapy after primary chemotherapy compared with 30 (35%) women in the control arm. In Institut Curie 1994, 102 (51%) women received exclusive radiotherapy after primary chemotherapy compared with 87 (46%) women in the control arm. Although these studies did not separately report loco-regional recurrence rates for these patients,

except for Bordeaux 1991 (13/44=29.5%), they did show an increased overall loco-regional recurrence rate compared to the remaining eight studies: 163/843 (19.3%) and 407/4198 (9.7%), respectively.

### **General comments**

Applicability to this question is limited due to inclusion of studies of patients with disease stages I-II.

Most outcomes are reported as hazard ratios for primary (preoperative) versus postoperative chemotherapy arms and are therefore not relevant to this question. Selected outcomes of relevance are cited.

Overall survival data are of limited applicability to this question because the data are not reported by the individual locoregional therapies (combinations of surgery and/or RT), but combined (see Appendix AAtable). In the primary chemotherapy arms of the RCTs, surgery and/or RT were often given according to the response to primary chemotherapy. In addition the studies vary in their primary chemotherapy regimens, use of axillary surgery, hormone therapy and, in primary chemotherapy arms, whether adjuvant chemotherapy was also given.

Re: Tabulated data on 'Effect on outcome of downstaging: ratio outcomes for downstaged vs planned breast conserving surgery in primary chemotherapy arms of two RCTs': the direction of effect is in favour of planned breast conserving surgery after primary chemotherapy versus breast conserving therapy achieved by down-staging by primary chemotherapy, but the 95% confidence intervals for the pooled results cited (and also the results of the primary studies) include the null hypothesis value of 1; therefore the effect is not statistically significant. The result may be nevertheless, clinically important.

#### Literature search:

Cochrane Breast Cancer Group Specialist Register of RCTs searched on 4.8.05; includes published and unpublished trials; no language restrictions. Keywords: 'early' and 'chemo' and 'locally advanced' and 'chemo'. In addition the authors searched reference lists of related literature reviews.

#### Study selection:

Two review authors independently applied the selection criteria on the methods sections of the selected trials. The review authors were blinded to all but the methods section. Any disagreements were resolved by consensus.

#### Quality assessment:

Two review authors independently reviewed each included study based on:

- concealment of the allocation sequence
- generation of the allocation sequence
- comparability between groups at the baseline

- inclusion of all randomised participants in the analysis (Intention to treat)
- loss to follow-up

Allocation concealment was graded as follows:

Grade A - clearly adequate

Grade B - possibly adequate,

Grade C - clearly inadequate

Grade D - not used.

Data extraction:

At least two individuals independently extracted data from the studies identified for inclusion. Any disagreements were resolved by consensus.

**Table of survival data from RCTs of primary chemotherapy; from Cochrane Review by Mieog et al. 2007**

NB estimated 5-year and 10-year survival values read from bar graph

RCT	Population (stage)	Randomised comparison	Surgery/other treatment	5-year survival (%)		10-year survival (%)

RCT	Population (stage)	Randomised comparison	Surgery/other treatment	5-year survival (%)		10-year survival (%)	
				Pre-op	Post-op	Pre-op	Post-op
EORTC 2001	T1c-T3, T4b, N0-1, M0	Preop vs postop FEC  Arm A: 4 cycles of preoperative Fluorouracil - Epirubicin - Cyclophosphamide every 3 weeks.  Arm B: idem as for A, all postoperative	Mastectomy or BCS + RT (50 Gy in 5 weeks). Chest wall/parasternal: pts with initial tumour of 5 cm or more. Infra and supraclavicular fossa: pts with positive infraclavicular node after LN dissection. Tamoxifen: pts >50 yrs (regardless of ER/nodal status) received 20 mg daily for at least 2 yrs.	77	82	64	66
Institut Curie 1994	T2-3, N0-1, M0 (T size 3-7cm)	Preop vs postop FAC  Arm A: 2 cycles of preoperative 5-Fluorouracil on days 1, 3, 5, 8, Doxorubicin and Cyclophosphamide on day 1 and 8 every 4 wks. Followed by response assessment: Good responders: 2 additional cycles of preoperative FAC. Non-responders: loco-regional treatment  Arm B: 4 cycles of adjuvant FAC within 2 weeks of ending loco-regional treatment.	Primary RT: 54 Gy in 6 weeks to breast and axillary nodes + 45 Gy to supraclavicular nodes and internal mammary chain. Patients with CR or near CR received a boost to tumour bed (totalling 75-80 Gy) and had no surgery. N+ patients received a 10-15 Gy boost to inferior axilla if no surgery was performed. Surgery (mastectomy or lumpectomy) was limited to patients presenting with a persisting mass after 54 Gy. A total of 24 patients underwent mastectomy without RT.	84	77	64	60

RCT	Population (stage)	Randomised comparison	Surgery/other treatment	5-year survival (%)		10-year survival (%)	
				Pre-op	Post-op	Pre-op	Post-op
London 2001	T1-4, N0-1, M0 (24% T3-4)	<p>Preop and postop vs postop treatment. Either chemo- or endocrine therapy based on ER-status:</p> <p>Arm A: ER+ pts (47): endocrine treatment Premenopausal: Goserelin monthly for 12 weeks. Postmenopausal: Formestane every 2 weeks for 12 weeks. ER - pts: 4 cycles in 12 weeks of preoperative Mitozantrone every 3 weeks, Mitomycin C every 6 weeks, Methotrexate every 3 weeks with fonic acid rescue 4 times for 24 hours, starting 24 hrs after chemotherapy. After clinically assessing tumour response and surgery/radiotherapy: Responders: received a total of 8 cycles MMM or 18 months Goserelin or Formestane (doses as above). Non-responders: ER + pts: 8 cycles of MMM (as above) ER - pts: 8 cycles of 5-Fluorouracil - Epirubicin - Cyclophosphamide every 3 weeks.</p> <p>Arm B: ER+ pts: endocrine therapy Premenopausal: Goserelin as above for 18 months. Postmenopausal: Formestane as above for 18 months. ER - pts: 8 cycles of MMM as above.</p>	Primary surgery (mastectomy or BCS + RT to breast + boost to scar) or primary RT. Pts with involved axillary nodes: RT to axilla and supraclavicular fossa. Pts with tumours in medial half of breast: RT to ipsilateral mammary chain. When primary RT did not produce a response, a mastectomy was performed.	77	87	-	-

RCT	Population (stage)	Randomised comparison	Surgery/other treatment	5-year survival (%)		10-year survival (%)	
				Pre-op	Post-op	Pre-op	Post-op
NSABP 1998	T1-3, N0-1, M0 (no locally advanced disease)	Preop vs postop AC  Arm A: 4 cycles of preoperative Doxorubicin - Cyclophosphamide every 3 weeks. Women with progressive disease before completion of all 4 courses received the remaining courses after surgery.  Arm B: idem as for A, all postoperative.	Mastectomy or BCS + RT. Tamoxifen: pts >50 yrs (regardless of ER/nodal status) received 10 mg twice daily for 5 yrs	80	82	68	70
Royal Marsden 1998	T1-4, N0-1, M0 (7% T3-4)	Preop and postop vs postop MM(M)  Arm A: 4 cycles of preoperative Mitomycin C every 6 weeks, Mitoxantrone every 3 weeks, Methotrexate every 3 weeks or 2M (same as 3M, with the exclusion of Mitomycin C and increased dose of Mitoxantrone) followed by 4 cycles postoperative of 3M or 2M.  Arm B: idem as for A, all postoperative.	Mastectomy or BCT + RT (54 Gy to breast + 10 Gy boost to scar). Clinically involved lymph nodes: Level II axillary lymph node dissection. No axillary dissection for clinically node negative pts. RT to axilla and supraclavicular fossa was only given to those pts with palpable nodes at presentation, who did not have axillary dissection. Tamoxifen: 20 mg daily for 5 years simultaneously started with chemotherapy.	77	77	70	64
St Petersburg 1994	Stage IIb-IIIa: T3, N0-1; T2, N1; T1-2, N2, M0	Preop and postop vs postop TMF  Arm A: 1 or 2 cycle(s) of preoperative Thiotepa on days 1,3,5,7,9,11, Methotrexate - 5-Fluorouracil on days 1 and 8 every 4 weeks. Followed, starting during mastectomy, by 4-5 cycles of TMF.  Arm B: 6 cycles of postoperative TMF.	Preoperative RT: 60 Gy (2 Gy daily) to breast + 40 Gy to axillary area, supra- and subclavicular areas followed after 3-4 weeks by modified radical mastectomy.	87	78	-	-

Trudeau, Sinclair & Clemons . Neoadjuvant taxanes in the treatment of non-metastatic breast cancer: A systematic review. *Cancer Treat.Rev.* 31[4], 283-302. 2005.

## **Design**

Systematic review of RCTs (therapy), evidence level: 1 ++  
Country: Various, setting: Secondary care

## **Inclusion criteria**

For eligible studies:

A neoadjuvant taxane-containing regimen was evaluated using any of the publication types listed in the search strategy (randomized controlled trials or systematic reviews/metaanalyses).

Reported outcomes included rates of clinical response, pathologic response, breast conservation, DFS, or overall survival.

Clinical trial results were reported in either full papers or abstracts.

## **Exclusion criteria**

Non English language papers

Population

number of patients = 6225.

## **Interventions**

Aim: to review RCT evidence on the role of primary taxane chemotherapy in patients with non-metastatic breast cancer.

All patients underwent primary chemotherapy; at least one arm receiving primary taxane chemotherapy. All randomised arms planned surgery in addition, and some, radiotherapy and hormone therapy in addition.

## **Outcomes**

Response to primary chemotherapy (tumour and lymph nodes)

Proportion of patients who underwent breast conserving surgery

Disease-free survival (DFS)

Overall survival (OS)

## **Follow up**

See table below

## **Results**

17 RCTs were included, presented in 18 papers, one of which provided further analysis between subgroups for different primary taxane doses/schedules. In all trials the randomised comparison is either primary taxane chemotherapy versus non-taxane primary chemotherapy, primary

taxane versus adjuvant taxane, or different doses/schedules of primary taxane chemotherapy.

The studies provide some information on subsequent treatment, including surgery and radiotherapy, administered within RCT protocols.

Of 17 included RCTs only four provide data on DFS or OS, although the majority (12) were available only in abstract at the time of completion of the literature search (September 2004), suggesting that follow-up is immature.

Of 17 RCTs, nine omitted radiotherapy altogether and eight used radiotherapy in all randomised arms. In contrast all RCTs used surgery in all of their randomised arms. Some studies report the proportion of patients in whom breast conserving surgery was performed; the complement of this proportion represents patients who received mastectomy.

### **Primary chemotherapy, surgery, radiotherapy and hormone therapy**

In one trial (M. D. Anderson) patients were randomised to either paclitaxel or FAC primary chemotherapy, and then received surgery, adjuvant FAC, radiotherapy and hormone therapy. The respective proportions of patients who received breast conserving surgery were 46% and 35%. Respective DFS at 23 months was 94% and 89%. 17% of patients had initial stage III disease.

A second trial (Pouillart, 1999) randomised patients to either doxorubicin-paclitaxel or doxorubicin-cyclophosphamide primary chemotherapy. All patients then received surgery, radiotherapy and hormone therapy. DFS data are summarised for the latter arm only: 45% with unknown follow-up duration. 56% of patients underwent breast conserving surgery and 38% of patients had initial stage T3 tumours.

In a similar trial (ACCOG) patients were randomised to either doxorubicin-docetaxel or doxorubicin-cyclophosphamide primary chemotherapy. All patients then received surgery, radiotherapy and hormone therapy. 20% of patients in each arm received breast conserving surgery. At 32 months follow-up DFS was 75% and 69%, respectively, and OS was 86% and 84%, respectively. At outset 8% of patients had locally advanced disease and 15% inflammatory breast cancer. The remainder of patients had large, operable tumours.

### **Primary chemotherapy and surgery**

A fourth RCT treated patients initially with primary cyclophosphamide, vincristine, doxorubicin and paclitaxel (CVAP). Patients with complete response were randomised to either the same repeated primary chemotherapy regimen, or to docetaxel. After primary chemotherapy all patients underwent surgery. 41% of patients had initial stage III disease. Breast conserving surgery was performed in 67% of the CVAP group and

48% of the docetaxel group ( $p < 0.05$ ). Respective values for DFS at 38 months follow-up were 90% and 77% ( $p < 0.05$ ). Respective values for OS at 65 months follow-up were 93% and 78% ( $p < 0.05$ ).

### **Breast conserving surgery after primary chemotherapy**

In all 17 RCTs surgery was performed in every randomised arm. In total the proportion of patients who received breast conserving surgery was reported for 21 randomised arms in 14 RCTs. This proportion had mean 54%, median 56% and range 20% to 85%.

NB See Appendix A below for table of primary study details reported in systematic review.

### **General comments**

Well-conducted systematic review; limited applicability to this question owing to inclusion of patients with stage I-II breast cancer and sparse DFS/OS data. High clinical and methodological heterogeneity between studies; results presented with tabulated data/narrative.

Literature search strategy:

MEDLINE and EMBASE databases to September 2004. Search terms reported e.g. MEDLINE: Breast neoplasms[MeSH], Induction chemotherapy OR primary chemotherapy OR neoadjuvant chemotherapy OR preoperative chemotherapy[Title/Abstract] Taxoids[MeSH] Meta-analysis[pt] OR randomized controlled trial[pt] OR practice guideline [pt]. Also the Cochrane Library and online conference proceedings from the American Society of Clinical Oncology and the San Antonio Breast Cancer Symposium were searched.

Study quality assessment evident e.g. considering publication as peer-reviewed paper or abstract, method of randomisation and concealment, stratification for confounding variables, intention-to-treat analysis, power calculation.

**Table of primary study details reported in systematic review by Trudeau et al. 2005.**

## Randomised controlled trials

Baldini, Gardin, Giannessi, Evangelista, Roncella, Prochilo, Collecchi, Rosso, Lionetto, Bruzzi, Mosca & Conte . Accelerated versus standard cyclophosphamide, epirubicin and 5-fluorouracil or cyclophosphamide, methotrexate and 5-fluorouracil: a randomized phase III trial in locally advanced breast cancer. *Annals of oncology : official journal of the European Society for Medical Oncology / ESMO*. 14[2], 227-232. 2003.

### Design

Design: Randomized controlled trial (therapy), evidence level: 1 +  
Country: Italy, setting: Secondary care

### Inclusion criteria

150 patients with histologically documented stage IIIA/B breast cancer [including ipsilateral supraclavicular metastases], no distant disease, Eastern Cooperative Oncology Group (ECOG) performance status  $\leq 2$  and normal baseline organ function blood tests. Patients were treated between June 1992 and March 1997.

Stage IIIA: 19 (Group A) 15 (Group B)  
Stage IIIB: 37 (Group A) 34 (Group B)  
IBC: 18 (Group A) 18 (Group B)

### Exclusion criteria

Four of 150 patients were ineligible: one in arm A (metastatic disease) and three in arm B (two metastatic disease and one stage IIB).

### Population

number of patients = 150, age range 30 to 70 years, median age = 51 years.

### Interventions

Aim: to examine the effect of accelerated primary chemotherapy on the rate of pathological complete response in patients with locally advanced breast cancer.

Patients were randomised as follows:

Arm A (standard treatment; n=76). Both primary and adjuvant chemotherapy were given at 3-week intervals. Patients received three courses of primary CEF (cyclophosphamide 600 mg/m<sup>2</sup>, epirubicin 60 mg/m<sup>2</sup> and 5-fluorouracil 600 mg/m<sup>2</sup>, day 1), followed by local therapy (surgery or radiotherapy) and subsequent adjuvant chemotherapy consisting in one course of CEF alternated with one course of CMF (cyclophosphamide 600 mg/m<sup>2</sup>, methotrexate 40 mg/m<sup>2</sup>, 5-fluorouracil 600 mg/m<sup>2</sup>, day 1) for a total

of six courses.

Arm B (dose-dense treatment; n=70). Both primary and adjuvant chemotherapy were given at 2-week intervals. Patients received three courses of primary CEF plus GM-CSF (300 micrograms total dose subcutaneously days 4-13), followed by local therapy and subsequent adjuvant chemotherapy consisting in one course of CEF plus GM-CSF alternated with one course of CMF plus GMCSF for a total of six courses. Doses of drugs were the same in both arms.

In cases of clinical remission or stable disease, with operable lesions, patients underwent surgery (radical mastectomy or segmental mastectomy with axillary node dissection) within 3 weeks after the completion of induction chemotherapy (ICT). Inoperable cases or patients refusing surgery (with no evidence of distant metastasis) received radiotherapy.

At the end of adjuvant chemotherapy (ACT), in both arms, patients with T4 tumours received radiotherapy for a total dose of 50-60 Gy to the breast or chest wall, internal mammary lymph nodes and supraclavicular fossa. Patients with hormonal receptor-positive tumours received tamoxifen for 5 years.

## **Outcomes**

Chemotherapy toxicity (not cited)

Primary outcome: clinical complete response (cCR): complete disappearance of the tumour mass and adenopathy; Other categories of response:

Partial response (PR): >50% reduction in the product of the two largest perpendicular diameters of the breast mass and adenopathy;

Stable disease (SD), <50% reduction in the product of the two largest perpendicular dimensions of the breast mass and adenopathy.

Progressive disease (PD): >25% increase in the sum of the products of the two perpendicular diameters of all measurable lesions, or the appearance of new lesions or distant metastases

Pathological complete response (pCR): no residual invasive tumour in the breast and axillary nodes (includes DCIS, N0; excludes any cases of positive axillary nodes).

Disease-free survival (DFS): from the date of complete response (whether this was achieved with chemotherapy or surgery) to first relapse or last observation/death.

Progression-free survival (PFS): from the date of randomisation to evidence of relapse or last observation/death.

Overall survival (OS): from the date of randomisation to death or last observation

relapse or last observation/death

## Follow up

Time-to-event outcomes reported at 5 years (range 1-96 months)

## Results

### Response to primary chemotherapy

The overall response rate to primary CEF was 62.3% (95% CI 51% to 73%) in arm A and 61.6% (95% CI 49% to 73%) in arm B; two cCRs were obtained in arm A and one in arm B.

Twenty-six (33.8%) and 24 (32.9%) stabilizations were reported in arms A and B, respectively. Seven patients were not evaluable for response: two patients were missing data and one was ineligible in arm A; one patient was missing data and three were ineligible in arm B. No patient progressed during induction chemotherapy.

Two pCRs (2.6%) (95% CI 0.32% to 9.07%) were observed in arm A and three (4.1%) (95% CI 0.86% to 11.5%) in arm B ( $P = 0.95$ ); three additional patients in arm B achieved a primary tumour pCR only (no invasive breast tumour with positive axillary nodes).

### Surgery and radiotherapy

Local treatments were as follows: radical mastectomy, 65 (84.4%) patients in arm A and 60 (82.2%) patients in arm B; conservative surgery, five (6.5%) patients in arm A and seven (9.6%) patients in arm B; radiotherapy alone, six (7.8%) and five (6.8%) patients in arms A and B, respectively.

After primary CEF and loco-regional therapy 137 of 150 patients (91%) were disease-free: subsequent adjuvant chemotherapy was completed, as planned, for 63 patients (81.8%) in arm A and 60 patients (82.1%) in arm B. Main reasons for earlier discontinuation was patient refusal (arm A, 12 patients and arm B, 9 patients).

### Recurrence and survival

Five year disease-free survival rates were 48% and 60% in arms A and B, respectively ( $P = 0.18$ ); 5-year progression-free survivals were 52% in the standard arm and 56% in the experimental arm ( $P = 0.3$ ) while 5-year overall survival rates were 52% and 54% in arms A and B, respectively ( $P = 0.64$ ).

## General comments

Centralised randomisation: stratified by participating institutions.

The randomised groups were visibly well-balanced for patient/tumour characteristics.

Power calculation performed. No mention of blinding to allocated treatment or

analysis by intention-to-treat; 4 patients with ineligible disease stage excluded after randomisation.

Buchholz, Strom, Oswald, Perkins, Oh, Domain, Yu, Woodward, Tereffe, Singletary, Thomas, Buzdar, Hortobagyi & McNeese . Fifteen-year results of a randomized prospective trial of hyperfractionated chest wall irradiation versus once-daily chest wall irradiation after chemotherapy and mastectomy for patients with locally advanced noninflammatory breast cancer. *Int.J.Radiat.Oncol.Biol.Phys.* 65[4], 1155-1160. 2006.

### **Design**

RCT (therapy), evidence level: 1 -  
Country: USA, setting: Secondary care

### **Inclusion criteria**

108 patients with stage III histologically proven breast cancer who underwent randomisation to one of two radiotherapy regimens between the years 1985-1989.

Initial stage:

IIB: 39 (19.5%)

IIIA: 87 (43.5%)

IIIB: 58 (29%)

IIIC: 13 (6.5%)

Other: 4 (2%)

### **Exclusion criteria**

Congestive heart failure  
Abnormal blood markers for systemic disease

NB published results exclude patients who did not respond to initial primary chemotherapy.

### **Population**

number of patients = 179, age range 15 to 75 years.

### **Interventions**

Aim: to investigate whether hyperfractionated chest wall RT is safe for patients treated with primary chemotherapy, mastectomy and adjuvant chemotherapy for locally advanced breast cancer.

200 patients were treated with primary chemotherapy (vincristine, doxorubicin, cyclophosphamide and prednisolone (VACP) in 3 cycles).

Patients who responded (no definition provided) underwent mastectomy.

Patients with  $\geq 1\text{cm}^3$  residual tumour underwent randomisation to one of two

adjuvant chemotherapy regimens (either continued VACP until 500 mcg/m<sup>2</sup> of doxorubicin attained or 6 cycles of a regimen of methotrexate, 5-fluorouracil, leukovorin and vinblastine). Patients with residual tumour of size <1cm<sup>3</sup> continued VACP until 500 mcg/m<sup>2</sup> of doxorubicin was attained.

Patients were also offered randomisation to one of two adjuvant chest wall and supraclavicular fossa radiotherapy regimens as follows:

Standard radiotherapy group: received 60Gy in 30 fractions, once daily (2Gy) to the chest wall and 50Gy in 25 fractions once daily (2Gy) to the supraclavicular fossa

Hyperfractionated radiotherapy group: received 72Gy in 60 fractions twice daily (1.2Gy) to the chest wall and 50Gy in 25 fractions once daily (2Gy) to the supraclavicular fossa.

### **Outcomes**

Locoregional recurrence-free survival (Kaplan-Meier method)

Overall survival (Kaplan-Meier method)

Late toxicity (Kaplan-Meier method)

Acute toxicity (crude rate)

Follow up

Estimated 15-year rates of outcome presented.

### **Results**

Non-response rate to primary chemotherapy = 21/200 = 10.5% (no definition of 'response' reported).

15-year estimated rate of locoregional recurrence-free survival:

Standard radiotherapy group: 7%

Hyperfractionated radiotherapy group: 12% (p=0.36, log-rank test)

15-year estimated rate of overall survival:

Standard radiotherapy group: 45%

Hyperfractionated radiotherapy group: 33% (p=0.54, log-rank test)

15-year estimated rate of moderate-to-severe late toxicity, potentially related to radiotherapy:

Standard radiotherapy group: 6%

Hyperfractionated radiotherapy group: 11% (p=0.54, log-rank test)

The crude rate of severe acute toxicity was similar between randomised arms:

Standard radiotherapy group: 4%

Hyperfractionated radiotherapy group: 5% (no p value reported).

Authors conclude that no benefit was achieved through the hyperfractionated

radiotherapy regimen.

### **General comments**

The distribution of patients within the radiotherapy randomised comparison by randomised group for comparison of adjuvant chemotherapy is not known. Patients were similar in terms of many patient/disease-related variables (by statistical testing), but adjuvant chemotherapy group was not one of the factors investigated for similarity, and may confound the results. Reportedly, outcomes did not differ according to the allocated adjuvant chemotherapy (results published separately).

Assessment of outcome was in part retrospective, by review of medical records (re: acute and late toxicity attributed to radiotherapy). For this reason it is difficult to correctly define an adverse effect from radiotherapy. Study was not blinded.

Analysis was by intention-to-treat; one patient switched from the hyperfractionated arm to the standard arm; 2 patients in the standard arm ceased radiotherapy due to distant metastases; 1 patient in the hyperfractionated arm switched to a palliative dose due to local recurrence.

Power calculation related to assessment of effect of adjuvant chemotherapy, not adjuvant radiotherapy.

The role of the subgroup of patients with residual tumour of size  $<1\text{cm}^3$  after mastectomy who were non-randomly allocated to continue VACP until 500 mcg/m<sup>2</sup> of doxorubicin was attained, is not clear.

Evans, Yellowlees, Foster, Earl, Cameron, Hutcheon, Coleman, Perren, Gallagher, Quigley, Crown, Jones, Highley, Leonard & Mansi . Phase III randomized trial of doxorubicin and docetaxel versus doxorubicin and cyclophosphamide as primary medical therapy in women with breast cancer: an anglo-celtic cooperative oncology group study. J.Clin.Oncol. 23[13], 2988-2995. 2005.

## Design

Design: Randomized controlled trial (therapy), evidence level: 1 +  
Country: Europe, setting: Tertiary care

## Inclusion criteria

363 women with histologically proven (core biopsy) breast cancer with large primary (>3 cm) tumours, inflammatory breast cancer, or locally advanced disease who were considered to be candidates for primary chemotherapy before surgical intervention. All patients were required to have adequate performance status (Eastern Cooperative Oncology Group performance status  $\leq 1$ ); adequate hematologic, renal and liver function; and to have no evidence of metastatic disease.

Patients were treated between 1999 and 2001 in 25 centers in the United Kingdom, Ireland, and Belgium.

Table: tumour operability (pre-primary chemotherapy)

Subgroup	AC (n=180)	AD (n=183)	All patients (n=363)
Operable by mastectomy	140 (78%)	140 (77%)	280 (77%)
Inflammatory breast cancer	26 (14%)	28 (15%)	54 (15%)
Locally advanced tumour	14 (8%)	15 (8%)	29 (8%)

## Exclusion criteria

Patients were excluded from the study if there was any evidence of active cardiac disease, prior history of malignancy other than basal cell carcinoma of the skin, or in situ cancer of the cervix.

## Population

number of patients = 363, age range 25 to 74 years, median age = 48 years.

## Interventions

Aim: to compare two combinations of primary chemotherapy drugs in patients with large or locally advanced breast cancer tumours.

AC group (n=180): received doxorubicin and cyclophosphamide as primary chemotherapy

AD group (n=183): received doxorubicin and docetaxel as primary chemotherapy plus dexamethasone and prophylactic ciprofloxacin.

In both arms on completion of chemotherapy, surgery was intended, including axillary node dissection, with the choice of surgical procedure for local control of the primary breast lesion at the discretion of the surgeons at the participating centers:

Table: interventions

Treatment	AC (n=180)	AD (n=183)	All patients (n=363)
BCS	36 (20%)	37 (20%)	73 (20%)
Mastectomy	136 (76%)	133 (73%)	269 (74%)
RT	148 (82%)	143 (78%)	291 (80%)
Endocrine therapy	106 (59%)	121 (66%)	227 (63%)

NB not all patients received surgery.

Postoperative radiotherapy and tamoxifen were administered according to existing management guidelines. Some patients received conventional-dose chemotherapy (six cycles of cyclophosphamide, methotrexate, and fluorouracil) or high-dose chemotherapy with peripheral stem-cell support as part of a different study.

### Outcomes

Relapse-free survival

Overall survival

(Kaplan-Meier survival analysis and log-rank test)

### Follow up

Median 32 months

### Results

Table: disease-related events (median follow-up 32 months)

Event	AC (n=180)			AD (n=183)			All patients (n=363)		
	n	%	95% CI	n	%	95% CI	n	%	95% CI
Recurrence	55	30.6%	24%-37%	45	24.6%	18%-31%	100	27.5%	23.2%-32.4%
Distant recurrence	36	20%	14%-26%	26	14%	9%-19%	62	17.1%	13.6%-21.3%

Death	28	16%	10%-21%	25	14%	9% to 19%	53	14.6%	11.3%-18.6%
-------	----	-----	---------	----	-----	-----------	----	-------	-------------

There was no significant difference in the recurrence-free survival ( $p=0.17$ ) or in overall survival ( $p=0.57$ ) between the two groups, although authors acknowledge that follow-up is immature.

Table: recurrence by site

Site of relapse	AC (n=55)	AD (n=45)	All patients (n=100)
Local relapse only	14	17	31
Contralateral breast cancer	1	0	1
Local + distant recurrence	10	7	17
Distant recurrence only	26	19	45
Site of distant relapse	AC (n=36)	AD (n=26)	All patients (n=62)
Bone	13	9	22
Liver	5	7	12
Lung	4	8	12
Pleura	5	0	5
Other	10	4	14

Summary: 363 patients with breast cancer with large primary (>3 cm) tumours, inflammatory breast cancer, or locally advanced disease received primary chemotherapy with either AC or AD regimens. 74% of patients underwent subsequent mastectomy, 20% BCS, 80% RT and 63% endocrine therapy. In all patients at a median follow-up of 32 months the rate of recurrence was 27.5% (95% CI 23.2%-32.4%) and the mortality rate was 14.6% (95% CI 11.3%-18.6%).

### General comments

Applicability to this question is limited since only 23% of patients had locally advanced or inflammatory breast cancer.

Randomisation was stratified according to tumour operability at baseline and participating centre. Baseline characteristics were well balanced between randomised arms (tabulated data).

Data collection was performed by statistical staff, not investigators, but the study does not specify concealment of allocation nor blinding to allocation.

6 patients (1.9%) were withdrawn from the study; 5 due to chemotherapy toxicity and one due to protocol violation.

Analysis was by intention-to-treat.

Tan, Cheung, Willsher, Blamey, Chan & Robertson . Locally advanced primary breast cancer: medium-term results of a randomised trial of multimodal therapy versus initial hormone therapy. Eur.J.Cancer 37[18], 2331-2338. 2001.

**Design**

Design: Randomized controlled trial (therapy), evidence level: 1 +  
Country: UK, setting: Tertiary care

**Inclusion criteria**

108 patients with locally advanced primary breast cancer (i.e. T size >= 5cm, inflammatory breast cancer and/or with skin involvement or chest wall/axillary node fixity but with no distant metastases), treated between January 1989 and December 1994.

Table: patient characteristics

Variable	Primary hormone therapy	Multimodal therapy
n	52	56
Median age (range) (years)	62 (36-73)	58 (32-71)
Mean T size	6.2 cm	6.5 cm
Inflammatory breast cancer	6 (12%)	5 (9%)
T2, N2 tumour	12 (23%)	7 (13%)
T3 tumour	34 (64%)	44 (79%)

**Exclusion criteria**

Not reported; defined by inclusion criteria

**Population**

number of patients = 108, age range 32 to 73 years.

**Interventions**

Aim: to compare, in patients with locally advanced/inflammatory breast cancer, primary hormone therapy with multimodal therapy consisting of primary chemotherapy, Patey mastectomy, post-operative radiotherapy and adjuvant hormone therapy.

Patients were randomised to two groups:

1. Primary hormone therapy (n=52): treated as follows:  
 Post-menopausal patients (n=45): tamoxifen i.e. sole hormone therapy  
 Pre-menopausal patients (n=7): tamoxifen plus goserelin i.e. sole hormone therapy  
 On discovery of progressive disease (PD): hormone therapy ceased; and either surgery, RT, or adjuvant chemotherapy given.  
 On discovery of further PD: the next appropriate therapy was given.

NB one treatment modality was given at a time

2. Multimodal therapy group (n=56): treated as follows:

Primary chemotherapy with mitoxantrone, methotrexate and mitomycin (n=55); followed by either breast RT (n=2) or Patey mastectomy (n=53) followed by RT: 40 Gy to the chest wall (n=50) and hormone therapy (n=53): tamoxifen for post-menopausal patients and tamoxifen plus goserelin for pre-menopausal patients.

On discovery of locoregional failure or distant metastases, the most appropriate treatment was given.

### **Outcomes**

Initial response to primary chemotherapy

Locoregional failure

Distant metastasis

Overall survival

### **Follow up**

Median (range):

Primary hormone therapy: 45 (7-113) months

Multimodal therapy: 52 (6-120) months

### **Results**

NB Results are cited for multimodal therapy arm only.

Initial response to primary chemotherapy:

Complete response: 5 (9%)

Partial response: 26 (47%)

Stable disease: 22 (40%)

Progressive disease: 2 (4%)

Recurrence and survival:

Estimated 5-year proportion of patients free of locoregional failure: 74%

Estimated 5-year proportion of patients free of distant metastasis: 50%

Estimated 5-year overall survival: 50%

### **General comments**

Only the multimodal therapy arm of this RCT is applicable to this question.

1 patient in the multimodal therapy arm refused primary chemotherapy, surgery and RT and received Megestrol acetate.

Analysis appears to be by intention-to-treat; patients who refused particular therapies are reported, and 100% of randomised patients completed the trial. The authors acknowledge that no prospective power calculation was performed, and that the sample size is small, and that the rates of late-occurring events are based on small numbers.

Patient/investigator blinding not reported, but unlikely to be feasible due to multimodal nature of therapy.

Patients were randomised irrespective of ER status, which was known for 103 patients.

Time-to-event outcomes are read from graphs in paper.

Veyret, Levy, Chollet, Merrouche, Roche, Kerbrat, Fumoleau, Fargeot, Clavere & Chevallier . Inflammatory breast cancer outcome with epirubicin-based induction and maintenance chemotherapy: Ten-year results from the French Adjuvant Study Group GETIS 02 trial. *Cancer* 107[11], 2535-2544. 2006.

### **Design**

Design: Randomized controlled trial (therapy), evidence level: 1 +  
Country: France, setting: Tertiary care

### **Inclusion criteria**

120 patients with nonmetastatic, unilateral, inflammatory breast cancer, treated between February 1990 and September 1992 in 9 centres.

### **Exclusion criteria**

Not reported

### **Population**

number of patients = 120.

### **Interventions**

Aim: to evaluate the role of G-CSF to support patients with inflammatory breast cancer who receive high dose primary chemotherapy.

120 patients received primary chemotherapy consisting of high dose fluorouracil, epirubicin and cyclophosphamide and were randomised to receive in addition, G-CSF (n=61) or placebo (n=59).

Of the whole study population 115 patients successfully completed primary chemotherapy and 5 stopped treatment due to disease progression, toxicity or protocol violation. Thereafter 102 patients received surgery (quadrantectomy; n=27; mastectomy; n=75) and 114 patients received RT (60 Gy to the chest wall (n=112) and axilla (n=77), 50 Gy to the internal mammary chain (n=97), and 46 Gy to the supraclavicular fossa (n=107). From 4 to 6 weeks after the first irradiation, a 20-Gy boost was delivered to the breast in patients who underwent breast-conserving surgery (n=31).

109 patients received adjuvant chemotherapy consisting of standard dose fluorouracil, epirubicin and cyclophosphamide, including 83 patients before RT and 36 patients after RT. 102 patients successfully completed adjuvant chemotherapy and 7 stopped treatment due to neutropenia, infection, reduction in cardiac output, patient refusal or other reasons.

### **Outcomes**

Response to primary chemotherapy

Disease-free survival (Kaplan-Meier method)  
 Factors to predict recurrence (univariate and multivariate analysis)  
 Overall survival (Kaplan-Meier method)

**Follow up**

Median 120 months (range 30-140 months)

**Results**

Overall clinical response rate to primary chemotherapy: 91.1%.  
 Overall pCR rate: 14.7%.

Estimated 10-year disease-free survival: 35.7%  
 Median time to recurrence: 39 months (95% CI 25-53 months)

Pattern of recurrence: local recurrence (26.3%), soft tissues (9.2%), lymph nodes (9.2%), bone (36.8%), lung (17.1%), liver (26.3%), and other sites (17.1%).

Table: rate of recurrence by locoregional treatment

<b>Treatment</b>	<b>N</b>	<b>n (recurrence)</b>	<b>Rate n/N (%)</b>
No surgery	18	10	55.6%
No mastectomy	45	15	33.3%
Breast conserving surgery	27	5	18.5%
RT only	14	12	84.6%

Among the patients who underwent modified mastectomy, 5 patients developed local chest wall recurrences (6.7%).

Sixty-eight of 76 patients (89.5%) developed recurrent disease during the first 4 years after diagnosis. In the patients who were treated according to the protocol (n=108 patients), the recurrence rate was similar between those who received maintenance chemotherapy before radiotherapy or after radiotherapy (59.8% vs. 53.8%, respectively); however, this rate increased dramatically in patients who received only radiotherapy as locoregional treatment (84.6%; table, above).

Univariate analysis for prognostic factors showed that no surgery (HR 2.02; 95% CI 1.45-2.59; p=0.01), diffuse inflammatory signs, or no pCR were correlated significantly with disease recurrence. In multivariate analysis (Cox proportional hazards model), there was no significant prognostic factor for recurrence.

Table: Prognostic Factors for Recurrence

<b>Factor</b>	<b>Univariate analysis</b>	<b>Multivariate analysis</b>
---------------	----------------------------	------------------------------

	HR (95% CI)	p	HR (95% CI)	p
G-CSF (no vs. yes)	0.92 (0.47–1.37)	0.7		NS
Menopausal status (premenopausal vs. postmenopausal)	1.01 (0.55–1.47)	0.98		NS
Surgery (no vs. yes)	2.02 (1.45–2.59)	0.01	1.40 (0.00–3.48)	0.75
Quadrantectomy vs. modified mastectomy	0.58 (0.00–1.20)	0.08	1.20 (0.36–2.04)	0.67
Inflammatory signs (limited vs. diffuse)	0.48 (0.00–0.97)	0.003	0.73 (0.12–1.34)	0.31
Breast pCR (no vs. yes)	2.36 (1.68–3.04)	0.01	1.79 (0.32–3.26)	0.44
Lymph nodes pCR (no vs. yes)	2.52 (1.91–3.13)	0.003	1.93 (1.09–2.77)	0.12
Overall pCR (no vs. yes)	3.03 (2.12–3.94)	0.02	1.04 (0.00–2.89)	0.97

Seventy patients died (58.3%), and the estimated 10-year overall survival rate was 41.2%.

Median survival: 61 months (95% CI, 43-79 months).

### General comments

No differences in outcome were observed for the randomised comparison; results are reported for all 120 patients together.

Analysis is by intention-to-treat.

Authors do not define criteria for pathological complete response (pCR)

Avril, Faucher, Bussieres, Stockle, Durand, Mauriac, Bonichon, Dilhuydy & Campo . [Results of 10 years of a randomized trial of neoadjuvant chemotherapy in breast cancers larger than 3 cm.]. [French]. Chirurgie 123[3], 247-256. 1998.

### Design

Design: Randomized controlled trial (therapy), evidence level: 1 -  
Country: France, setting: Tertiary care

### Inclusion criteria

272 women of age  $\leq 70$  years with operable breast cancer tumours larger than 3 cm (stage T2-3/N0-1/M0) treated between January 1, 1985 to April 30, 1989.

Table: distribution of disease stage:

Stage	Group A (n=136)	Group B (n=134)
T2	119	106
T3	19	29
N0	56	64

Mean tumour diameter: 43mm

### Exclusion criteria

Age  $> 70$  years, bilateral cancer, other associated cancer, Also patients were excluded from analysis due to refusal of treatment, or contraindication of treatment e.g. poor anaesthetic risk.

### Population

number of patients = 272.

### Interventions

Aim: to evaluate the use of neo-adjuvant chemotherapy in patients with operable breast cancers of T size  $> 3$  cm.

Group A (n = 138): received mastectomy and axillary node dissection. Adjuvant chemotherapy ( 3 cycles of epirubicine, vincristine and methotrexate followed by 3 cycles of mitomycine, thiotepa and vindesine) was indicated for 104 patients with axillary node involvement (n = 82) or negative oestrogen and progesterone receptors (n = 22).

Group B (n = 134): received primary chemotherapy (identical regimen as in group A) followed by locoregional treatment according to the response: RT alone in cases of complete tumour remission (n=44), BCS + RT in cases of residual tumour  $\leq 2$ cm in size (n=40) and mastectomy in cases of residual tumour  $> 2$ cm in size (n=49).

## Outcomes

Locoregional recurrence  
Recurrence-free survival  
Overall survival

## Follow up

Median 124 months (range 87-148 months)

## Results

In group B (primary chemotherapy), 49 patients (36.5%) were resistant to chemotherapy, warranting mastectomy. In the remaining 84 patients BCS was performed (62.6%). In this last subgroup, 19 (22.6%) needed a secondary mastectomy because of locoregional recurrence.

Table: 10-year crude data for recurrence:

Recurrence type	Group A (mastectomy; n=136)	Group B (primary chemotherapy; n=134)
Locoregional recurrence alone	1	14
Locoregional and distant recurrence	19	27
Distant recurrence alone	37	26

Table: estimated overall survival:

Analysis point	Group A (mastectomy; n=136)	Group B (primary chemotherapy; n=134)
5-year	80%	80%
10-year	60%	60%

Table: estimated recurrence-free survival:

Analysis point	Group A (mastectomy; n=136)	Group B (primary chemotherapy; n=134)
5-year	65%	58%
10-year	57%	50%

## General comments

Data extracted from English language abstract and French language paper. Study reports survival analysis by Kaplan-Meier, but reports no p values for differences in survival between randomised groups. Study has limited applicability to this question since not all patients had stage III disease (see

stage data in 'inclusion criteria').

Randomisation was stratified by ER-PR status.

Cocconi, di, Bisagni, Alberti, Botti & Anghinoni . Neoadjuvant chemotherapy or chemotherapy and endocrine therapy in locally advanced breast carcinoma. A prospective, randomized study. Am.J.Clin.Oncol. 13[3], 226-232. 1990.

### Design

Design: Randomized controlled trial (therapy), evidence level: 1 -  
Country: Italy, setting: Secondary care

### Inclusion criteria

49 patients with locally advanced (T3b-T4; any T,N2; M0) breast cancer, treated within the years 1978-1983 with disease characteristics as follows:

Table: patient characteristics

Factor	CMF group	CMF + T group
<b>Stage</b>		
T2-3a	1	2
T3b	5	5
T4a, b, c	16	16
T4 inflammatory	2	2
N2	6	6
<b>ER status</b>		
Unknown	7	5
Known	17	20
ER+	13	12
ER-	4	8

### Exclusion criteria

Patients with clinical stage N3 supraclavicular nodes or positive bone scans.

### Population

, age range 41 to 76 years.

### Interventions

Aim: to compare the efficacy of two treatment regimens in patients with locally advanced breast cancer, as follows:

CMF group (n= 24): received four courses of primary cyclophosphamide, methotrexate and 5-fluorouracil (CMF) chemotherapy, followed by mastectomy and then four courses of the same chemotherapy in the adjuvant setting, then adjuvant RT.

CMF + T group (n= 25): received four courses of primary CMF chemotherapy with concurrent tamoxifen, followed by mastectomy and then four courses of the same chemotherapy/hormone therapy in the adjuvant setting, then

adjuvant RT.. Tamoxifen was ceased at the end of the adjuvant regime.

### Outcomes

Adherence to primary chemotherapy regime (all 8 cycles)  
Response to primary chemotherapy (see reference below);  
Median time to progression or recurrence (from initiation of primary chemotherapy)  
Median overall survival  
Median survival from time progression or recurrence

### Follow up

Median 6 years

### Results

Adherence to primary chemotherapy regime (all 8 cycles):  
CMF: 21/24 = 87.5%  
CMF+T: 20/25 = 80%

Table: response to primary chemotherapy

Response	CMF (n=24)	CMF+T (n=25)
Progression	2	1
No change	5	8
Partial remission	16	13
Complete remission	1	3
Complete and partial remission	17	16

Median time to progression or recurrence (from initiation of primary chemotherapy, months)  
CMF: 58.3  
CMF+T: 29.1 (p=0.38, Cox-Mantel test)

Median overall survival (months)  
CMF: 79.7  
CMF+T: 41.5 (p=0.05, Cox-Mantel test)

Median survival from time progression or recurrence (months)  
CMF: 17.3  
CMF+T: 7.5 (p=0.09, Cox-Mantel test)

### General comments

Response to primary chemotherapy was assessed according to the UICC criteria reported in: Hayward JL, Carbone PP, Heuson JC, Kumaoka S, Segaloff A, Rubens RD. Assessment of response to therapy in advanced breast cancer: a project of the Programme on Clinical Oncology of the International Union Against Cancer, Geneva, Switzerland. Cancer. 1977

Mar;39(3):1289-94. No abstract available.

ER testing was not consistently available during this study; the authors report the limitation that they'd have preferred to exclude patients with ER- tumours. There were slightly more patients with ER- tumours in the CMF+T group.

Randomisation method: randomly permuted blocks of three with stratification for T stage (any T versus inflammatory breast cancer), node stage (N0-1b versus N2) and menopausal status (premenopausal versus postmenopausal <5 years versus post menopausal  $\geq$ 5 years)

Wording of paper is ambiguous on whether all patients underwent mastectomy, or only those who responded to primary chemotherapy. On balance it appears that all patients underwent mastectomy.

Analysis appears to be by intention-to-treat, but the study is neither blinded, nor placebo-controlled. The study is further limited by small size; the study was stopped prior to the target accrual point of 130 patients in total owing to less favourable outcome in the CMF+T arm.

Pouillart, Palangie, Jouve, Garcia-Giralt, Vilcoq, Bataini, Calle, Fenton, Mathieu, Rousseau & Asselain . [Inflammatory breast carcinoma treated with a combination of chemotherapy and radiation therapy. Results of a randomized trial studying the therapeutic role of an immunotherapy with BCG (author's transl)]. [French]. Bull.Cancer (Paris) 68[2], 171-186. 1981.

### **Design**

Design: Randomized controlled trial (therapy), evidence level: 1 -  
Country: France, setting: Tertiary care

### **Inclusion criteria**

77 patients with either primary (n=41) or secondary (n=36) inflammatory breast carcinoma treated between march 1977 and september 1979.

Nodal stage:

N0-N1a: 14

N1b-N2: 46

N3: 17

Hormone receptor status (known for 31 patients):

ER+PR+: 2

ER+PR-: 1

ER-PR+: 1

ER-PR-: 27

### **Exclusion criteria**

Not known

### **Population**

number of patients = 77, age range 25 to 70 years, median age = 49 years.

### **Interventions**

All patients were treated with the same primary chemotherapy (adriamycin, vincristine, cyclophosphamide and 5-fluorouracil (AVCF)) plus RT (70 Gy over 7 weeks) schedule. Each course of chemotherapy was repeated every 28 days for one year. Patients were then given a maintenance course of chemotherapy for one year (cyclophosphamide, melphalan and methotrexate). Patients were randomised as follows:

Group 1 (n=36): patients received chemotherapy and RT alone

Group 2 (n=41): patients received chemotherapy and RT plus live BCG vaccinations.

### **Outcomes**

Actuarial disease-free and overall survival

### Follow up

Maximum: 36 months; median: not known.

### Results

Table: objective response to treatment

<b>Response</b>	No.	%
<b>Initial response to chemotherapy</b>		
Complete regression of inflammatory disease	29	51
Partial regression of inflammatory disease	18	31.5
Persistence/progression of inflammatory disease	10	17.5
Total evaluable	57	100
<b>Response to chemotherapy + RT</b>		
Complete regression of tumour	38	50.6
Tumour remaining	37	49.4
Total evaluable	75	100

In all patients actuarial survival at 34 months follow-up was 50% (i.e. mean overall survival 34 months), with no statistically significant difference between randomised arms. There was a statistically significant difference in actuarial survival according to initial response to chemotherapy, with longest survival in the complete response subgroup and shortest survival in the persistence/progression group ( $p=0.002$ ; no further data reported). In all patients mean disease-free survival was 26 months.

### General comments

Data extracted from French language paper and English language abstract; some detail may be lost. It is difficult to determine whether this trial was blinded or had concealment of allocation or analysis by intention-to-treat. Median follow-up not known. Study has small size, with no apparent power calculation.

Rainer, Denck, Fritsch, Spitzky, Alth, Dinstl, Depisch, Haider, Jakesz, Kolb, Mader, Reiner, Schennach, Schuller, Smola, Steger, Steindorfer, Tuchmann & Wildauer . Prospective randomized clinical trial of primary treatment in breast cancer stages T3/4, N+/-, MO: Chemotherapy vs. radiotherapy. Anticancer Res. 13[5 C], 1917-1923. 1993.

### **Design**

Design: Randomized controlled trial (therapy), evidence level: 1 -  
Country: Austria, setting: Tertiary care

### **Inclusion criteria**

151 patients with T3/4, N+/-, M0 locally advanced breast cancer, treated in 52 centres.

### **Exclusion criteria**

31 patients with inflammatory breast cancer (not included in survival analysis, since these patients were non-randomly allocated to the chemotherapy arm)

### **Population**

number of patients = 151.

### **Interventions**

The RCT compared two treatment regimens as follows:

Primary chemotherapy group (n=76): received primary chemotherapy comprising fluorouracil, methotrexate, cyclophosphamide, vincristine and mitoxantrone; followed by mastectomy; followed by the same regimen of chemotherapy as adjuvant therapy.

Primary RT group (n=75): received 40Gy RT as primary therapy; followed by mastectomy; followed by 20Gy RT as adjuvant therapy.

### **Outcomes**

Rates of delayed mastectomy wound healing  
Relapse-free survival  
Overall survival

### **Follow up**

Data are based on 1900 days of study enrollment; i.e. maximum follow-up of 5.2 years.

### **Results**

29/76=38% of patients in the primary chemotherapy group did not respond to primary chemotherapy and following mastectomy were crossed over to adjuvant RT instead of adjuvant chemotherapy, as permitted in the study

protocol.

Rates of delayed mastectomy wound healing:

Chemotherapy group: 36%

RT group: 47%

Median relapse-free survival:

Chemotherapy group: 2.9 years

RT group: 2.4 years

Over the entire follow-up period, relapse free survival was statistically significantly better in the chemotherapy group than the RT group ( $p=0.018$ ).

Overall survival:

In the chemotherapy group, the median overall survival was not reached; 3-year estimated overall survival in the chemotherapy group was 70%, and in the RT group, 56%.

Over the entire follow-up period, overall survival was statistically significantly better in the chemotherapy group than the RT group ( $p=0.047$ ).

### **General comments**

Paper reports poorly the number of included/excluded patients.

Randomisation was stratified according to patient age, tumour size, localisation and lymph node involvement.

The two groups were comparable with regard to patient/tumour variables; statistically tested (although only data from the chemotherapy arm inform this question).

Study does not report whether there was concealment of allocation, blinding of subjects or investigators, analysis by intention-to-treat, nor whether patients dropped out of the study.

Scholl, Asselain, Palangie, Dorval, Jouve, Garcia, Vilcoq, Durand & Pouillart . Neoadjuvant chemotherapy in operable breast cancer. Eur.J.Cancer 27[12], 1668-1671. 1991.

## Design

Design: Randomized controlled trial (therapy), evidence level: 1 -  
Country: France, setting: Tertiary care

## Inclusion criteria

196 patients with T2-3, N0-1b operable breast cancer treated within the period: November 1983 to March 1986.

Table: disease stage

Stage	Primary chemotherapy group (n=95)		Adjuvant chemotherapy group (n=86)	
	n	%	n	%
T2 N0	0	0%	3	3%
T2 N1b	43	45%	26	30%
T3 N0	24	23%	24	28%
T3 N1b	28	29%	33	38%
Total	95	100%	86	100%

Mean T size:

Primary chemotherapy group: 5.4 cm

Adjuvant chemotherapy group: 5.0 cm

## Exclusion criteria

Prior cancer;

Concomitant serious illness;

Age >65 years.

15 patients were excluded after randomisation due to randomisation errors, poor compliance or receipt of treatment in a non-participating centre.

## Population

number of patients = 181.

## Interventions

Aim: to compare the effects of two treatment strategies: one based on primary chemotherapy and the other based on primary RT with adjuvant chemotherapy.

Primary chemotherapy group (n=100): received 2 cycles of doxorubicin, cyclophosphamide and fluorouracil (ACF), followed by assesment of tumour response and locoregional treatment (see below). Patients with a good initial response to primary chemotherapy received adjuvant chemotherapy consisting of 4 further cycles of ACF, whereas patients with a poor response received 4 cycles of doxorubicin, methotrexate, vindesine and thiotepa as adjuvant chemotherapy

Adjuvant chemotherapy group (n=96): received locoregional treatment (see below) followed by 6 cycles of ACF as adjuvant chemotherapy.

All patients received steroid drugs.

Table: locoregional treatment:

Treatment	Primary chemotherapy group (n=95)		Adjuvant chemotherapy group (not applicable; n=86)	
	n	%	n	%
Mastectomy	22	23%	31	36%
Lumpectomy	32	34%	26	30%
No surgery	41	43%	29	34%
RT	95	100%	86	100%

RT consisted of 55Gy to the whole breast with boost to the tumour bed to make a total dose of 75-80Gy. 45-55Gy were applied to the node bearing tissues.

In the primary chemotherpay group, only patients with residual tumour after primary chemotherapy underwent surgery, with surgical procedure determined according to individual patients' needs.

### Outcomes

Local recurrence (defined as tumour presence at or after 9 months from the start of treatment, because not all patients underwent surgery)

Disease-free survival

### Follow up

Median 54 months (range 35-70 months).

Two patients were lost to follow-up at 35 and 38 months

### Results

Local recurrence rate in all patients in the primary chemotherapy arm at a median follow-up of 54 months: 18%.

In the subgroup of patients within the primary chemotherapy arm who completed all planned chemotherapy (n=77; 81% of the randomised arm) disease-free survival at 36 months follow-up was as follows:  
80% in patients with >50% tumour regression when assessed after 2 cycles of primary chemotherapy;  
68% in patients with ≤ 50% tumour regression when assessed after 2 cycles of primary chemotherapy (figures read from chart).  
This difference by tumour response was not statistically significant over the entire follow-up period (median 54 months; p=0.058).  
No data are available for patients randomised to primary chemotherapy, but who ceased treatment (e.g. due to stage N0 nodes, or toxicity).

### **General comments**

Only results from the primary chemotherapy group are applicable to this question.

All patients had RT, but surgery is considered by the authors as an outcome (BCS rate) and is not a randomised treatment.

The disease-free survival result reported for the primary chemotherapy arm is based only on patients who completed all chemotherapy (i.e. not an intention-to-treat analysis).

In all patients in either group with N0 status revealed by surgery, any chemotherapy was discontinued. This occurred in 18 patients in the primary chemotherapy group and 21 patients in the adjuvant chemotherapy group.

No mention of randomisation method or blinding. Not all analyses are by intention to treat.

Willsher, Robertson, Chan, Jackson & Blamey . Locally advanced breast cancer: early results of a randomised trial of multimodal therapy versus initial hormone therapy. *European journal of cancer* (Oxford, England.: 33[1], 45-49. 1990.

### **Design**

Design: Randomized controlled trial (therapy), evidence level: 1 -  
Country: UK, setting: Tertiary care

### **Inclusion criteria**

108 patients with locally advanced breast cancer treated between January 1989 and December 1994. Locally advanced breast cancer was defined as T size > 5cm or gross skin involvement, chest wall fixity or fixed axillary nodes.

Mean maximal diameter of primary tumour (primary chemotherapy arm):  
6.5cm

### **Exclusion criteria**

Not reported.

### **Population**

number of patients = 55.

### **Interventions**

Aim: to compare two treatment strategies for patients with locally advanced breast cancer as follows:

1. Minimal therapy arm (n=53): received initial hormone therapy (tamoxifen +/- goserelin) with assessment of response after 6 months of treatment; patients continued with hormone therapy until evidence of recurrence emerged. At recurrence, therapy was chosen by clinicians and patients and included RT (n=24), hormone therapy (n=18), mastectomy (n=9), chemotherapy (n=7) and excision of local recurrence (n=2).

Multimodal therapy arm (n=55): received four cycles of primary chemotherapy with mitoxantrone, methotrexate and mitomycin. Patients were then assessed for response. Subsequent therapy consisted of mastectomy (n=52) and 40 Gy RT to the chest wall in 15 fractions (n=49). All patients who underwent mastectomy received adjuvant tamoxifen (n=52) and in 10 cases, goserelin.

### **Outcomes**

Response to primary chemotherapy (assessed after 6 months) defined as:

Complete response: resolution of tumour;

Partial response: >50% reduction in bidimensional product of tumour;

Static disease: <50% reduction, or <25% increase in bidimensional product of tumour;

Progressive disease: >25% increase in bidimensional product of tumour.

Rate of distant metastases, locoregional recurrence, survival.

### **Follow up**

Median 30 months

### **Results**

All cited results are for patients in the primary chemotherapy arm

Response to primary chemotherapy (n):

Complete response: 5

Partial response: 26

Static disease: 21

Progressive disease: 2

Objective response rate (primary chemotherapy arm):  $31/54 = 57\%$

Rate of distant metastases: 45%

Rate of locoregional recurrence:  $12/55 = 22\%$

Rate of uncontrollable local recurrence:  $2/55 = 3.6\%$

Median overall survival: 43 months.

### **General comments**

Only data from the multimodal therapy arm (n=55) is applicable to this question; results from other arm not cited.

Patients were randomised irrespective of ER status, which was not routinely assessed at enrolment.

Small trial, with no reporting of blinding (unlikely to be feasible); adherence to planned therapy reported, analysis appears to be by intention-to-treat (not reported).

## Systematic reviews of combined study designs

Shenkier, Weir, Levine, Olivotto, Whelan, Reyno & Steering Committee on Clinical Practice Guidelines for the Care and Treatment of Breast Cancer. Clinical practice guidelines for the care and treatment of breast cancer: 15. Treatment for women with stage III or locally advanced breast cancer.[see comment]. [Review] [73 refs]. CMAJ.Canadian.Medical.Association.Journal 170[6], 983-994. 2004.

### Design

Design: Systematic review of combined study designs (therapy), evidence level: 2 +

Country: Canada, setting: Tertiary care

### Inclusion criteria

Studies of patients with locally advanced breast cancer (LABC), considered stage III disease, defined as:

1. large breast tumours (> 5 cm in diameter) associated with either skin or chest-wall involvement or with fixed (matted) axillary lymph nodes or with disease spread to the ipsilateral internal mammary or supraclavicular nodes.
2. Inflammatory breast cancer

### Exclusion criteria

Not made explicit: all identified, English language studies were included, but also relevant non-randomised studies, as reflects the nature of the evidence base.

### Population

-

### Interventions

Aim: To define the optimal treatment for women with LABC.

Treatments include primary chemotherapy and locoregional treatment (surgery and RT).

### Outcomes

Locoregional control (defined as freedom from recurrence in the breast, chest wall or regional lymph nodes)

Disease-free survival (DFS; defined as survival free of breast cancer recurrence)

Overall survival (OS).

### Follow up

Not reported.

## Results

a) Operable tumours (NB as reported in the subsequent Cochrane Review by Mieog et al. 2007)

Data was from 1 retrospective study and 5 RCTs that compared preoperative and postoperative chemotherapy. These studies involved patients mainly with stage I or stage II disease and included a small proportion of women with tumours greater than 5 cm in diameter. No difference in DFS and OS was detected between the preoperative and postoperative chemotherapy groups. Preoperative chemotherapy often caused shrinkage of the tumour and permitted the performance of breast-conserving surgery (BCS) when a mastectomy was originally planned. However, results from 2 trials suggested that patients whose tumours were down-staged so that BCS could be performed when it was not initially planned were at higher risk of local recurrence and had worse survival (NB: in the Cochrane Review these results were not statistically significant; but may be clinically important).

b) Inoperable tumours (NB the majority of these studies were not included in the subsequent Cochrane Review by Mieog et al. 2007)

Multivariate analyses in 1 RCT and 3 observational studies have shown that the primary tumour response is correlated with patient outcome and that patients who have pathological evidence of a complete response following primary therapy have a superior DFS and OS compared with those who do not have such a response. Clinical response is seen in about 80% of patients who receive primary chemotherapy.

Three small RCTs compared mastectomy alone with locoregional RT alone following primary chemotherapy. The results of these studies suggest that both treatments are equally effective after primary chemotherapy in inoperable disease. No RCTs were found that compared mastectomy plus RT with mastectomy alone following primary chemotherapy, but 2 observational studies demonstrated that locoregional control was better if both mastectomy and RT were performed.

There was insufficient evidence on the importance of sequence of surgery and RT, or on breast conserving surgery, in patients with inoperable tumours who are treated with primary chemotherapy. No evidence was found to guide locoregional management of patients with stage IIIC disease who respond to primary chemotherapy.

## General comments

The systematic review informs a Canadian clinical practice guideline. Only the findings of primary studies are cited, and not authors' recommendations for practice. Results presented as narrative. Study selection criteria and quality consideration are adequate.

Literature search strategy:

English-language literature retrieved from MEDLINE (1984 to June 2002) and CANCELIT (1983 to June 2002). Search terms used were "breast neoplasms," "locally advanced breast cancer," "stage III breast cancer," "drug therapy," "neo-adjuvant," "primary systemic therapy," "radiotherapy or irradiation," "surgery," "randomised trials" and "high-dose therapy." A nonsystematic review of the literature was continued through December 2003. Additional data were identified by reviewing references in retrieved reports and by monitoring major conferences on breast cancer.

Study quality assessment:

A 5-level hierarchy of evidence was applied, based on: Sackett DL. Rules of evidence and clinical recommendations on the use of antithrombotic agents. Chest 1989;95(Suppl):2S-4S.

## Observational studies

Huang, Tucker, Strom, McNeese, Kuerer, Buzdar, Valero, Perkins, Schechter, Hunt, Sahin, Hortobagyi & Buchholz . Postmastectomy radiation improves local-regional control and survival for selected patients with locally advanced breast cancer treated with neoadjuvant chemotherapy and mastectomy.[erratum appears in J Clin Oncol. 2005 Jan 1;23(1):248]. J.Clin.Oncol. 22[23], 4691-4699. 2004.

### Design

Design: Retrospective comparative study (therapy), evidence level: 3  
Country: USA, setting: Tertiary care

### Inclusion criteria

676 patients with locally advanced breast cancer treated within 6 trials of doxorubicin-based primary chemotherapy between the years 1974 and 2000.

Table: clinical stage:

Clinical stage	No RT (n=134)		RT (n=542)		p
	n	%	n	%	
I	1	1	0	0	<0.001
IIA	21	16	8	1	
IIB	45	34	83	15	
IIIA	29	22	164	30	
IIIB	32	24	233	43	
IV	6	4	54	10	

### Exclusion criteria

31 patients who experienced recurrence within 2 months of mastectomy or completion of adjuvant therapy (15 in the RT group and 16 in the no RT group; this was done to remove from the analysis patients who received RT due to recurrence, rather than as planned therapy).

Patients with distant metastases.

Patients treated with breast conserving surgery after primary chemotherapy.

### Population

number of patients = 676.

### Interventions

Aim: to retrospectively examine outcomes in patients treated for locally advanced breast cancer with primary chemotherapy and mastectomy; comparing those who received adjuvant RT with those who did not. Two groups were retrospectively defined:

1. RT group (n=542): patients received primary chemotherapy, mastectomy and RT: typically 50 Gy to chest wall/axilla with 10 Gy boost to chest wall.

2. No RT group (n=134): patients received primary chemotherapy and mastectomy.

In the whole study population primary chemotherapy was as follows:  
Fluorouracil, doxorubicin and cyclophosphamide (FAC), or high-dose FAC: n=351  
Vincristine, doxorubicin, cyclophosphamide and prednisolone: n=160  
FAC or paclitaxel: n=101  
Doxorubicin and docetaxel: n= 64

640 patients (95%) received also adjuvant chemotherapy and 233 patients (34%), tamoxifen.

### Outcomes

Local recurrence rate (defined as disease recurrence on the ipsilateral chest wall or in the ipsilateral axillary, supraclavicular, infraclavicular, or internal mammary lymph nodes. Any other site of recurrence was considered distant metastasis).

Local recurrence rate as first site of failure

Overall survival

Cause-specific survival (rates estimated by Kaplan-Meier method)

Factors associated with locoregional recurrence and cause-specific survival

### Follow up

Median values:

RT group: 73 months

No RT group: 66 months

All patients: 69 months

### Results

10-year estimated rate of locoregional recurrence:

RT group: 11%

No RT group: 22% (p=0.0001; log-rank test)

Table: multivariate (Cox regression) analysis of factors associated with locoregional recurrence

Factor	HR	95% CI	p
--------	----	--------	---

No radiation	4.68	2.70 to 8.13	<0.0001
>= 20% sampled nodes positive	3.58	2.11 to 6.08	<0.0001
Stage >= IIIB	2.38	1.42 to 4.02	0.001
No tamoxifen	2.19	1.19 to 4.06	0.012
Minimal or worse clinical response to neoadjuvant chemotherapy	1.88	1.10 to 3.23	0.021
ER negative	1.69	1.04 to 2.76	0.033
Clinical complete response	No data	No data	NS
Pathological complete response	No data	No data	NS

10-year estimated rate of overall survival:  
RT group: 54%  
No RT group: 47% (p=0.063; log-rank test)

10-year estimated rate of cause-specific survival:  
RT group: 58%  
No RT group: 55% (p=0.85; log-rank test)

Table: multivariate (Cox regression) analysis of factors associated with cause-specific survival

Factor	HR	95% CI	p
Stage >= IIIB	2.35	1.77-3.11	<0.0001
Residual tumour (positive pathology) after primary chemotherapy	2.13	1.27-3.57	0.004
No RT	2.03	1.41-2.92	<0.0001
>= 4 positive lymph nodes	1.67	1.20-2.31	0.002
Minimal or worse clinical response to neoadjuvant chemotherapy	1.62	1.21-2.17	0.001
<10 lymph nodes sampled	1.53	1.15-2.06	0.004
No tamoxifen	1.40	1.03-1.90	0.030
ER negative	1.39	1.06-1.82	0.19
Clinical complete response	No data	No data	NS
Pathological complete response	No data	No data	NS

### General comments

Retrospective study with post-hoc analyses and several groups of patients excluded. Patients were not randomly allocated to RT or mastectomy, but on the basis of clinician/patient choice; the authors acknowledge this possible selection bias.

The patients with recorded stage IV disease had disease-positive

supraclavicular lymph nodes but no distant metastases.

**Comparability of groups:**

A greater percentage of RT group patients had more advanced clinical T-stage, clinical N-stage, combined clinical stage, poorer clinical response to primary chemotherapy, higher numbers of pathologically positive nodes and close or positive surgical margins ( $p < .01$  for all comparisons). There were no differences between the two groups with respect to age, use of tamoxifen, use of adjuvant chemotherapy, pathological tumor size, number of dissected axillary nodes, or percentage of ER negative tumours.

Update Evidence

McGuire, Gonzalez-Angulo, Huang, Tucker, Kau, Yu, Strom, Oh, Woodward, Tereffe, Hunt, Keurer, Sahin, Hortobagyi, & Buchholz. Postmastectomy radiation improves the outcome of patients with locally advanced breast cancer who achieve pathological response to neoadjuvant chemotherapy.
<b>Design:</b> Retrospective Analysis <b>Evidence Level:</b> 3
<b>Country:</b> USA
<b>Aim:</b> To investigate the role of postmastectomy radiation therapy in women with breast cancer who achieved a pathological complete response to neoadjuvant chemotherapy.
<b>Inclusion criteria</b> Patients with primary breast cancer who had a pathologic complete response (pCR) following receipt of neoadjuvant chemotherapy.  Treated with mastectomy following neoadjuvant chemotherapy.
<b>Exclusion criteria</b> Inflammatory breast cancer
<b>Population</b> N=106
<b>Interventions</b> Postmastectomy radiation therapy
<b>Outcomes</b> Rates of LRR in radiated group vs. irradiated group. Rates of LRR according to clinical and pathological factors in patients with Stage III disease. 10 year survival rates.
<b>Results</b> 10 year actuarial rates of LRR did not significantly differ between the irradiated and radiated

groups ( $p=0.40$ ) despite a significantly greater percentage of patients in the irradiated group having more advanced clinical disease stages at presentation ( $p<0.001$ ).

Radiation therapy was significantly associated with a lower 10 year rate of LRR in patients who initially presented with Stage III disease -  $7.3\% \pm 3.5\%$  in the irradiated group vs.  $33.3\% \pm 15.7\%$  in the non-irradiated group ( $p=0.040$ ).

In patients presenting with Stage III disease survival rates were as follows:

10 year distant metastasis free survival (DMFS) rate was  $87.9\% \pm 4.6\%$  in the irradiated group and  $40.7\% \pm 15.5\%$  in the non-irradiated group ( $p = 0.0006$ ).

10 year cause specific survival (CSS) rate was  $87\% \pm 5\%$  for the irradiated group and  $40\% \pm 16\%$  for the non-irradiated group ( $p=0.0014$ ).

10 year overall survival (OS) rate was  $77.3\% \pm 6\%$  for the irradiated group and  $33.3\% \pm 14\%$  for the non-irradiated group ( $p=0.0016$ ).

#### **General comments**

92% of patients received anthracycline as a component of neoadjuvant chemotherapy, 38% received a taxane either pre or post operatively.

The decision regarding whether or not to have postmastectomy radiation was made by the patient and physician.

## **Chapter 8 - Complications of local treatment, menopausal symptoms and psychological support**

### ***8.1 What strategies are effective in preventing lymphoedema in patients with breast cancer?***

#### **Short Summary**

The quality of the evidence for this question is varied, including few randomised controlled trials (RCTs) and several observational studies. There appear to be few studies of interventions aimed to prevent lymphoedema in the population of patients with breast cancer (including patients who have received surgery and adjuvant treatment) who are at risk of developing the condition.

Evidence from recent RCTs suggests that arm or shoulder exercise interventions after surgery for breast cancer do not affect subsequent rates of lymphoedema and that their effect upon shoulder mobility is inconsistent. An earlier systematic review of studies with mixed design found that shoulder exercise therapy does improve shoulder mobility. It should be noted that there is high heterogeneity across the studies: the interventions investigated differed considerably in their design, time of commencement and intensity. Control groups were also treated differently across studies. (Bendz and Fagevik 2002; Box *et al.* 2002a, 2002b; Cave and Jones 2006; Cheema *et al.* 2008)

Evidence from one RCT and a systematic review supports the role of aerobic exercise in patients treated for breast cancer, with some demonstrable benefit in terms of shoulder mobility and quality of life, but not consistently. Evidence from observational studies suggests that aerobic exercise is beneficial both physically and in terms of psychological well being. (Karki *et al.* 2001; Lane 2005; Sandel *et al.* 2005).

There was very limited evidence for the effectiveness of cognitive-behavioural interventions and arm massage. A poor quality RCT by Forchuk *et al.* (2004) found that an intervention whereby patients' partners were instructed to perform distal-to-proximal circular arm massage had no demonstrable effect on shoulder range of motion at four months postoperatively. The intervention group experienced significantly greater arm swelling than the control group at 14 weeks and four month postoperatively. An RCT by Braden and Badger (2000) found that patients who received an intervention designed to help them manage uncertainty arising from breast cancer reported better coping with arm swelling than patients in the control group, over a seven month period of follow-up. This result should be interpreted with caution as full trial details are not currently available.

Observational evidence suggests that where information is provided to patients on lymphoedema, it is done so by different healthcare professionals, with no apparent dominant group. (Cordero *et al.* 2003; Coward 1999; Karki *et al.* 2004; Yik *et al.* 2001)

## PICO

Population	Intervention	Comparison	Outcome
Patients with breast cancer who have received surgery, radiotherapy or no treatment	Any strategy with the aim of preventing lymphoedema e.g.: <ul style="list-style-type: none"> <li>• Education</li> <li>• Exercise</li> <li>• Compression Garments</li> <li>• Pneumatic Devices</li> <li>• Skin Care</li> <li>• Simple Lymph drainage massage</li> <li>• Advice on interventions to avoid</li> <li>• Pharmaceuticals</li> <li>• Physiotherapy</li> <li>• Psychological support</li> </ul>	Any or no strategy	<ul style="list-style-type: none"> <li>• Risk of developing lymphoedema</li> <li>• Incidence of lymphoedema</li> <li>• Measures of lymphoedema</li> <li>• Anxiety/Depression measures/psychological morbidity associated with lymphoedema</li> <li>• Subsequent use of healthcare services</li> <li>• Cost effectiveness</li> </ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

### Evidence Summary

There appear to be few studies of interventions aimed to prevent lymphoedema in the population of patients with breast cancer (including patients who have received surgery and adjuvant treatment) who are at risk of developing the condition. Some of the studies reviewed touch on wider issues in the same population i.e. interventions for earlier diagnosis, prevalence and time of onset of lymphoedema, risk factors, provision of education to patients and extent of patients' knowledge subsequently.

Applicability is reasonable since the study populations are in European or Western countries with the exception of Yik *et al.* (2000) (Hong Kong). The study by Braden and Badger (2000) specified that the population studied was Mexican American women.

In general the degree of consistency of the findings across the studies is poor for the primary focus of interventions to prevent lymphoedema. Prevalence data for lymphoedema is also very variable (as discussed below). There is high heterogeneity across the studies: the interventions investigated differed considerably in their design, time of commencement and intensity. Control groups were also treated differently across studies.

Evidence suggests that arm or shoulder exercise interventions after surgery for breast cancer do not affect subsequent rates of lymphoedema and that their effect upon shoulder mobility is inconsistent. An earlier systematic review of studies with mixed design found that shoulder exercise therapy does improve shoulder mobility.

Evidence supports the role of aerobic exercise in patients treated for breast cancer, with some demonstrable benefit in terms of shoulder mobility and quality of life, but not consistently.

Evidence suggests that where information is provided to patients on lymphoedema, it is done so by different health professionals, with no apparent dominant group

## **Effectiveness of interventions**

### **Exercise/physiotherapy to the shoulder/arm**

Four RCTs reviewed do not provide evidence that interventions consisting of arm/shoulder exercise or physiotherapy in patients at risk of lymphoedema affect subsequent rates of lymphoedema. Two RCTs found that such interventions improved shoulder function (Bendz and Fagevik 2002, Cave and Jones 2006) whereas the RCT by Box *et al.* (2002a, 2002b) found no significant effect in shoulder function as a result of their interventions.

- Box *et al.* (2002a and 2002b) evaluated a physiotherapy/exercise intervention initiated preoperatively and found no significant difference between intervention and control groups in rates of lymphoedema as defined *a priori*, or shoulder function at two years after surgery.
- Bendz and Fagevik (2002) evaluated a shoulder exercise programme initiated on the first post-operative day and found no significant differences in changes in arm volume between intervention and control groups at two years following surgery, nor in incidence of lymphoedema as defined *a priori*. At two years, the intervention group had significantly better shoulder mobility in two of four movements measured.
- Cave and Jones (2006) demonstrated that a shoulder physiotherapy/exercise intervention commenced at 6-8 weeks after surgery improved shoulder function at post-operative weeks 12 and 26.
- Kosir *et al.* (2002) found that an intervention consisting of structured patient education in shoulder exercises resulted in similar rates of lymphoedema compared to standard care, when assessed after 33 months of study accrual.

An earlier systematic review of 31 studies (including non randomised studies) by Karki *et al.* (2001) found no evidence that early shoulder exercise (immediately after surgery) was beneficial to delayed shoulder exercise in terms of shoulder mobility. However exercise therapy was found to improve shoulder mobility at 1-3 months post-operatively, compared to no exercise therapy.

A systematic review which included mixed study designs summarised the efficacy of prescribed progressive resistance training (PRT) following breast cancer surgery (Cheema *et al.* 2008). The included studies reported unilateral, upper extremity lymphoedema was an entry criterion and cases of lymphoedema were reported in other studies and did not preclude participation in these trials. One trial prescribed the use of compression sleeves during exercise in each enrolled participant while the use of compression sleeves was a decision made in conjunction with a lymphoedema specialist in other trials. Lymphoedema incidence, secondary to exercise was tracked as an adverse effect in three RCTs and in three uncontrolled trials. No incidence or exacerbation of lymphoedema, either quantified or self-reported was attributed to the training regime. No improvements in lymphoedema were reported.

De Rezende *et al.* (2006) conducted a small RCT to compare two schemes of exercise, directed or free, following modified radical mastectomy or quadrantectomy with axillary dissection, evaluating postoperative complications such as shoulder dysfunction and lymphatic disturbance. There was no difference between the directed and free groups in the average range of motion for adduction, extension and internal rotation between preoperative and 42<sup>nd</sup> day postoperative when analysing the groups individually. There was a statistically significant difference in the average range of motion for abduction, flexion and external rotation when analysed individually. There was significant differences between the directed and free groups in the average range of motion for abduction ( $p=0.0077$ ), flexion ( $p=0.0087$ ), extension ( $p=0.0447$ ) and external rotation ( $p=0.0403$ ) between preoperative and 42<sup>nd</sup> day postoperative when analysed in relation to the exercise groups. There was no statistically significant difference between the two groups in relation to lymphatic disturbance and no clinically significant difference in the groups in relation to arm circumference. Statistically significant increases in the arm circumference at 7.5cm above the humeroradial joint were observed in the free group.

An observational study with methodological flaws by Gordon *et al.* (2005a) found that health related quality of life, measured by four instruments, improved from 6-12 months following diagnosis in patients who received two different shoulder rehabilitation programmes and also in a control group. There were no statistically significant differences between the three groups as measured on any instrument.

#### **Generalised or aerobic exercise**

- A cross-over RCT by Sandel *et al.* (2005) found that quality of life measured by the FACT-B scale significantly improved in response to a 13 week movement and dance programme, compared to a control group. However the effect was not consistent across different quality of life scales. Shoulder range of movement increased significantly in both groups over a 26 week period and there were no significant changes in arm circumference in either group over the same period.

- The systematic review by Karki *et al.* (2001) cited above found that aerobic exercise after breast cancer surgery was beneficial in terms of psychological well-being.
- An observational study by Lane (2005) found that a 20 week, structured exercise programme for women treated for breast cancer, with dragon boat racing as its focus, resulted in a significant increase in upper body strength. Whilst arm circumference and arm volume significantly increased, there were no significant changes in the affected arm relative to the contralateral arm during the programme. A qualitative study by Unruh and Elvin (2004) of women with breast cancer who participate in dragon boat racing found that the women reported benefits from participation including physical and emotional well-being.

A poor quality RCT by Forchuk *et al.* (2004) found that an intervention whereby patients' partners were instructed to perform distal-to-proximal circular arm massage had no demonstrable effect on shoulder range of motion at four months post-operatively. The intervention group experienced significantly greater arm swelling than the control group at 14 weeks and four month post-operatively.

### **Cognitive-behavioural interventions**

An RCT by Braden and Badger (2000) found that patients who received an intervention designed to help them manage uncertainty arising from breast cancer reported better coping with arm swelling than patients in the control group, over a seven month period of follow-up. This result should be interpreted with caution as full trial details are not currently available.

### **Diagnostic interventions**

A small, non-randomised study by Campisi *et al.* (2006) studied the utility of lymphoscintigraphy as a test to select patients at risk of lymphoedema, combined with early intervention with microsurgery. Patients in the intervention group experienced a significantly lower incidence of lymphoedema than those in the control group, up to five years after initial surgery.

A diagnostic study of multiple frequency bioelectrical impedance analysis (MFBI) to predict early onset of lymphoedema with clinical diagnosis as gold standard was undertaken by Cornish *et al.* (2000) and presented as an interim report. Although the data reported look promising (representing sensitivity 100%, specificity 97.6%, positive predictive value 90.5%, negative predictive value 100%) they should be interpreted with caution due to problems including short follow up and fallible gold standard.

### **Prevalence of lymphoedema**

Evidence from the studies identified suggests that prevalence of lymphoedema is between 13.8% to 49% of patients at risk due to treatment for breast cancer. Possible explanations for this large range include different methods to define lymphoedema and variable extent of follow-up between studies (Table 1). The longest follow-up period of is the retrospective cohort

study by Petrek et al. (2001) which reports the highest prevalence at 49% using objective arm measurements. Considering only the studies where all patients are followed up for at least 5 years, prevalence range becomes 20% to 49%.

Evidence from two studies that graded lymphoedema for severity (based on objectively assessed extent of arm swelling) suggests that the swelling is severe in 13% of this patient group (Petrek *et al.* 2001, Berlin *et al.* 1999).

### **Time of lymphoedema onset**

Evidence from the studies identified suggests that lymphoedema incidence is higher within 3 years of baseline: usually diagnosis or definitive surgery. (Petrek *et al.* 2001, Berlin *et al.* 1999, Yik *et al.* 2001, Coward 1999) The retrospective cohort study by Petrek *et al.* (2001) found that 77% of cases occurred within 3 years of diagnosis and in the remaining 30 patients the rate of onset was gradual at approximately 10 patients per 5 year interval. The observational study by Berlin *et al.* (1999) found that 37% of patients who developed lymphoedema did so within 6 months of surgery and 63% within 1 year of surgery. The risk of developing lymphoedema was highest during the first year following surgery.

**Table 1. Sources of lymphoedema prevalence data**

<b>Study</b>	<b>Prevalence</b>	<b>Assessment method</b>	<b>Follow up</b>
Box et al. (2002)	21%	Objective	2 years
Bendz and Fagevik (2002)	13.8%	Objective	2 years
Petrek et al. (2001)	49%	Objective	20 years
Campisi et al. (2006)	22	Clinical diagnosis (subjective)	5 years
Cornish et al. (2000)	18.6%	Clinical diagnosis (subjective)	88% of patients were followed up for >18 months.
Berlin et al. (1999)	20%	Objective	5 years
Loerzel et al. (2005)	22%	Patient reported (subjective)	2-12 months
Yik et al. (2001)	45.6%	Patient reported (subjective)	In the order of 3 months to 3 years (approximately)
Coward (1999)	37.5%	Patient reported (subjective)	median 2.6 years, range 2 months to 17

			years

### **Risk factors for developing lymphoedema**

*NB: Questions 2a and 2b address the risk of lymphoedema after different surgical axillary staging procedures and their data is expected to supplement the data presented here.*

Some of the studies identified reported factors associated with lymphoedema, but the focus of the research question towards interventions to prevent lymphoedema will not have identified all of the prognostic evidence and so the results should be interpreted with caution.

There is some observational study evidence to implicate radiotherapy, particularly to the axilla as also a risk factor for subsequent lymphoedema (Yik et al. 2001, Coward 1999, Cordero et al. 2003), but the studies do not consistently single out the role of radiotherapy from other treatments applied. However all studies except Yik (2001) state that patients underwent axillary surgery.

There is some evidence from one RCT (as a secondary finding) and from one retrospective cohort study to suggest that weight gain following treatment may also be a risk factor for lymphoedema (Box et al. 2002, Petrek et al. 2001) as may injury or infection to the arm on the treated side (Box et al. 2002).

- The RCT by Box et al. (2002) found that of numerous treatment and patient factors explored, only increasing BMI in the two years following surgery was found to be a risk factor for the presence of lymphoedema at 2 years follow up: OR 1.21 (95% CI 1.04-1.41, p=0.01).
- The retrospective cohort study by Petrek et al. (2001) examined many demographic, disease-related and treatment-related variables for their relationship with lymphoedema prevalent at 20 years following treatment. Only history of arm infection /injury and weight gain since treatment were found to be associated with the presence of lymphoedema.
- The observational study by Berlin et al. (1999) found that significantly more patients with severe or moderate lymphoedema had received radiotherapy (anatomical site not specified, p<0.01, no further details provided).
- The observational study by Yik et al. (2001) found that of 16 different treatment combinations examined, the combination of mastectomy, lymph node dissection, chemotherapy and radiotherapy had a statistically higher than expected rate of lymphoedema (83/171=48.5%, Chi square=6.305, p=0.043).
- The observational study by Coward (1999) found that women reporting lymphoedema were more likely to have received radiotherapy to the axilla (Chi square=5.486, df=1, p=0.02) and to the breast (Chi square=4.192, df=1, p=0.04).
- The observational study by Cordero et al. (2003) found that 98.5% of patients with lymphoedema had received axillary clearance and 75.4% radiotherapy (site of treatment not specified).

### **Anxiety/ depression measures/psychological morbidity associated with lymphoedema**

These outcomes have been reported above, according to the interventions evaluated in the studies.

### **Subsequent use of healthcare services e.g. out patients appointments, primary care consultations – to be summarised.**

None of the studies identified provided information on these outcome measures.

### **Cost effectiveness**

Very little data was identified on the cost-effectiveness of interventions to prevent lymphoedema. The poor quality RCT by Forchuk et al. (2004) described above which evaluated an intervention whereby patients' partners performed post-operative arm massage, found no significant differences between randomised groups in subsequent health utilisation related costs.

### **Provision of information on lymphoedema to patients and patients' adherence to preventive strategies**

Evidence from observational studies suggests that the information provided to patients with breast cancer at or near the time of their surgery is very variable. Different studies estimate the proportion of patients reporting that they received health education on lymphoedema (or that they have some knowledge of the condition ) to be between 3% and 82.5%. The study designs are generally susceptible to recall bias and assess patients at different follow-up points. All studies originate from outside of the UK. However the same level of evidence suggests that length of hospital stay does not affect the education given to patients and that older patients receive less information than younger patients (Karki et al. 2004). Two studies that measured patient knowledge of arm care following breast cancer treatment using numerical scores demonstrated that patients' knowledge is relatively low (Yik et al. 2001, Coward 1999). In the studies reviewed the proportion of patients reporting that they use at least one lymphoedema prevention strategy was between 40.3% and 76%.

- The observational study by Loerzel et al. (2005) found that 79.3% of patients reported that they received lymphoedema information when evaluated within one year of diagnosis. Of these, 40.3% used taught strategies to prevent lymphoedema and 58.8% did not use the strategies at all.
- The observational study by Yik et al. (2001) found the mean score for knowledge of lymphoedema (of a possible range of 0-9, 9 representing most knowledge) in a sample of patients to be 4.07 (SD=2.35, mode=2) The authors reported this as a low value. 82.5% of patients reported that they knew they were at risk of lymphoedema. The level of knowledge did not vary significantly according to whether patients had developed lymphoedema, nor whether patients had attended a talk on lymphoedema.  
61.4% of patients reported that they performed arm exercises on the advice of a health professional, with a reported frequency of once daily

to less than once weekly. Only 6.4% patients performed manual lymphatic massage on the instruction of a health professional.

- An observational study Coward (1999) measured patients' knowledge of lymphoedema using a numerical scale (possible range 0-18, 18 reflecting most knowledge), based on based on knowledge of 18 recommendations used in clinical practice. Patients' scores had mean 8.6 (SD 4.3), median 9 and mode 8. Thus, patients typically reported being told of 8 or 9 of the 18 strategies to prevent/manage lymphoedema. 76% of respondents reported using at least one lymphoedema prevention/management strategy.
- The observational study by Cordero et al. (2003) found that only 24.6% of patients reported receiving any information after surgery on lymphoedema. Of these, 3% reported a discussion of risk factors for lymphoedema whereas 87.5% were taught basic arm exercises and 87.5% were told to avoid exertion.
- The observational study by Karki et al. (2004) found that length of hospital stay did not have any statistically significant effect on the education provided for shoulder mobility, oedema prevention/treatment, strength training and use of the upper limb. However older patients were significantly more likely to report less instruction for oedema prevention/treatment than younger patients. Of all patients who received modified radical mastectomy, 67% received sufficient information on shoulder movement, 33% received sufficient instruction for strength training and 38% received sufficient information for use of the upper limb.
- The observational study by Yik et al. (2001) found that nurses were the most frequently cited source of education on lymphoedema, followed by doctors, physiotherapists and friends/relatives.
- The observational study by Coward (1999) found that surgeons were the most frequent source of information followed by reading material and other survivors. However advice on blood pressure measurement and venepuncture was most commonly reported as coming from nurses.
- In the observational study by Cordero et al. (2003), patients reported that information on lymphoedema was given by (in descending order) oncologists, medical rehabilitation professionals and 'others', family doctors and surgeons.

In the observational study by Karki et al. (2004), 57.1% of patients reported that physiotherapists and physiotherapy assistants were the individuals providing the most information.

## Randomized controlled trials

Box, Reul-Hirche, Bullock-Saxton & Furnival . Physiotherapy after breast cancer surgery: results of a randomised controlled study to minimise lymphoedema. Breast cancer research and treatment. 75[1]. 2002.

Design: Randomized controlled trial (therapy), evidence level: 1+  
Country: Australia, setting: Secondary care

**Inclusion criteria** Women scheduled to undergo breast conserving surgery (complete local excision and axillary dissection) or modified radical mastectomy at two hospitals in Brisbane between 1996 and 1997.

**Exclusion criteria** Confused mental state or inability to follow the exercise guidelines (n=5)

Concurrent reconstructive surgery (n=3)

Residence beyond 50km radius of either hospital and no monitoring as an outpatient (n=20)

Refusal of random allocation (n=9)

Insufficient time to obtain consent/perform preoperative assessment (n=8)

Absence of principal investigator at time of recruitment (n=5)

**Population** number of patients = 65, mean age = 56 years.

**Interventions** Aim: To measure the effect of a physiotherapy management care plan (PMCP) for women undergoing breast cancer surgery.

Intervention group (n=32):

Provision of an exercise programme and lymphoedema awareness education which started preoperatively and continued post-operatively. The PMCP also included therapeutic intervention with exercise when secondary lymphoedema was detected.

Control group (n=33):

Provision of exercise instruction booklet only (but physiotherapy intervention was initiated when lymphoedema was detected: see comment on ITT analysis).

**Outcomes** Difference in arm circumference (CIRC) between operated arm and non-operated arm.

Difference in volume (VOL) between operated arm and non-operated arm.

Ratio of extra-cellular water content between operated arm and non-operated arm, determined by multi-frequency bioimpedance analysis (MFBIA) i.e. impedance spectroscopy.

The threshold for lymphoedema was set at:

>=5cm difference in CIRC from the preoperative measurement;

>=200ml difference in VOL from the preoperative measurement;

MFBIA ratio (operated arm:non-operated arm) below the 95% CI determined from preoperative data.

**Follow up** 2 years, with assessment at following stages:

Pre-operative

Prior to randomisation

Post-operatively at day 5, 1 month, 3 months, 6 months, 12 months and 24 months.

**Results** Of 57 patients who were assessed at 24 months, 12 (21%) had lymphoedema using the VOL criteria: incidence was 3 (11% [95% CI 0.7-22.9%]) in the intervention group compared to 9 (30% [95% CI 13.6-46.4%]) in the control group (p=0.08).

Only the VOL method of lymphoedema measurement was found to accurately assess the presence of lymphoedema (presumably using clinical examination as the gold standard: see comment).

By log regression, only increasing BMI was found to be a risk factor for the presence of lymphoedema at 24 months follow up: OR 1.21 (95% CI 1.04-1.41, p=0.01). No other variable explored was found to be a risk factor (axillary dissection level, no. lymph nodes removed, wound infection, cording, wound drainage volume, seroma, age, dominant operated arm, radiotherapy, occupation). However these results should be considered with the low event rate.

**General comments** Randomisation was performed after informed consent and stratified by planned surgical procedure.

Single blind design: participants were blinded, physiotherpists were not entirely blind to allocation.

No specific power calculation performed for lymphoedema outcomes. Low event rate observed therefore results are mostly descriptive.

Two patients received bilateral procedures and were excluded from the analysis. At 24 months follow up 57 patients provided data.

Lymphoedema measurement was objective, based upon difference in measurements between operated and non operated arms, at preoperative and subsequent follow up points.

Subjective clinical examination was used as a gold standard to assess diagnostic consistency of the three measures of lymphoedema.

This paper does not report the incidence of lymphoedema after the 2 year follow up point.

Design: Randomized controlled trial (therapy), evidence level: 1 +  
Country: Australia, setting: Secondary care

**Inclusion criteria** Women scheduled to undergo breast conserving surgery (complete local excision and axillary dissection) or modified radical mastectomy at two hospitals in Brisbane between 1996 and 1997. 49% of patients received breast conserving surgery. According to local practice, patients did not receive axillary radiotherapy (but may have received breast radiotherapy).

**Exclusion criteria** Confused mental state or inability to follow the exercise guidelines (n=5).

Concurrent reconstructive surgery (n=3).

Residence beyond 50km radius of either hospital and no monitoring as an outpatient (n=20)

Refusal of random allocation (n=9)

Insufficient time to obtain consent/perform preoperative assessment (n=8)

Absence of principal investigator at time of recruitment (n=5)

**Population** number of patients = 65, mean age = 56 years.

**Interventions** Aim: To measure the effect of a physiotherapy management care plan (PMCP) for women undergoing breast cancer surgery.

Intervention group (n=32):

Provision of an exercise programme and lymphoedema awareness education which started preoperatively and continued post-operatively. The PMCP also included therapeutic intervention with exercise when secondary lymphoedema was detected.

Control group (n=33):

Provision of exercise instruction booklet only (but see comments on ITT analysis).

**Outcomes** Recovery of active shoulder movement on the operated arm:

Abduction, flexion, extension, internal rotation, external rotation.

Functional status assessment

Wound drainage, incidence of postoperative complications and lymphoedema

Factors that may contribute to delayed recovery.

**Follow up** 2 years, with assessment at following stages:

Pre-operative

Prior to randomisation

Post-operatively at day 5, 1 month, 3 months, 6 months, 12 months and 24 months.

**Results** Two years after surgery, 80% of all patients reported no residual problems with shoulder stiffness or functional actions.

The rate of residual problems at two years were not significantly different between groups: 14% [95% CI 1-28%] of the intervention group reported residual problems compared with 26% [95% CI 9.9-40%] of the control group.

The intervention group demonstrated greater abduction compared to the control group at 3 months follow-up [156 degrees versus 142 degrees respectively (values read from graph),  $p < 0.05$ ] which was maintained to 2 years follow-up 150 degrees versus 143 degrees respectively,  $p < 0.01$ ].

No significant differences were found for flexion, internal rotation or external rotation, but significant associations were found by ANOVA between limitations in these movements and difficulties with 6 of 12 assessed functional tasks:

Back scratching: abduction, flexion and external rotation [ $p < 0.02$ ]

Putting on a shirt: abduction and flexion [ $p < 0.01$ ]

Brushing hair: abduction [ $p < 0.01$ ]

Doing up a bra: extension and internal rotation [ $p < 0.05$ ]

Zippering a back fastening dress: extension and internal rotation [ $p < 0.02$ ]

Making a double bed: abduction [ $p < 0.022$ ]

Authors conclude that the PMCP intervention resulted in greater recovery of shoulder range of movement during the first two years following breast cancer surgery.

**General comments** Randomisation was performed after informed consent and stratified by planned surgical procedure.

Single blind design: participants were blinded, physiotherapists were not entirely blind to allocation.

Range of movement measurements objectively performed.

Power calculation performed.

All analyses were controlled for age, number of lymph nodes excised, level of axillary dissection, history of previous shoulder problem, radiotherapy, chemotherapy and wound infection. Analysis was by ITT: 3 patients in the control group received physiotherapy as per the intervention group according to a rule set a priori due to poor recovery at a specified level.

59 of the 65 recruited patients were fully evaluated.

Bendz & Fagevik . Evaluation of immediate versus delayed shoulder exercises after breast cancer surgery including lymph node dissection - A randomised controlled trial. Breast 11[3]. 2002.

Design: Randomized controlled trial (therapy), evidence level: 1+  
Country: Sweden, setting: Secondary care/home

**Inclusion criteria** Women patients undergoing radical mastectomy or quadrantectomy, including those with axillary dissection for breast cancer between November 1994 and December 1996.

**Exclusion criteria** Age >80 years, senility, bilateral surgery or co-morbidity affecting the outcome e.g. rheumatoid arthritis, stroke.

**Population** number of patients = 230, mean age = 58 years.

**Interventions** Intervention group: patients were given preoperatively a shoulder/arm exercise programme of to be started on the first post-operative day.

Control group: patients were advised to use the arm as much as was comfortable but to avoid lifting/carrying/forced movements for 14 post-operative days.

After 14 days patients in both groups received an exercise programme to perform (no 'stopping date' reported) i.e. comparison is immediate post-operative versus delayed (14 days) shoulder/arm exercise.

**Outcomes** Lymphoedema: percentage change in arm volume as measured by water displacement: lymphoedema was defined as a 10% increase in volume on the operated arm compared to the non-operated arm, corrected for preoperative differences and the dominant arm.

Arm flexion, abduction and external/internal rotation using a goniometer. Hand grip strength using a vigorimeter.

Subjective estimation of pain, heaviness and tension in the operated arm using a visual analogue scale (mild, moderate, severe).

**Follow up** Patients were seen at the preoperative, 2 week, 1 month, 6 month and 2 year post-operative points.

A total of 49/230 patients were lost to follow up due to death (n=16), moving away (n=12), comorbidity (n=5), contralateral surgery (n=4) and personal reasons (n=12).

**Results** There were no significant differences in changes in arm volume between randomised groups at any follow up point up to 2 years post-operatively. At 2 years follow up there was no significant difference between randomised groups in the proportion of patients with lymphoedema as defined a priori: intervention group (13%) versus control group (12%),  $p>0.05$ . The overall incidence of lymphoedema was 6.5% at 6 months and 13.8% at 2

years.

All measured movements in both randomised groups were reduced at 2 weeks and 1 month post-operatively.

At 2 weeks post-operatively arm elevation was 73% of its preoperative level in the intervention group compared to 55% of its preoperative level in the control group ( $p < 0.001$ ).

At 2 years follow up the intervention group had statistically significantly better movement than the control group for:

flexion (167 degrees versus 164 degrees respectively,  $p < 0.05$ )

abduction (154 versus 145 degrees respectively,  $p < 0.05$ ).

At 2 years follow up there were no statistically significant differences between groups for:

external rotation (88 degrees in both groups,  $p > 0.05$ )

internal rotation (70 degrees in both groups,  $p > 0.05$ )

There were no statistically significant differences in volume change or arm mobility between patients who received radiotherapy and those who did not receive radiotherapy (NB all radiotherapy was to the chest wall only, not the axilla).

There were no statistically significant differences between randomised groups for hand grip strength at any follow up point.

There were no statistically significant differences between randomised groups for subjectively assessed pain, heaviness and stiffness at any follow up point. Where symptoms were reported they were mild or moderate.

Authors conclude that the early exercise start does not affect the incidence of lymphoedema compared to a delayed (14 days) exercise start, but is of value in avoiding deterioration of shoulder mobility.

**General comments** NB: From the data provided, 47% of all patients in this study appear to have received either mastectomy only or quadrantectomy only i.e. no axillary surgery, which could be expected to bring about a lower incidence of lymphoedema.

No statistically significant differences existed between groups at outset for age, dominant hand, mastectomy only, quadrantectomy only and treatment with radiotherapy. There were statistically significantly more operations on the right hand side in the control group, but volume measurements were corrected for dominance.

Uncertain whether analysis by whether radiotherapy was received was a sub-group analysis (by randomised group) or a separate analysis, by radiotherapy status alone. Approximately 50% of patients in the study received radiotherapy.

Units of measurement not always reported: range of movement units assumed to be degrees. Confusion arises on the outcomes reported: 'elevation' is cited in results although not stated in the methods section. Methods of reporting are variable.

Small differences between groups may have arisen since the control group were also 'fairly mobile' with regard to their arms. However patients were discharged early with drains in situ as standard.

Cave & Jones . Physiotherapy improves shoulder function after treatment in women with early breast cancer. Cancer Treatment Reviews 32. 2006.

Design: Randomized controlled trial (therapy), evidence level: 1+  
Country: Denmark, setting: Secondary care

**Inclusion criteria** 139 women scheduled for unilateral surgery for breast cancer at the Aarhus University Hospital, Denmark.

All women underwent modified radical mastectomy (including level I and II axillary dissection) or breast conserving surgery plus level I and II axillary dissection.

**Exclusion criteria** Pre-operative illness affecting upper limbs

**Population** number of patients = 139.

**Interventions** This study aimed to determine whether physiotherapy in the immediate post-operative period improves shoulder function in women treated for breast cancer.

Intervention group:

Standard immediate post operative treatment (daily instruction in shoulder and vein pump exercises in the first week after surgery) plus physiotherapy (two 60 minute sessions per week for 6 weeks) commenced in 6th-8th post-operative week.

Control group:

Standard immediate post-operative treatment as above, with physiotherapy commenced as standard i.e. after the 26th post-operative week.

**Outcomes** Shoulder function assessed by constant shoulder score (based upon pain, range of movement and strength; range 0-100); includes subjective and objective parameters.

**Follow up** Assessment of outcome was made at 6, 12 and 26 weeks post-operatively.

**Results** At 6 weeks post-operatively there was no significant difference in change in constant shoulder score: 21 in the intervention group versus 17 in the control group (Mann-Whitney U-test, p=NS).

Physiotherapy improved shoulder function compared with no physiotherapy at 12 and 26 weeks after surgery (median change [in constant shoulder score from preoperative value] = 4 in intervention group versus 9 in control group at 12 weeks, Mann-Whitney U-test, p=0.001; median change = 2 versus 7 respectively at 26 weeks, Mann-Whitney U-test, p=0.001).

Authors state that careful case selection must be made for early physiotherapy as evaluated here, based upon treatment and patient factors.

**General comments** Study does not measure shoulder function in the longer

term e.g. 12-18 months, where the control group would also have received physiotherapy as per standard treatment.

It is not reported how many patients received radiotherapy, nor to which site, but authors state that some patients in the intervention received radiotherapy prior to the intervention, which may underestimate the treatment effect.

Braden & Badger . Side effects experienced by women receiving treatment for breast cancer: depression by self-help intervention by time effects on arm swelling side effect... 33rd Annual Communicating Nursing Research Conference/14th Annual WIN Assembly, "Building on a Legacy of Excellence in Nursing Research," held April 13-15, 2000 at the Adam's Mark Hotel, Denver, Colorado. Communicating Nursing Research 33. 2000.

Design: Randomized controlled trial (therapy), evidence level: 1-  
Country: United States, setting: Secondary care

**Inclusion criteria** Two studies contributed data with a total of 600 women treated for operable invasive breast cancer in North Carolina and Arizona. The women in Arizona were younger ( $\leq 49$  years) than those in North Carolina ( $\geq 50$  years).

Participants had low financial income and represented Mexican-American women, African American women and Anglo American women.

NB Only the Mexican-American women from Arizona ( $n = 79$ ) who provided objective arm measurement data across all time points are represented in this analysis (i.e. low income women of age  $\leq 49$  years).

Participants were divided into high and low risk groups for depression based upon the Centre for Epidemiological Studies Depression Scale (CES-D) score.

The majority of women received axillary dissection and a minority, sentinel lymph node biopsy. Women did not receive axillary radiotherapy.

**Exclusion criteria** None reported.

**Population** number of patients = 79, age range 0 to 49 years.

### **Interventions**

Intervention group:

Patients received a cognitive-behavioural intervention. Although addressing arm problems was not the focus of the intervention, information about protecting the arm on the operated side and support for discussing any concerns with their physician was provided to women who indicated uncertainty about management of arm problems.

Control group:

Patients received standard care.

**Outcomes** Arm circumference measured objectively at 4 points, based on an assessment protocol from a rehabilitation centre;

Patient-reported pain and weakness in the arm on the operated side (frequency, ability to manage and a measure of 'how much it bothered the

patient').

**Follow up** Data were collected at three points over a follow-up period of 7 months.

**Results** Over the seven month period of follow-up:

Patients in the intervention group reported significantly more ability in terms of the 'managing arm swelling' item in the self-report measure, compared to patients in the control group ( $F=7.3$ ,  $2/73$ ,  $p=0.01$ ). This result was observed regardless of level of depression.

Patients in the intervention group experienced significantly less arm swelling as measured objectively at the forearm point ( $F=5.74$ ,  $2/73$ ,  $p=0.004$ ). This result was observed regardless of level of depression.

**General comments** Results cited are from published abstract and correspondence with first author.

Statistics reported are by repeated measures MANOVA.

Apart from the results shown (i.e. those abstracted) it is not fully known what factors were explored, but found to have no statistically significant effect on outcome; it appears that a large number of patient-reported factors were reported e.g. 'difficulty sleeping, fatigue, quality of life, psychosocial adjustment). For this reason, which arises from an incomplete set of results in abstract form, the results cited should be taken with caution. Caution also arises due to the focus of the intervention, which was not to address arm problems; advice on arm care was given only to 'patients who indicated uncertainty about management of arm problems'.

The cited significant result for 'managing arm swelling' may arise in part, because specific arm care advice was given to patients in the intervention group who 'indicated uncertainty about management of arm problems', and where blinding was not likely to have been feasible; it is not surprising that these patients might report their ability to manage arm swelling favourably when asked at a later date.

Forchuk, Baruth, Prendergast, Holliday, Bareham, Brimner, Schulz, Chan & Yamine . Postoperative arm massage: a support for women with lymph node dissection. Cancer Nursing 27[1]. 2004.

Design: Randomized controlled trial (therapy), evidence level: 1-  
Country: Canada (federal state, Commonwealth Realm), setting: Secondary care

**Inclusion criteria** Patients 18 years of age or older, scheduled for lymph node dissection as part of surgery for breast cancer. Patients had to plan on having their significant other present (within 1 hour of leaving post anaesthesia care) after surgery, and both patient and significant other needed to consent to participate and be fluent in English.

The significant others included spouses (n=49, 83.1%), parents (n=4, 6.8%), other relatives (n=2, 3.4%), firends (n=1, 1.7%) and others (n=3, 5.1%).

**Exclusion criteria** Organic brain disease;  
Pre-existing disorder affecting arm function or the lymphatic system.

**Population** number of patients = 59, age range 21 to 78 years, mean age = 56 years.

**Interventions** Intervention group (n=30):

Patients' significant others were taught how to perform a distal to proximal arm massage in circular pattern and encouraged to do so from the immediate post-operative period. No set parameters for frequency and duration of massage were set other than a suggested 10 minute duration.

Control group (n=29)

Patients received standard post-operative care.

**Outcomes** Pain, measured on numeric rating scale (0-10), reported at it's most, least and average each day.

Pain control achieved by analgesia, measured on the same scale as above.

Stress experienced by patients' families, measured using the family stressor inventory.

Shoulder function, measured subjectively, using the disability section of the shoulder pain and disability index (SPADI).

Shoulder range of motion (ROM) measured objectively by a single, trained individual.

Arm volume, estimated by circumferential measurements at 4 inch intervals.

Health related costs, based upon patient reported episodes (e.g. physician visits); ascertained at 10-14 days and 4 month post-operative points, and

projected to a yearly rate, based on an Ontario health utilisation instrument.

**Follow up** Outcomes were measured preoperatively and at 24 hours, 10-14 days and 4 months post-operatively.

Pain and frequency of massage were recorded daily by patients and significant others.

**Results** Pain control data not shown, as reporting is incomplete and suspicious (see comments).

In the intervention group the mean number of massages performed on days 1, 2 and 3 post-operatively was 1.72, 2.28 and 2.44 respectively. This value peaked on day 4 at 2.69 and then progressively tailed off.

No results shown for family stressor inventory data: Different subsets of data are reported at different follow-up points i.e. whole data set not reported in paper, just selected results.

Prior to surgery there were no significant differences within the SPADI scale for shoulder mobility between randomised groups. At 10-14 days post surgery the intervention group reported statistically significantly less difficulty than the control group in the following tasks (with  $p < 0.05$  by t test):

Washing their back;

Putting on a shirt;

Placing an object on a high shelf;

Placing an object in a back pocket.

There was no significant difference between randomised groups for ROM at the 10-14 days and 4 months post-operative follow up points (No assessment was made at the 24 hour post-operative point).

The intervention group experienced statistically significantly more swelling at the 10-14 day post-operative follow-up point (e.g. proximal girth measurements 16.95 versus 16.20 respectively,  $t=53$ ,  $p < 0.05$ ) and also the 4 month follow up point (no statistics reported). These differences ceased to be statistically significant when outliers were removed from the analysis (no details shown).

There were no significant differences between randomised groups in health utilisation related costs, (e.g. based on consultations with nurses, post-operative tests, medication).

**General comments** Study lacks a standard regime of massage as an intervention; frequency and compliance may have faltered with no prescribed regime (authors report poor compliance after 4 days post-operatively) 10-14 days as second follow-up point represents a variable follow-up point between patients.

Entire SPADI criteria shown (Nonsignificant results may not be reported in

paper).

Study had a large amount of incomplete data.

ROM was measured by two individuals and not the intended sole individual.

Findings for pain control appear very suspicious: suggestive that authors summed pain relief from two sources, implying independent efficacy. Authors contacted for clarification.

Overall this appears to be a flawed RCT. No details of random allocation are given and the validity is otherwise questionable.

Kosir, Rymal, Du, Koppolu, Smith, Mood, Rice, Northouse, Aref, Brown & Youseef . Lymphedema prophylaxis utilizing perioperative education. Era of Hope, Department of Defence Breast Cancer research program meeting. 2002.

Design: Randomized controlled trial (therapy), evidence level: 1-  
Country: United States, setting: Secondary care

**Inclusion criteria** Patients treated for breast cancer with surgery including axillary dissection and/or radiotherapy at the Karmanos Cancer Institute, Detroit.

Of 173 enrolled patients (target 176) 154 were randomised. A total of 20 patients died or dropped out leaving 153 evaluable patients of which 113/158=71.5% yielded a full data set.

**Exclusion criteria** No details available.

**Population** number of patients = 113.

**Interventions** Intervention group (n=51 fully evaluable):  
Received standard care (written breast rehabilitation materials and preoperative counselling by the breast surgeon) plus structured education in breast surgery rehabilitation including range of motion exercises, lymphoedema arm precautions and management of complications).

Control group (n=62 fully evaluable):  
Received standard care alone.

**Outcomes** Incidence of lymphoedema and infection (lymphoedema was determined on the basis of a 10% volume increase or a >1cm arm circumference increase, with verification by a lymphoedema specialist); Quality of life (QOL) measured by the functional assessment of cancer therapy-breast (FACT-B) survey and the medical outcome study short form health survey (MOS SF-36) and sexuality subscales of the cancer rehabilitation evaluation system (CARES); Patient knowledge and practice of lymphoedema protective skills, measured by testing.

**Follow up** Data are reported at the interim stage after 33 months of accrual. Mean follow-up period not known.

**Results** Interim results within the first 33 months of accrual:

52.9% (27/51) of evaluable patients in the intervention group had lymphoedema versus 46.8% (29/62) of evaluable patients in the control group.

49.6% (56/113) of all evaluable patients developed lymphoedema within the first 33 months of accrual, including acute lymphoedema (described as occurring within one year of surgery) and chronic lymphoedema.

Authors report that the lymphoedema rate observed is higher than that reported in the literature.

**General comments** RCT appears to be ongoing: unpublished interim material cited ('Year III report', identified by standard search methods).

Results are only shown for 113 fully evaluable patients: no 'worst case' or 'best case' analyses performed.

Sandel, Judge, Landry, Faria, Ouellette & Majczak . Dance and movement program improves quality-of-life measures in breast cancer survivors. Cancer Nursing 28[4]. 2005.

Design: Randomized controlled trial, evidence level: 1-  
Country: United States, setting: Community

**Inclusion criteria** Patients treated for breast cancer MidState Medical Center, Conneticut, having undergone surgery at least one month previous, but within the preceding 5 years.

The mean time since surgery was 11 months.

Of 38 included participants, 35 completed measurements at 26 weeks.

**Exclusion criteria** Patients with metastatic breast cancer or the inability to stand unaided for 3 minutes.

**Population** number of patients = 35, age range 38 to 82 years, mean age = 61 years.

**Interventions** This trial aimed to measure the effect of a dance and movement programme on quality of life, body image, shoulder function and arm circumference in patients treated for breast cancer.

Intervention group (n=19):

Underwent a 12 week dance exercise program of a planned 18 sessions. At week 14 patients resumed their normal activities.

Control group (n=16):

Maintained normal activity until week 14, when they undertook the dance programme as above, from weeks 14-25.

The dance programme included warm up, core exercises (to shoulder, elbow and wrist), dance movements and stretching.

**Outcomes** The following outcomes were assessed using a patient-administered questionnaire:

Functional Assessment of Cancer Therapy-Breast (FACT-B) quality of life instrument, which has physical, social, functional and emotional domains plus 9 questions that are breast cancer specific;

Health related quality of life using the SF-36 instrument;

The Body Image Scale;

Shoulder range of movement (ROM) in abduction, flexion, rotation and extention (as a sum [degrees] of all measurements);

Arm circumference, summed from measurements at 3 points and compared to the untreated arm.

**Follow up** Outcome measures were obtained at baseline, 13 weeks and 26 weeks.

**Results** FACT-B significantly improved in the intervention group at 13 weeks from 102.0 (SD15.8) to 116.7 (SD16.9), compared to the control group 108.1 (SD 16.4) to 107.1 (SD 21.3), (ANOVA time by group effect,  $p=0.008$ ). The observed increase of 14 points in the intervention group was reported as a large gain in clinical terms.

During the crossover phase, the FACT-B score increased in the control group from 106.1 (SD 22.3) to 113.5 (SD 18.0) (ANOVA time by group effect,  $p=0.008$ ). Mean scores were stable in the intervention group in the crossover phase.

The overall effect of the training at 26 weeks was significant in explaining variance in FACT-B scores (time effect,  $p=0.03$ ), and the order of training was also significant ( $p=0.015$ ).

For other quality of life scales, some similar, significant effects were observed, but not consistently: mean SF-36 mental health summary score improved during the intervention periods over the 26 weeks (time effect,  $p=0.006$ ), but not the SF-36 physical summary score (time effect,  $p=0.06$ ). Body image score improved as a result of the intervention over 13 and 26 weeks with (time effect)  $p=0.001$  and  $p=0.001$  respectively.

ROM in the involved shoulder increased in both groups at 13 weeks: 15 degrees (sum) in the intervention group and 8 degrees in the control group (ANOVA time effect,  $p=0.03$ ; time by group,  $p=0.58$ ).

At 26 weeks ROM increased in both groups: 26 degrees in the intervention group and 20 degrees in the control group (ANOVA time effect,  $p=0.006$ , training order effect, not significant). Greater improvements were seen in the involved shoulder than the contralateral shoulder, but not significantly so ( $p=0.23$ ).

In all subjects, the summed arm circumference at baseline in the arm on the side of breast surgery was greater than that on the non-operated side (118.6 [SD 12.1] cm versus 116.2 [SD 9.8] cm,  $p=0.004$ ).

There were no changes in arm circumference in either group at 13 weeks or 26 weeks for either involved arm or non-involved arm.

**General comments** RCT had crossover design: patients in the control group received the same intervention as those in the intervention group, but at a later stage, whereupon those in the intervention group became 'controls'. This assumes that each group was in a comparable state when receiving the intervention (or acting as control), which is likely to not be the case. However it meant that the programme (already in place and thus regarded as beneficial) could be offered to more participants.

The planned 18 dance sessions was designed to accommodate some non-

attendance (No report is made of compliance).

Analysis was by ITT and women were asked to complete all outcome measures regardless of compliance with the programme.

Shoulder ROM and arm circumference were measured by a physiotherapist, blinded to allocation.

The two groups were similar at baseline for time since surgery, type of surgery and extent of axillary surgery. 8 patients were receiving chemotherapy or radiotherapy during the programme.

The ANOVA test to assess for a training order effect due to crossover study design (for an interaction for time by group) is reported as 'exploratory' i.e. it is limited since for a full analysis, the control group should be assessed a further 13 weeks later i.e. at 39 weeks. Therefore this does not fully overcome the flaw of crossover design.

Follow-up is relatively short at 26 weeks.

## Systematic reviews of combined study designs

Karki . Efficacy of physical therapy methods and exercise after a breast cancer operation: a systematic review. *Critical Reviews in Physical and Rehabilitation Medicine* 2001;13(2-3):159-90. [2-3]. 2001.

Design: Systematic review of combined study designs (therapy), evidence level: 2 -

Country: Finland/UK, setting: Secondary care/community

**Inclusion criteria** RCTs and observational studies written in English or Scandinavian languages that meet the following criteria:

Prospective clinical trial;

Sample of patients with breast cancer;

Design that is experimental, pre-experimental (no control group), quasi-experimental or true experimental;

Post-operative therapy, therapy used with late symptoms or therapeutic exercise training.

**Exclusion criteria:** Defined by inclusion criteria.

**Interventions** A Physical therapy for existing lymphoedema

B Early versus delayed shoulder exercise after breast cancer surgery

C Exercise therapy (provided by exercise therapists) after breast cancer surgery

D Aerobic exercise after breast cancer surgery

**Outcomes** A Limb volume, circumference measurement, subjective feelings, others.

B Drainage volume, complications, range of movement (ROM), functional outcome measures, pain, length of hospital stay

C ROM measures, subjective feeling

D Cardiovascular measurements, subjective feelings, weight, body mass index

**Follow up** Not reported collectively: follow-up period varied amongst 31 included studies but ranged from immediate postoperative period to months/years after interventions.

**Results** 31 studies were included:

B Early versus delayed shoulder exercise after breast cancer surgery (7 studies, 989 patients):

No study found that early shoulder exercise would benefit the later outcome of shoulder mobility.

Methodological quality score had range 31-49 (out of 70).

No meta-analysis was possible due to heterogeneity of data.

C Exercise therapy (provided by exercise therapists) after breast cancer surgery (4 studies, 354 patients):

In all three studies with a control group, patients in the intervention groups had significantly better shoulder ROM results at a follow-up time of between

1-3 months.

The control group in two studies experienced difficulty in functional movements, particularly using back-fastening zips, making a double bed and washing the upper back on the opposite side.

Methodological quality score had range 18-49 (out of 70).

No meta-analysis was possible due to heterogeneity of data.

D Aerobic exercise (e.g. walking, cycling.) after breast cancer surgery.

Programmes lasted 8 weeks-6 months (4 studies, 140 patients):

The studies evaluated exercise programmes during radiotherapy/chemotherapy. The programmes employed were notably different in intensity and duration, as were the outcomes measured by the studies and also the assessment of baseline performance.

1 study found that aerobic exercise improved functional capacity.

1 study found that the exercise group showed less fatigue and anxiety and reported higher satisfaction with their bodies than the control group.

1 study found that patients who improved in a walking test had less decline in a quality of life score but also that fatigue was provoked by both lack of exercise and high-intensity exercise.

Methodological quality score had range 40-48 (out of 70).

No meta-analysis was possible due to heterogeneity of data.

Authors conclude:

Evidence quality in the field of physical exercise therapy after breast cancer surgery is poor and follow-up generally short.

Early shoulder exercise (immediately after surgery) over delayed shoulder exercise does not appear to be justified.

Aerobic exercise appears to confer a psychological benefit in patients with breast cancer but the optimal frequency and intensity are uncertain.

### **General comments**

Outcome group A represent advanced breast cancer guideline scope; not reported here.

Systematic review with adequate details of literature search strategy, inclusion criteria and assessment of quality of primary studies with a unique scoring scheme. Strength of evidence weakened by inclusion of observational studies and poorly conducted RCTs. The range of physical interventions studies is diverse and reporting of results is mostly in narrative with little further analysis.

## Retrospective cohort studies

Petrek, Senie, Peters & Rosen . Lymphedema in a cohort of breast carcinoma survivors 20 years after diagnosis. Cancer 92[6]. 2001.

Design: Retrospective cohort study (other), evidence level: 2-  
Country: United States, setting: Community

**Inclusion criteria** Surviving patients within a cohort of patients consecutively treated for breast cancer at Memorial Sloan-Kettering Cancer Center between October 1976 and June 1978. Of 923 original participants, a total of 263 were alive at 20 years follow up and were eligible and willing to be studied further.

52 (20%) patients had received subsequent contralateral breast cancer treatment with axillary dissection and 211 (80%) patients received only treatment to one side.

All patients received a similar extent of axillary dissection (detail not reported)

Less than 5% of participants received radiotherapy, and none of these to the axilla.

The majority (60%) of patients were aged between 65 and 79 at the time of 20 year follow up.

**Exclusion criteria** Death, refusal to participate, mental/physical incapacitation, loss of contact.

**Population** number of patients = 263.

**Interventions** The study aimed to retrospectively gather data on lymphoedema and its risk factors using the following methods:  
Telephone interview conducted by a Research Nurse;  
Questionnaire requesting further data including that based upon patients measuring their weight and arm circumference;  
Review of data from initial cohort investigations, including medical notes.

**Outcomes** Incidence of lymphoedema based upon patient-performed arm circumference measurements at three sites on both arms and calculated as follows:

Greatest difference of three points of measurement between both arms:

Severe Lymphoedema: difference  $\geq 2$ " (5.08cm);

Moderate lymphoedema: difference between 0.5" (1.27cm) and 2" (5.08cm);

Mild lymphoedema: difference  $< 0.5$ " (1.27cm) and with subjective reporting of arm swelling by the patient;

No lymphoedema: difference  $< 0.5$ " (1.27cm) and without subjective reporting of arm swelling by the patient.

Risk factors explored were:

Demographic (age, education);

Surgical/pathological (type of mastectomy, removal of thoracodorsal nerve

bundle and/or pectoralis muscle, total drainage volume, number of axillary lymph nodes excised, radiotherapy, primary tumour size, number of positive axillary nodes);

Subsequent events (using two scales of physical activity levels, occupation/hobbies, chronic illnesses, weight at time of treatment, change in body weight since treatment, arm infections, injuries or elective surgery).

**Follow up** This study was performed at the 20 year follow-up point, in survivors within the original cohort.

**Results** 49% (128/263) of the surviving cohort had lymphoedema and 51% (135/263) did not. Severity of lymphoedema was as follows:

Severe 13% (33/263) of surviving cohort;

Moderate 17% (45/263)

Mild 19% (50/263).

Of 211 women with unilateral axillary dissection only the results were similar:

Severe 13% (27/211)

Moderate 18% (38/211)

Mild 19% (40/211)

None 50% (106/211)

Subjectively, 40% (21/52) of the patients treated bilaterally for breast cancer reported swelling in the 'first treated' arm compared to 51% (108/211) of patients treated unilaterally.

The 21 bilaterally treated patients who reported arm swelling all reported less swelling in the 'second treated' arm than in the 'first treated' arm.

All 60% (31/52) of the patients treated bilaterally for breast cancer subjectively reporting no swelling in the 'first treated' arm also reported no swelling in the 'second treated' arm.

In all surviving patients, of all potential risk factors examined, only two were associated with the presence of lymphoedema:

History of infection/injury: 74% (41/55) of patients with one or more episodes of infection/injury had lymphoedema at 20 years compared to 42% (87/208) of patients with no episode (by Chi square for a trend,  $p=0.001$ );

Weight gain since treatment: 60% (50/84) of patients with a weight gain  $>4.54$ kg since treatment had lymphoedema at 20 years compared to 51% (40/79) of patients with a weight gain of 4.54kg or less and 39% (39/100) of patients with no weight gain (by Chi square for a trend,  $p=0.02$ ).

Considering only the 211 patients treated unilaterally for breast cancer, the results were similar except that weight at time of treatment replaced weight change since treatment as a risk factor for lymphoedema at 20 years.

Time to onset:

In the entire surviving cohort 77% (203/263) of patients reported that swelling occurred within 3 years of diagnosis. In the remaining 30 patients the rate of onset was gradual at approximately 10 patients per 5 year interval.

Only infection/injury was found to be an independent risk factor for late onset lymphoedema (no data shown).

**General comments** Authors report that a 2.5cm difference between arms is a common definition for lymphoedema.

No baseline arm circumference measurements were taken at original outset of the cohort study so potentially a problem arises in estimating lymphoedema in patients with bilaterally swollen arms, especially those treated for bilateral breast cancer. This would serve to underestimate incidence. However incidence and severity of lymphoedema are similar between patients treated bilaterally and patients treated unilaterally.

Definition of lymphoedema was based on a mixture of objective and subjective measurements, such that it is difficult to separate objective findings from subjective findings. Subjective reporting of lymphoedema by patients may have been influenced by their own objective measurements. The patients' objective measurements were validated in a different study population.

Authors acknowledge a possible recall bias re: reporting of infections since standard advice to patients was aimed at avoiding infection/injury. This may overestimate the importance of infection/injury as a risk factor when data is gathered retrospectively.

## Prospective comparative studies

Campisi, Davini, Bellini, Taddei, Villa, Fulcheri, Zilli, Da Rin, Eretta & Boccardo . Is there a role for microsurgery in the prevention of arm lymphedema secondary to breast cancer treatment? *Microsurgery* 26[1]. 2006.

Design: Prospective comparative study (therapy), evidence level: 3  
Country: Italy, setting: Tertiary care

**Inclusion criteria** Patients treated in 'different' centres (Genoa specified) in Italy between April 1992 and June 1994. Specified inclusion criteria were:  
Invasive T1 or T2 tumours;  
Treatment with axillary lymphadenectomy and radiotherapy.

**Exclusion criteria** None specified.

**Population** number of patients = 50.

**Interventions** Patients were allocated to two groups (allocation not reported as random):

Intervention group (n=25)

Received lymphatic scintigraphy, physical examination and volume estimation by water displacement at 1, 3 and 6 months and 1, 3 and 5 years after surgery. Patients with identified lymphoedema received a physical rehabilitation regime (manual and peristaltic-mechanical lymphatic drainage, multilayer elastic bandage and elastic stocking). Where lymphoedema persisted, microsurgery was performed, to create lymphatic-venous anastomoses.

Control group (n=25)

Received physical examination and volume estimation alone at the same frequency as above.

**Outcomes** Incidence of lymphoedema (based upon a volumetric difference of  $\geq 150$ ml)

Preventative value of early intervention

**Follow up** 1, 3 and 6 months and 1, 3 and 5 years after surgery.

**Results** In the intervention group lymphoscintigraphy indicated lymphatic impairment in 22 patients between 1 month and 3 years after treatment. All 22 patients underwent physical rehabilitation and clinically evident lymphoedema occurred in 2 patients. These 2 patients underwent microsurgery and experienced long term regression of lymphoedema (minimum 4 years post surgery at time of writing).

Lymphoedema occurred in 9 patients in the control group.

Lymphoedema incidence was higher in the control group (9/25) than in the

intervention group (2/25) (Fisher's exact test,  $p=0.01$ ).

**General comments** Small, non-randomised study.

Uncertain whether the 50 patients included represent a complete series of eligible patients or a convenience sample.

Patients represented are those heavily treated in the axilla: axillary lymphadenectomy plus radiotherapy. Mean number of nodes excised 14 (range 12-26). Radiotherapy was performed in post-operative weeks 3-6.

Baseline for arm volume changes not reported.

It appears that only patients in the intervention group were treated; possibly the paper omits reporting of treatment of patients for lymphoedema in the control group. No statement is included of ethical approval.

It is difficult to determine whether the interventions were performed according to a pre-defined study protocol or whether patients were treated ad hoc.

It is possible that the authors report on two observational groups of patients treated according to individual need/choice.

Cornish, Chapman, Thomas, Ward, Bunce & Hirst . Early diagnosis of lymphedema in postsurgery breast cancer patients. Annals of the New York Academy of Sciences 904. 2000.

Design: Prospective comparative study, evidence level: 3  
Country: Australia.

**Inclusion criteria** 102 patients treated with surgery for breast cancer at the Wesley Breast Clinic in Brisbane were selected at random for inclusion in this study.

**Exclusion criteria** None reported.

**Population** number of patients = 102.

**Interventions** This study aimed to assess the efficacy of \_\_\_\_\_ to predict the early onset of lymphedema in breast cancer patients following treatment.

Patients received diagnostic testing for lymphoedema using multiple frequency bioelectrical impedance analysis (MFBIA): a small AC current was passed through patient's operated and non-operated arms and volume differences between arms were estimated as a function of electrical impedance.

MFBIA measurements were recorded presurgery, at one month and three months after surgery, and then at two-month intervals for up to 24 months postsurgery.

MFBIA measurements were evaluated against clinical diagnosis by clinical diagnosis by the patients' physician(s) as an apparent 'gold standard' and also against volume estimation by limb circumferential measurement (but with no criteria stated for a positive result).

**Outcomes** Performance of MFBIA as an early diagnostic test compared to clinical diagnosis as a gold standard. A positive result by MFBIA was indicated by a value outside the 99.7% CI.

they were referred to their physician for clinical assessment

**Follow up** At the time of reporting 90/102 patients were monitored for >18 months and 52/102 for >24 months.

**Results** 19 patients developed clinically apparent lymphedema and, of these, 12 received treatment.

There were positive tests in 21 patients by MFBIA, including all patients with clinically diagnosed lymphoedema, and preceding clinical diagnosis by up to four months.

At the time of reporting there were no false negative results by MFBIA.

The data presented represent sensitivity 100%, specificity 97.6%, positive predictive value 90.5%, negative predictive value 100% but should be interpreted with caution: see comments.

Limb volume by arm circumference measurement as a test for lymphoedema had positive result in 1 patient.

**General comments** Paper represents interim report of a study before final accrual point is reached, and without the full intended analyses.

The 99.7% CI used as a threshold for a positive lymphoedema result by MFBIA was based upon testing of group of healthy control subjects (n = 50).

Although a result is cited for volume estimation by arm circumference measurement, no details are provided for criteria for a positive result for lymphoedema using this method.

Although 88% of patients were followed up for 18 months or more, further incident cases of lymphoedema would weaken the diagnostic performance of MFBIA.

Clinical diagnosis of lymphoedema is fallible as a gold standard. Inter-observer error may occur if the patients had different treating physicians. It is not reported that diagnosing clinicians were blind to MFBIA results. The 'gold standard' was not independent of the MFBIA test since only patients with positive MFBIA result were sent for clinical confirmation. It is possible that given a negative MFBIA result, a positive clinical assessment may have arisen (if referrals were thus permitted) due to the subjective nature of lymphoedema diagnosis.

The study used bi-monthly MFBIA testing to achieve the results shown, which may have accessibility and resource implications.

Gordon, Battistutta, Scuffham, Tweeddale & Newman . The impact of rehabilitation support services on health-related quality of life for women with breast cancer. Breast Cancer Research & Treatment 93[3]. 2005a.

Design: Prospective comparative study (therapy), evidence level: 3  
Country: Australia, setting: Community/secondary care

### **Inclusion criteria**

Intervention groups:

Women attending the DAART and STRETCH programmes between May 2002 and July 2003 in Queensland, Australia, who:

Were diagnosed with primary, unilateral breast cancer;

Spoke English;

Had no cognitive problems;

Were aged 25-74 years.

Control group:

Women recruited to the project titled 'Pulling through - a breast cancer recovery study'

**Exclusion criteria** Women who are 'too ill' or had previously attended one of the two interventions;

In the DAART group, women who were recruited in a known trial of sentinel node biopsy.

**Population** number of patients = 275, mean age = 56 years.

**Interventions** This study aimed to compare health-related quality of life (HRQOL) and upper body disability between patients receiving two community interventions and also with a non-intervention control group. Groups were as follows:

DAART group (n=36) = patients sampled from those receiving the programme of the Domiciliary Allied Health and Acute Care Rehabilitation Team (DAART): a 6 week programme commencing 4-5 days post-surgery.

STRETCH group (n=31) = patients sampled from those receiving the programme: Strength Through Recreation Exercise Togetherness Care Health (STRETCH): an 8 week programme commencing 8 weeks post-operatively.

Both the above programmes focussed on physical therapy for shoulder mobility after surgery.

Control group (n=208) = patients sourced through an existing research programme i.e. patients from the same locality identified through population-based methods.

Intervention: Patients in all three groups were sent a self-administered questionnaire at four time points: pre-intervention, post-intervention, 6 months and 12 months from date of diagnosis.

**Outcomes** HRQOL was assessed using four validated instruments:

Functional Assessment of Cancer Therapy including a breast cancer subscale (FACT-B);

Functional Assessment of Cancer Therapy (FACT-G, = general), which excludes the breast cancer specific subscale;

Extended Functional Assessment of Cancer Therapy with a specific arm morbidity subscale (FACT-B+4);

Disability of the Arm, Shoulder or Hand (DASH) scale, a scale based on performing daily activities.

**Follow up** Assessment was made at at four time points: pre-intervention, post-intervention, 6 months and 12 months from date of diagnosis (pre-intervention was post-surgery, but varied from between 3-8 weeks post-diagnosis for DAART and STRETCH groups, respectively).

**Results** Comparing pre/post-intervention measures, benefits were evident for functional well-being, including reductions in arm morbidity and upper-body disability (DASH) for participants completing the DAART service at one-to-two months following diagnosis.

In contrast, minimal changes were observed between pre/post-intervention measures for the STRETCH group at approximately 4-months post-diagnosis.

Overall, mean HRQoL scores (adjusted for age, chemotherapy, hormone therapy, high blood pressure and occupation type as confounding variables) improved gradually across all groups from 6- to 12-months post-diagnosis, and no prominent differences were found.

Adjusting for known confounders (see comments) there were no statistically significant differences between the three treatment groups compared for any subscale of any instrument evaluated (physical, functional, breast cancer, arm morbidity, FACT-G, FACT-B, FACT-B+4 and DASH).

However the control group had clinically important higher scores than the intervention groups for the functional, breast cancer, FACT-G and FACT-B subscales.

20-40% of women at 12 months post-diagnosis had declining HRQOL scores, despite receiving supportive care services.

**General comments** A study drawback is that the three study groups were independent of each other, representing different research/rehabilitation-support settings and as such, differed considerably; subjects were candidates specifically for the DAART and STRETCH interventions, and the control group is a convenience sample based upon existing, ongoing research.

In particular the DAART participants had poorer socio-demographic variables (e.g. older age, less income), STRETCH participants had more serious disease and treatment-related variables (more positive nodes, more chemotherapy) and the control group had poorer general health (e.g. cardiovascular disease, high blood pressure, asthma).

NB there were more statistically significant differences for these characteristics than there were for the outcomes of interest and several (age, chemotherapy, hormone therapy, occupation and high blood pressure were found by testing to be significant confounders).

The instruments used to measure HRQOL included meaningful levels of change that are, in validation studies in the literature, considered to represent clinical importance, irrespective of statistical significance. These, and the alpha level for the latter, were defined a priori.

Since so many scales are used, many of which have overlapping subscales, some clarity and meaning is lost in the results.

The recruitment rate was approximately 50% of eligible patients.

Study does not provide any compelling evidence: results seen may be severely influenced by unknown interactions/confounders.

## Prospective case series

Berlin, Gjores, Ivarsson, Palmqvist, Thagg & Thulesius . Postmastectomy lymphoedema. Treatment and a five-year follow-up study. International Angiology 18[4]. 1999.

Design: Prospective case series (harm), evidence level: 3  
Country: Sweden, setting: Secondary care/community

**Inclusion criteria** Patients treated with modified radical mastectomy for breast cancer between 1979 and 1983 at Central Hospital, Vaxjo, Sweden. Of 238 eligible patients, 226 were included in the study.

**Exclusion criteria** None reported.

**Population** number of patients = 226.

**Interventions** All patients in the series underwent arm volume measurement by water displacement

**Outcomes** Incidence and severity of postmastectomy arm oedema, determined as follows:

Slight: increase in arm volume of between 100ml and 400ml;

Moderate: increase in arm volume of between 400ml and 750ml;

Severe: increase in arm volume  $\geq$ 750ml

(In unilateral cases differences were based upon the untreated arm. In bilateral cases, differences were based on the pre-treatment value).

Onset of arm oedema.

Correlation of arm oedema to lymph node metastasis and post-operative radiotherapy.

**Follow up** 5 years in total. Assessment was performed preoperatively, 6 months post-operatively and then yearly to 5 years post-operatively.

**Results** 20% (46/226) of patients developed lymphoedema in the 5 year follow-up period with severity as follows:

Slight: 57% (26/46) of patients with lymphoedema;

Moderate: 30% (14/46);

Severe: 13% (6/46).

The mean volume increase was 418ml.

37% (17/46) of patients developing lymphoedema did so within 6 months of surgery and 63% (29/46) within 1 year of surgery. The risk of developing lymphoedema was highest during the first year following surgery (by Chi square,  $p=0.002$ ).

Significantly more patients with severe or moderate lymphoedema had received radiotherapy ( $p<0.01$ , no further details provided).

5/6 cases of severe lymphoedema developed in patients with positive axillary nodes detected peri-operatively plus radiotherapy.

**General comments**

Modified radical mastectomy includes dissection of axillary lymph nodes.

During follow-up:

53 patients died

9 patients moved away

7 left the study due to non breast cancer illness

157 (70%) were followed for 5 years.

10 patients received bilateral mastectomy. Otherwise, few patient details provided.

Reported result re: axillary node involvement is confounded by subsequent radiotherapy.

Lane . The effect of a whole body exercise programme and dragon boat training on arm volume and arm circumference in women treated for breast cancer. *European Journal of Cancer Care* 14[4]. 2005.

Design: Prospective case series, evidence level: 3  
Country: Canada, setting: Community

**Inclusion criteria** 18 women volunteered to participate in this study, of 100 women present at a novice meeting of 'Abreast in a boat' in January 2003 in Vancouver, Canada.

Eligible participants were those who had completed their treatment for Stage I-III breast cancer over 6 months ago, could satisfactorily complete a physical activity readiness questionnaire (PAR-Q) and were naive to dragon boat paddling.

2 women dropped out at the first assessment point leaving 16 women who completed the programme.

12/16 women had received axillary dissection in addition to breast surgery.  
15/16 women had received radiotherapy to the axilla.  
Time from diagnosis had range 6 months to 17 years.  
No participant had clinical lymphoedema on entry to the study.

**Exclusion criteria** Defined by inclusion criteria

**Population** number of patients = 16, mean age = 52 years.

**Interventions** This study aimed to examine the effect of a dragon boat racing exercise programme on arm circumference, arm volume and upper body strength.

The exercise programme consisted of:  
Aerobic exercise and resistance training 3 times a week, over the entire study period;  
Dragon boat training, twice a week from week 8.  
The programme was supervised and progressive in terms of frequency, duration and intensity.

**Outcomes** Body Mass Index;  
Arm circumference determined at two points: 10cm proximal to the styloid process of the ulna (CIRC 10) and 15cm proximal to the lateral epicondyle (CIRC 15);  
Arm volume determined by water displacement;  
Upper body strength as measured using 1-RM bench press assessment.

**Follow up** Assessment of outcome was made at three points:  
T1 (week 0): Prior to the start of the exercise programme;  
T2 (week 8): Immediately prior to the start of the dragon boat training;  
T3 (week 20): At completion of the dragon boat season

**Results** There was no significant change in BMI over the whole study period ( $p=0.377$ ).

The 1-RM measure of body strength increased significantly from T1 to T3 (55.3kg and 66.2kg respectively,  $p<0.0001$ ).

A 2 arm by 3 session MANOVA analysis indicated that there was no significant difference between the ipsilateral and contralateral arms at any of the assessment points (no further details shown).

The mean difference in CIRC 10 and CIRC 15 increased from T1 to T3: (CIRC10: difference,  $d=0.49$  cm, 95% CI 0.25 to 0.73,  $p<0.0001$ ; CIRC15:  $d=1.33$  cm, 95% CI 0.78 to 1.88,  $p<0.0001$ ).

Arm volume significantly increased from T1 to T3 ( $d = 100$ ml, 95% CI 69 to 130,  $p< 0.0001$ ).

Authors conclude that the 20 week exercise intervention was not found to cause lymphoedema.

**General comments** A power calculation indicated a minimum of 13 patients were required.

Time from initial breast cancer diagnosis had large range, with regard to risk of developing lymphoedema.

Authors' conclusion that the increase in arm circumference and volume is due to muscle hypertrophy and not lymphoedema should be interpreted with caution in this non randomised trial; authors report that using a threshold of a difference of 2.54cm in circumference between arms, 1 participant in this study had mild lymphoedema at the T3 assessment point. The longest assessment point was at 20 weeks i.e. end of the programme.

However the results may be promising since the majority (12/16) of the patients had received both axillary dissection and axillary radiotherapy.

Loerzel, Dow, Subramanian & Ramaswamysanthanam (2005). Secondary analysis of lymphedema incidence, prevention and management in breast cancer survivors. *Oncology Nursing Forum* 32[2]. 2005.

Design: Prospective case series (therapy), evidence level: 3  
Country: United States, setting:

**Inclusion criteria** Study population was patients treated for breast cancer in Orlando, Florida. All 150 subjects were within the first year of diagnosis of breast cancer and were part of a larger study called the Breast Cancer Education Intervention (BCEI).

**Exclusion criteria** None reported.

**Population** number of patients = 150.

**Interventions** This study aimed to:

Measure the incidence of lymphoedema in a series of patients treated for breast cancer;  
Discuss the use of self-care interventions to prevent and manage lymphoedema.

**Outcomes** Incidence of lymphoedema, self-reported by patients.  
Patient application of preventive strategies.  
Patient reported reasons for non-application of preventive strategies.

**Follow up** Incidence of lymphedema was obtained during this first year at a time point ranging from 2 to 12 months after diagnosis.

**Results** The lymphoedema incidence in the period studied was 33/150=22%.

119/150=79.3% of patients received lymphoedema information. Of these 48/150=40.3% used the strategies to prevent lymphoedema and 70/150=58.8% did not use the strategies at all.

Patients did not believe they were at risk for lymphoedema because:

They were unaware of the existence of lymphoedema;

Their oncology team told them they were not at risk;

They had a personal belief that they were not at risk.

**General comments** Information extracted from conference abstract plus contact with first author.

Neither time of onset of lymphoedema nor its severity were measured.

## Prospective cross sectional studies

Yik, So, Suet & Suk . Lymphoedema care of breast cancer patients in a breast care clinic: A survey of knowledge and health practice. Supportive Care in Cancer 9[8]. 2001.

Design: Prospective cross sectional study, evidence level: 3  
Country: Hong Kong, setting: Secondary care

**Inclusion criteria** Convenience sample of patients attending a breast cancer clinic at the Prince Of Wales Hospital, Hong Kong. Specific criteria were:

Diagnosis of breast cancer;

Either gender;

Age 18 years or above;

Ability to read Chinese;

Previous treatment with any combination of surgery, chemotherapy and radiotherapy for breast cancer.

Age of respondents ranged from under 30 years to over 60, with 41.5% aged between 40 and 49 years.

**Exclusion criteria** Defined by inclusion criteria.

**Population** number of patients = 171.

**Interventions** This study aimed to measure, using a patient questionnaire:

Prevalence of lymphoedema;

Patient knowledge of lymphoedema, including methods of preventing/treating lymphoedema;

Demographic/disease factors associated with lymphoedema.

**Outcomes** The questionnaire measured:

Section I: demographic data;

Section II: patients' knowledge of lymphoedema prevention and care;

Section III: Occurrence and management of lymphoedema;

Section IV: Practice of physiotherapy.

**Follow up** Single point of assessment, but not reported in terms of follow-up periods for patients or time since their diagnoses.

**Results** Knowledge of lymphoedema:

The mean score for knowledge of lymphoedema (of a possible range of 0-9, 9 representing most knowledge) was 4.07 (SD=2.35, mode=2) The authors cited this as 'on the low side'. 82.5% of patients reported that they knew they were at risk of lymphoedema.

There was no significant difference in the level of knowledge between patients who had developed lymphoedema and those who had not, nor between patients who had attended a health talk on lymphoedema and those who had not (Chi square, no details provided).

Nurses were the most frequently cited source of education on lymphoedema

(with frequency of 70), followed by doctors (65) and physiotherapists (61), health talk (52) and friend/relative (45).

105/171=61.4% of patients reported that they performed arm exercises on the advice of a health professional, with frequency of once daily (40.5%) to less than once weekly (36.8%). Only 11 (6.4%) patients performed manual lymphatic massage on the instruction of a health professional.

Occurrence and management of lymphoedema:  
Lymphoedema was reported by 78/171=45.6% of patients.

Of 16 different treatment combinations received, the combination of mastectomy, lymph node dissection, chemotherapy and radiotherapy had a statistically higher than expected rate of lymphoedema (83/171=48.5%, Chi square=6.305, p=0.043).

The most frequent time intervals from start of treatment to onset of lymphoedema were  $\leq 3$  months (26.9% of cases) and between 1-3 years (29.5% of cases). Treatment modality was not found to be significantly associated with time to onset of lymphoedema.

Of 78 patients with lymphoedema, 26 (34.7%) had been referred for physiotherapy.

**General comments** 'Convenience sample' appears to be a case series, but no period of recruitment reported.

The questionnaire, designed by researchers, was assessed for reliability using Cronbach's alpha with values of 0.6395, 0.9984, 0.7274 and 0.9914 for sections I, II, III and IV respectively.

No ethnic data are provided but all respondents spoke Chinese.

Response rate was 171/180=95%.

Prevalence of lymphoedema result was based on patient reporting: no detail provided on the definition presented to patients in the questionnaire. Similarly, true extent of follow-up not reported.

The sources of information cited may be misleading since we do not know who provided the 'health talks' e.g. nurse etc.

Radiotherapy is not reported by anatomical site.

All outcomes are patient reported and therefore subject to recall bias or suggestion by the questionnaire.

Unruh & Elvin . In the eye of the dragon: women's experience of breast cancer and the occupation of dragon boat racing. Canadian Journal of Occupational Therapy 71[3]. 2004.

Design: Prospective cross sectional study, evidence level: 3  
Country: Canada, setting: Community

**Inclusion criteria** 3 women treated for breast cancer were identified and contacted via a brochure about the dragon boat racing team to which they belonged.

All women were in their early 50s and were diagnosed with breast cancer 2-4 years previously. The women became interested in dragon boat racing between 6 months and 3 years following their diagnoses.

2/3 women had received surgery, 2/3 chemotherapy and 3/3 radiotherapy.

**Exclusion criteria** None reported.

#### **Interventions**

The aim of this small study was to investigate the impact of dragon boat racing on psychological well being of women treated for breast cancer.

Each woman underwent two semi-structured interviews designed to prompt conversation about:

1. The attraction of dragon boat racing;
2. Organisation of the dragon boat team and the woman's involvement;
3. The benefits and risks of involvement;
4. The overall meaningfulness of dragon boat racing to the participant's life.

Interview transcripts underwent content analysis and thematic analysis to create a thematic framework to present the findings.

**Outcomes** Themes and subthemes identified from the analysis i.e. where reported by 2 or more participants.

**Follow up** Single point of assessment; all women were diagnosed with breast cancer 2-4 years previously.

**Results** 7 themes were identified:

1. The attraction of dragon boat racing

Women were attracted to the sport for two reasons: a) Active support - the support inherent in being with other women who shared the cancer experience; b) Enthusiasm and positive energy - the energising/motivating effect of dragon boat racing.

2. Physical and emotional well-being

Women spoke more often about emotional well being but it was clear that this came from the physical achievement and of being together. Women cited

also their noted improvements in physical fitness/ability. Dragon boat racing helped the women put a positive interpretation on a negative experience, regain self-confidence and make personal changes for their well-being.

### 3. Competition as positive energy

Competition provided: a) An impetus for change - competition provided the emotional and physical benefits that the women experienced; b) Individual and team pride - generated amongst middle aged women who might not normally be expected to be involved in such vigorous physical activity.

### 4. Dragon boat racing as social support

Support given to each other was implicit and informal but it also had tangible and practical dimensions: a) support was implicit by a need to do something positive about their health without focusing on the disease itself; b) tension existed between the goals of providing support for one another and the goal of competitive racing.

### 5. Transcendence/connectedness/oneness

Transcendence over the cancer experience, connectedness with other women and oneness with all the women who struggled with breast cancer was a recurrent theme e.g. before racing, teams visualised together to ensure they were thinking positively.

### 6. Recurrence of breast cancer and death of team members: fear, identification and coping

Recurrence of breast cancer renewed fears for the individual, and the team appeared to be caught off guard when a team member died, with no prepared way of dealing with the loss.

### 7. Increasing public awareness and perceptions of breast cancer

The women spoke about the opportunity to promote public awareness and positive health behaviours e.g. by providing information about risk factors and screening. The positive interpretation of the negative experience of breast cancer was an important part of their public stance; the racing activities in national competitions publicly challenged the impression that women with breast cancer were ill and limited in their ability to do things.

Authors conclude that the study demonstrated that dragon boat racing holds meaning for women with breast cancer in many different ways and that future research should further explore the relationship between activity and experiences of serious illness.

**General comments** Study is limited by its sample size of n=3.

The three women sampled were already active dragon boat racing participants; therefore findings of study do not automatically apply to the whole population of patients with breast cancer.

## Retrospective cross sectional studies

Coward . Lymphedema prevention and management knowledge in women treated for breast cancer. Oncology Nursing Forum 26[6]. 1999.

Design: Retrospective cross sectional study (other), evidence level: 3  
Country: United States, setting: Secondary care

**Inclusion criteria** A convenience sample of 160 women treated for breast cancer and who used the services of the Austin Breast Cancer Survivor Centre were sent questionnaires. 72 (45%) women returned questionnaires. The research was undertaken in Austin, Texas.

Most respondents stated that they had stage I (n=29) or stage II (n=31) breast cancer.

71/72 = 98.6% of women reported that they had undergone lymph node surgery.

16/72 reported that they had received radiotherapy to the axilla.

**Exclusion criteria** None reported.

**Population** number of patients = 72.

**Interventions** The study had two aims:

1. To measure what information patients treated for breast cancer recall being given on lymphoedema prevention/management and what activities they used;
2. To examine factors related to the occurrence of lymphoedema.

These data were gathered using a questionnaire measuring patient knowledge and disease/treatment variables.

**Outcomes** Score on a lymphoedema knowledge scale (LKS). Highest possible score (reflecting most knowledge) = 18, where score is based on knowledge of 18 recommendations of the US National Lymphoedema Network.

Incidence and time of onset of lymphoedema.

Disease characteristics, treatment variables, problems during treatment that may precipitate lymphoedema.

Use of lymphoedema prevention strategies.

**Follow up** Study has single point of measurement. The time since initial diagnosis had mean 3.9 years, median 2.6 years and range 2 months to 17 years.

**Results** Score on LKS had mean 8.6 (SD 4.3), median 9 and mode 8. Thus, patients typically reported being told of 8 or 9 of the 18 strategies to prevent/manage lymphoedema.

The most frequently reported items (i.e. by 50% of respondents or more) were:

Risk of lymphoedema;

That lymphoedema can occur at any time;  
To not permit blood pressure measurement/venepuncture on the operated arm;  
To avoid heavy lifting;  
To be aware of inflammation/infection;  
To avoid trauma.

For all items, surgeons reportedly provided the most information followed by reading material and other survivors. However advice on blood pressure measurement and venepuncture was most commonly reported as coming from nurses.

55/72=76% of respondents reported using at least one lymphoedema prevention/management strategy; most commonly avoiding heavy lifting (n=29) and trauma (n=16). However the mean number of strategies used was only 2.9 (SD=3.2).

27/72=37.5% of respondents reported experiencing lymphoedema.

The mean length of time from diagnosis to onset of lymphoedema was 12.6 months (range zero to 48 months) .

Women reporting lymphoedema were more likely to have received radiotherapy to the axilla (Chi square=5.486, df=1, p=0.02) and to the breast (Chi square=4.192, df=1, p=0.04).

No association was detected between lymphoedema occurrence and type and stage of breast cancer, cancer on the side of the dominant arm, any other treatment variable or reporting of problems (e.g. infection, fluid collection in the breast) after surgery.

No statistically significant difference was found in LKS score between women reporting lymphoedema and those reporting no lymphoedema (t=-0.837, df=69, p=0.40), nor in the mean number of prevention strategies reported (t=1.004, df=70, p=0.32).

Women reporting lymphoedema were statistically significantly more likely to report the use of any prevention strategy than those reporting no lymphoedema (Chi square=4.444, df=1, p=0.04).

**General comments** Retrospective survey susceptible to recall bias; the questionnaire apparently sought medical details from respondents such as number of lymph nodes biopsied. The patient-reported 'triggers' for lymphoedema are particularly susceptible to recall bias or 'suggestion' by the questionnaire. The 45% response rate may mean that responders were more knowledgeable than non responders.

The study population represented are women who choose to use the Austin Breast Cancer Survivor Centre; and may not represent the population of all women treated in Austin, although they were reportedly similar to other

studies reported in the literature.

The questionnaire was verified by consulting 1 expert nurse and 1 well informed breast cancer survivor and by pilot testing in 5 patients (Cronbach's alpha = 0.85). The items explored appear to be comprehensive and based upon consensus amongst experts.

The finding that women with lymphoedema were more likely to use a prevention strategy may be affected by recall (e.g. notion that patients 'did what they could' to prevent the condition. Similarly the 'prevention' strategies may have been used after onset of lymphoedema.

No detailed definition is given for patient reported lymphoedema, although likely to be subjective.

Cordero, Garrido & Langa . Need for information to prevent postmastectomy lymphedema. *Rehabilitacion* 37[3]. 2003.

Design: Retrospective cross sectional study, evidence level: 3  
Country: Spain, setting: Secondary care

**Inclusion criteria** Patients with lymphoedema secondary to breast cancer surgery, operated on at two hospitals in Valencia between 1982 and 2001. 1.5% of participants had bilateral lymphoedema. Severity of lymphoedema was mild in 26.2% of patients, moderate in 47.7% of patients and severe in 26.2% of patients. 98.5% of patients had received axillary clearance and 75.4% radiotherapy (site of treatment not specified).

**Exclusion criteria** None reported.

**Population** number of patients = 65, age range 32 to 85 years, mean age = 57 years.

**Interventions** Patients were sent a questionnaire, designed to measure retrospectively, the extent of information given to patients after surgery, specifically:

Advice and lymphoedema prevention strategies;

Service;

Profession of the information provider.

**Outcomes** Patient reported extent of information provided.  
Professionals providing information.

**Follow up** Not directly reported; patients included those in whom lymphoedema developed at 10 years after initial surgery.

**Results** Only 24.6% of patients reported receiving any information after surgery. Of these:

37.5% reported hearing the word 'lymphoedema';

3% reported a discussion of risk factors for lymphoedema;

81.3% were told to lift their arm;

87.5% were taught basic arm exercises

87.5% were told to avoid exertion;

50% were advised to avoid venepuncture or blood pressure measurement in the affected arm.

Patients reported that the following professionals provided information on lymphoedema:

Oncologists (70.8% of patients who received information);

Medical rehabilitation professionals (10.8%);

Family doctors (4.6%);

Surgeons (3.1%);

Others (10.8%).

**General comments** Article written in Spanish.

Exact method to sample patients not reported; likely to have been based upon

clinical diagnosis of lymphoedema in medical notes, or where patients had ongoing contact with care setting.  
Study could be heavily affected by recall bias.  
Very limited applicability to the UK.

Karki, Simonen, Malkia & Selfe . Postoperative education concerning the use of the upper limb, and exercise and treatment of the upper limb: cross-sectional survey of 105 breast cancer patients. *Supportive Care in Cancer* 12[5]. 2004.

Design: Retrospective cross sectional study, evidence level: 3  
Country: Finland, setting: Secondary care

**Inclusion criteria** All patients who had undergone surgery for breast cancer at 3 hospitals in the Satakunta district of Finland in the year 1996-1997.

**Exclusion criteria** Subsequent local recurrence of breast cancer, acute psychiatric illness, serious co-morbidity (e.g. hip fracture) and hospitalisation.

**Population** number of patients = 105, age range 26 to 89 years, mean age = 59 years.

**Interventions** Questionnaire administered 6 months after surgery to collect qualitative and quantitative data on provision of information to patients concerning arm/shoulder mobilisation and prevention of lymphoedema.

Questionnaires were analysed in conjunction with review of medical notes for detailed information on treatment including physiotherapy.

**Outcomes** The questionnaire aimed to measure the amount and content of information given to patients prior to hospital discharge, specifically:

Recalled post-operative education;  
Instructions for shoulder movement;  
Instructions on prevention/treatment of lymphoedema;  
Instructions on use of the upper limb;  
The person providing the information.

Results are usually presented by two groups according to type of breast surgery:

MRM = modified radical mastectomy

BSO = breast saving operation

**Follow up** The questionnaire was administered at 6 months after surgery.

**Results** The mean hospital stay was 4.2 days (SD 1.58). Length of hospital stay was not found to have any effect on the education provided for shoulder mobility (Spearman rho  $r=-0.13$ ,  $p>0.05$ ), oedema prevention/treatment ( $r=-0.10$ ,  $p>0.05$ ), strength training ( $r=-0.20$ ,  $p>0.05$ ) and use of the upper limb ( $r=-0.03$ ,  $p>0.05$ ). Age had some effect: older patients reported that they received less instruction for oedema prevention/treatment than younger patients ( $r=-0.229$ ,  $p=0.021$ ).

Shoulder movement

67% of MRM patients and 55% of BSO patients reported receiving sufficient information on shoulder movement. Qualitatively patients reported that they were instructed to carry out daily shoulder exercises.

#### Strength training

33% of MRM patients and 27% of BSO patients reported that they received sufficient instruction for strength training. Qualitative data showed that conflicting information was given to different patients.

#### Use of the upper limb

38% of MRM patients and 27% of BSO patients reported receiving sufficient information for use of the upper limb. Qualitative data suggested that patients were instructed to avoid heavy lifting and having blood tests taken using the operated arm.

#### Person providing information

57.1% of all patients reported the physiotherapist or the physiotherapy assistant as the person providing the most information as set out above.

Authors conclude that there is insufficient time reserved for educating patients prior to discharge from hospital on use of their upper limb after breast cancer surgery and that the information provided was sometimes inconsistent; possibly because health professionals were not aware of information provided by others. Older patients appeared to receive less information than younger patients.

**General comments** The outcomes of interest were derived from a recommended framework setting out when and how to provide information on mobilising the upper limb. The framework itself was derived from a review of the literature, with no evidence that the review was systematic.

Of 110 eligible patients, 106 returned the questionnaire, of which 105 provided sufficient data for analysis.

Questionnaire not appended in paper.

The possibility exists that patients excluded due to requiring subsequent hospital care may have biased results e.g. patients requiring further hospitalisation may have yielded different results to those that did not.

In this setting the information investigated was routinely provided by physiotherapists: in the case of 85 patients (81%) a description of the physiotherapy consultation was found in the medical records.

Cheema, B., Gaul, C., Lane, K., Singh, M. (2008) Progressive resistance training in breast cancer: a systematic review of clinical trials *Breast Cancer Research and Treatment* 109;9-26

**Design:** Systematic Review      **Evidence Level:** 1-

**Country:**

**Aim:** to systematically review studies that prescribed progressive resistance training (PRT)

following breast cancer surgery; to summarise the efficacy of PRT and to delineate areas for future investigations.

**Inclusion criteria:** RCTs, non-randomised controlled trials and uncontrolled trials published in peer reviewed journals.

Studies involving adults diagnosed and treated for breast cancer and prescribing PRT in isolation or combination with other exercise modalities.

**Exclusion criteria:** Studies prescribing PRT prior to breast cancer surgery.

**Interventions:** Progressive Resistance Training (PRT)

**Outcomes:**

Significant outcomes from each of the individual studies were presented and included measures of flexibility, quality of life, depression and strength.

**Results**

Only results relevant to the PICO (i.e. lymphoedema results) are presented here.

12 articles retrieved presenting results of 10 trials, 4 uncontrolled trials, one non-randomised controlled trial and 5 randomised controlled trials.

Unilateral, upper extremity lymphoedema was an entry criterion in one RCT and cases of lymphoedema were reported in other studies and did not preclude participation in these trials. One trial prescribed the use of compression sleeves during exercise in each enrolled participant while the use of compression sleeves was a decision made in conjunction with a lymphoedema specialist in other trials.

Lymphoedema incidence, secondary to exercise was tracked as an adverse effect in three RCT's and in three uncontrolled trials. No incidence or exacerbation of lymphoedema, either quantified or self-reported was attributed to the training regime.

No improvements in lymphoedema were reported.

**General comments**

No detailed information or results for lymphoedema were presented in this review as it was not the primary outcome of interest.

De Rezende, L., Franco, R., de Rezende, M., Beletti, P., Morais, S., Gurgel, M. (2006) Two exercise schemes in postoperative breast cancer: comparison of effects on shoulder movement and lymphatic disturbance *Tumori* 92;55-61

**Design:** Prospective Randomised Controlled Trial

**Evidence Level:**

**Country:** Brazil

**Aim:** To compare two schemes of exercise, directed or free, following modified radical mastectomy or quadrantectomy with axillary dissection, evaluating postoperative complications such as shoulder dysfunction and lymphatic disturbance.

De Rezende et al. (2006) conducted a small RCT to compare two schemes of exercise, directed or free, following modified radical mastectomy or quadrantectomy with axillary

dissection, evaluating postoperative complications such as shoulder dysfunction and lymphatic disturbance. There was no difference between the directed and free groups in the average range of motion for adduction, extension and internal rotation between preoperative and 42<sup>nd</sup> day postoperative when analysing the groups individually. There was a statistically significant difference in the average range of motion for abduction, flexion and external rotation when analysed individually. There was significant differences between the directed and free groups in the average range of motion for abduction ( $p=0.0077$ ), flexion ( $p=0.0087$ ), extension ( $p=0.0447$ ) and external rotation ( $p=0.0403$ ) between preoperative and 42<sup>nd</sup> day postoperative when analysed in relation to the exercise groups. There was no statistically significant difference between the two groups in relation to lymphatic disturbance and no clinically significant difference in the groups in relation to arm circumference. Statistically significant increases in the arm circumference at 7.5cm above the humeroradial joint were observed in the free group.

**Inclusion criteria:** women undergoing their first surgery for invasive breast cancer (modified radical mastectomy or quadrantectomy with axillary dissection) and who were treated in the Oncology ward of the Center for Integral Attention to Women's Health of the University of Campinas (CAISM-Unicamp) from March 23<sup>rd</sup> 2003 to July 13 2003.

**Exclusion criteria:** Women who had immediate breast reconstruction or bilateral surgery. Women who showed a difference of more than 2cm in the circumferences of the arms prior to surgery. Women who showed limitation of movement in the ipsilateral limb prior to surgery. Women who were evaluated with a greater than 20-degree difference in flexion and abduction before surgery. Those who were unable to understand the proposed exercise programme.

**Population:** N=60

**Interventions:** Directed Physiotherapy (Kinesiotherapy based on spontaneous exercises including movement for flexion, extension, abduction, adduction and internal and external rotation of the shoulder, either combined or isolated) versus Free exercise.

The directed group performed physiotherapy with a regimen of 19 exercises, performed 10 times with a 60 second interval between exercises compared with the free group who performed the exercise following the biomechanical physiological movements of the shoulder, with the exercises being done to the rhythm of music and without a defined sequence or number of repetitions.

**Outcomes:**

Shoulder Movement (range of Motion for abduction, adduction, extension, flexion, external rotation and internal rotation)

Lymphatic Disturbance (average drainage volume, arm circumference)

**Results:**

There was no difference between the directed and free groups in the average range of motion for adduction, extension and internal rotation between preoperative and 42<sup>nd</sup> day postoperative when analysing the groups individually. There was a statistically significant difference in the average range of motion for abduction, flexion and external rotation when analysed individually.

There was significant differences between the directed and free groups in the average range of motion for abduction ( $p=0.0077$ ), flexion ( $p=0.0087$ ), extension ( $p=0.0447$ ) and external rotation ( $p=0.0403$ ) between preoperative and 42<sup>nd</sup> day postoperative when analysed in relation to the exercise groups.

There was no statistically significant difference between the two groups in relation to lymphatic disturbance and no clinically significant difference in the groups in relation to arm circumference. Statistically significant increases in the arm circumference at 7.5cm above the humeroradial joint were observed in the free group.

**General comments**

The p value provided for the statistically significant increases in arm circumference is 0.332, it is not clear whether this is a misprint and there are no figures/tables in which the correct information may have been provided.

**Authors Comment:** The results of the study demonstrate that directed exercises were more efficient in the rehabilitation of ROM in the movements of flexion, abduction and external rotation than free exercise.

Although the study did not permit a longer follow-up time and the study was underpowered due to small numbers, there appeared to be an impact on shoulder dysfunction without lymphatic disturbance in postoperative rehabilitation.

## Health Economics Summary

A systematic review was conducted to assess the cost-effectiveness of strategies used to prevent arm lymphoedema. The initial search identified 159 hits, from which 153 papers were excluded on the bases of the tittle and the abstract. Six papers were obtained for appraisal: 4 of them were excluded because they were not relevant for the study question or were not economic evaluations (Forchuk et al 2004; Morgan et al 2005; Norman et al 2001; Orr et al 1999), one of them was not written in English, and one study was rejected because, although it compared the effectiveness and costs of Australian rehabilitation programs for breast cancer patients, lymphoma was not assessed in the study (Gordon et al 2005b). Therefore, no economic evaluations were identified from the systematic review. The GDG considered there to be insufficient clinical information available to enable robust economic modelling.

## **8.2 What strategies are effective in reducing arm and shoulder mobility problems after breast cancer surgery?**

### **Short Summary**

There is a considerable body of high quality evidence that evaluates strategies to reduce arm and shoulder mobility problems after breast cancer treatment.

RCT evidence suggests that physiotherapy or exercise interventions can improve arm and shoulder function in patients who have received surgery for breast cancer. However the RCTs do not consistently show such improvements for all outcome measures. There is no evidence from RCTs of higher rates of long term complications following physiotherapy or exercise interventions (Bendz and Fagevik 2002; Dawson *et al.* 1989; Gordon *et al.* 2005a; Johannsson 2005; Kilbreath *et al.* 2006; Lauridsen *et al.* 2005; Le Vu *et al.* 1997; Sandel *et al.* 2005; Wingate *et al.* 1989). One poor quality RCT suggests that commencing exercise on the 1st postoperative day may increase short term complications (Dawson *et al.* 1989)

Data from two RCTs suggest that the addition of stretching exercise to physiotherapy has no benefit in terms of arm/shoulder function, quality of life, muscular strength or rate of adverse effects. However in one RCT data were reported unclearly and the other RCT studied only 22 patients (Kilbreath *et al.* 2006; Lee *et al.* 2007). Data from two RCTs suggest that massage can bring benefit in terms of arm function in the short term. However the trials did not consistently find massage to be advantageous for all outcome measures (Forchuk *et al.* 2004; Le Vu *et al.* 1997).

RCT evidence suggests that the timing of physiotherapy within the first two postoperative weeks does not affect outcomes that are assessed one month or later from the date of surgery. RCT evidence suggests that physiotherapy given in the first postoperative week to patients with surgical drains in situ is associated with a larger drainage volume, compared to delayed physiotherapy, or compared to other interventions (for example, massage). (Bendz and Fagevik 2002; Chen and Chen 1999; Jansen *et al.* 1990; Johannsson *et al.* 2001; Le Vu *et al.* 1997; Van der Horst *et al.* 1985). RCT evidence suggests that for exercise interventions that commence between 6 weeks and 26 weeks from the time of surgery, the precise timing of the exercises does not influence outcomes; Sandel *et al.* 2005)

RCT evidence suggests that instructed physiotherapy or instructed exercise interventions are associated with improved patient compliance, a better range of arm movement and lower rates of lymphoedema compared to control arms in which patients receive booklets or other education for unsupervised exercise (Beurskens *et al.* 2007; Box *et al.* 2002a; Cinar *et al.* 2008; Gerber *et al.* 1992; Lauridsen *et al.* 2005; Na *et al.* 1999; Wang *et al.* 2005). Data from one RCT suggest that patients treated with zaltoprofen have improved range of shoulder movement during physiotherapy compared to patients in a control group (Hase *et al.* 2006).

## PICO

Population	Intervention	Comparison	Outcome
Patients who undergo surgery due to breast cancer – axillary clearance  Axillary RT  Both	<ul style="list-style-type: none"><li>• Physiotherapy</li><li>• Exercise, rehabilitation classes for patients with breast cancer</li><li>• Education for post-surgical arm/shoulder exercise</li><li>• Timing of exercises</li></ul>	Versus each other or none	<ul style="list-style-type: none"><li>• Patient Acceptability</li><li>• Patient Compliance</li><li>• Cost-effectiveness</li><li>• Muscle Strength</li><li>• Pain</li></ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

### Evidence Summary

There are several RCTs specifically targeting arm and shoulder mobility treatment after breast cancer treatment. Although there were several high evidence level studies, most sample sizes were very small making it unlikely that statistically significant effects could be demonstrated, the method to generate the sequence of randomisation, the allocation concealment procedure, blinding, ITT analysis and withdrawals were rarely mentioned making it difficult to assess the validity of the trials.

Several trials are directly relevant to the question, however patients with pre-existing shoulder problems were often excluded from the trials and these may be the patients who are most at risk of complications so the best strategy for treating those patients would be especially important to know.

Physiotherapy is beneficial for arm and shoulder function and does not appear to cause more adverse events than non-treatment.

There is conflicting evidence for regimes offered directly after surgery, especially when the drains are still in place and for outcomes assessed close to surgery including drainage volume.

Instructed physiotherapy shows better results regarding function compared to exercise instruction booklets or other self-exercise programmes.

Stretching exercise in addition to physiotherapy has no clear additional beneficial effect on function, quality of life, strength or adverse effects.

### Exercises

#### Physiotherapy and 'exercises'

Physiotherapy is beneficial for arm and shoulder function. (evidence level 1+)

- Lauridsen *et al.* (2005) showed in a good quality RCT that patients receiving team instructed physiotherapy had significantly better shoulder function and

strength results after treatment and 6 months post-operatively than untreated patients.

- Bendz and Fagevik (2002) showed statistically significant differences in flexion, abduction, external and internal rotation between two groups randomised to early shoulder / arm exercises or no treatment in the first two weeks post-operational measured directly after treatment (after both groups received the programme most differences disappeared).
- Kilbreath *et al.* (2006) reported better functional results for a group randomised to resistance and stretching shoulder exercises compared to controls, e.g. 1° versus 7° difference between arms regarding forward flexion; given the sample size (N=22) it is unsurprising that the differences were not statistically significant.
- Dawson *et al.* (1989) showed less limitation regarding anteflexion and abduction in a group randomised to exercises starting on the first day post-operatively compared to immobilised patients but the effects were not statistically significant (N=100).
- Le Vu *et al.* (1997) showed better functional results at seven days post-operatively for patients randomised to receive mobilisation exercises compared to no treatment.
- Wingate *et al.* (1989) showed better shoulder abduction and flexion and less difficulties with tasks of the daily living for a group of modified radical mastectomy patients that had received physical therapy than untreated patients at five days and between one and three months post-operative.
- Johansson (2005) states in an editorial that active arm exercises are important in order to prevent reduced shoulder mobility. A non-systematic review (Anon. 2000) stated that exercise has the advantage of promoting recovery of arm strength and mobility and of capacity to pursue normal daily activities.

In this context, Gosselink can be cited who conclude from their case series tracing the recovery of upper limb function after axillary dissection that a continuation of physiotherapy after three months post-operatively is warranted. This provides evidence that can be held against the opinion that physiotherapy is unnecessary as recovery will come over time regardless of physiotherapy. However, Sandel *et al.* (2005) did not find an effect on shoulder range of motion for a dance and movement programme that included some upper extremity movement exercises when compared to waiting list controls, the authors only found a time effect (range of motion improving over time in both groups). Neither did Gordon *et al.* (2005a) find differences in functional measures when confounders were taken into account in a comparison of three groups (two were part of physiotherapy programmes, one received no physiotherapy).

Physiotherapy does not seem to cause more adverse events than non-treatment, especially when not offered directly after surgery (within a week) or when follow-ups of two weeks or more are chosen. (evidence level 1+)

- Lauridsen *et al.* (2005) found in a good quality RCT that patients receiving team instructed physiotherapy six weeks after surgery at the earliest had no more axially strings than untreated patients.

- Bendz and Fagevik (2002) found even no differences in adverse effects (e.g. lymphoma) between two groups (N=230) randomised to early shoulder / arm exercises or no treatment in the first two weeks post-operational.
- Kilbreath *et al.* (2006) reported in a small but relatively good quality RCT that more controls had an interlimb difference  $\geq 2\text{cm}$  than the exercise treatment group ( $p=0.03$ ) which started presumably started exercising after hospital discharge.
- Wingate *et al.* (1989) found no differences in post-operative complications, length of hospital stay or circumferential measurements for a group that had received physical therapy beginning on the first post-operative day compared to untreated patients at five days and between one and three months post-operative.
- Johansson (2005) states in an editorial that patients are sometimes advised to be careful with the affected arm to prevent lymphoedema but there is no empirical evidence to back this up.

There is conflicting evidence for regimes offered directly after surgery, especially when the drains are still in place and for outcomes assessed close to surgery including drainage volume: Dawson *et al.* (1989) report slightly more adverse effects (seroma, delayed wound healing; statistical significance unclear) for the exercised group in comparison to the immobilised group and they conclude that exercises before the 5<sup>th</sup> post-operative day should be abandoned, the studies mentioned under Timing come to different conclusions.

### Stretching

Stretching exercise in addition to physiotherapy has no clear additional beneficial effect on function, quality of life, strength or adverse effects. (evidence level 1+)

- Lee *et al.* (2007) did not find differences for several outcomes (five function measures, quality of life, strength, adverse effects) between a group that received a pectoral muscle stretching programme in addition to physiotherapy in a good quality RCT, but two small, statistically significant function effects might have been present (horizontal extension, forward flexion; reporting unclear).
- The technically good RCT by Kilbreath *et al.* (2006) also reported no statistically significant differences between groups of which one received an additional resistance and stretching shoulder exercise programme apart from usual upper limb exercises, however, this appears to be due to the small sample size (N=22).

### Massage

Massages in addition to standard post-operative care can initially be effective for selected outcomes and does not seem to be associated with additional health utilisation costs. (evidence level 1-)

- Forchuk *et al.* (2004) reported significantly fewer difficulties in several self-reported tasks such as placing an object on a high shelf two weeks post-surgery, better self-reported pain control on the first day post-operatively and no significant differences in health utilisation related costs in a group randomised to massage executed by their significant others in addition to

standard post-operative care [unclear what this is]; objectively measured range of motion showed no differences and the intervention group experienced more swelling at some follow-up points.

- Le Vu *et al.* (1997) showed the best functional results for a combination of massage and mobilisation exercises as compared to one or the other or no treatment on day seven post-operatively.

### Dance and Movement

A dance and movement programme improves breast cancer specific quality of life. (evidence level 1-)

- Sandel *et al.* (2005) concluded after randomising patients to a dance and movement programme that this substantially improved a breast cancer specific quality of life measure (Functional Assessment of Cancer Therapy – Breast Questionnaire (FACTB, version 3)) compared to waiting list controls; there were no significant differences between groups for SF-36 scores or range of motion measures.

### Immobilisation

Immobilisation after surgery does not appear to be more beneficial than free shoulder movement. (evidence level 2-)

- Christodoulakis *et al.* (2003) reported that patients with immobilisation of the arm for four days after surgery had a significant longer hospital stay than patients that were allowed free shoulder movement, no other differences in post-operative complications, or drainage volume, number of days with drain were observed; it has to be noted that historic controls were used for this comparison.

Other: The use of walking poles may improve muscular endurance. (evidence level 1-)

- Sprod *et al.* (2005) showed in a randomised controlled trial with 12 participants that those walking with walking poles improved considerably regarding bench press, shoulder press and latissimus dorsi pull down (7, 1 and 13 repetitions more than pre-exercise in the pole group, versus -0.8, -0.4 and 5 repetitions in the normal walking group); the statistical significance is unclear.

## **Timing**

### Period directly after the operation

The timing of physiotherapy does not significantly affect effectiveness or adverse events at follow-ups of 1 month or later. (evidence level 1-)

- Jansen *et al.* (1990) found a similar pattern of recovery and no differences six months post-operative between a group of randomised patients that started physiotherapy on day one after surgery compared to a group that was immobilised for seven days before starting physiotherapy.
- Bendz and Fagevik (2002) showed differences in flexion throughout the two year follow-up of two groups randomised to early shoulder / arm exercises or no treatment in the first two weeks post-operational, but group differences in abduction, external and internal rotation disappeared by one month when all participants received an exercise programme; no differences were observed

in adverse effects (e.g. lymphoma) but it should be noted that the authors summarise the data as mobility recovers earlier in the early exercise group.

- Chen and Chen (1999) found no differences between randomised groups (N=344) that received early, late or delayed (after drain removal) shoulder exercises with regard to anteflexion, abduction and exo-rotation range of motion at day 7, 30, 60 or 180 post-surgery.
- Van der Horst *et al.* (1985) found no differences at the six month follow-up in the percentage of patients reaching full range of motion or with restrictions between small groups that were randomised to what the authors call early (immediately following surgery) versus late (day 7) shoulder exercises and adverse effects (lymphoedema, necrosis, wound infections) were not more common in the early group; it should be noted that both groups did isometric contraction exercises throughout.
- Le Vu *et al.* (1997) found no differences in self-reported abnormalities of the amplitude at 3 month or 8 to 24 months post-operatively regardless of whether patients were randomised to massage, mobilisation training, a combination of the two or no treatment in the first week after surgery (later all patients received massages and mobilisation exercises).
- In contrast, Johansson *et al.* (2001) advocated that physiotherapeutic management pays special attention to early impairments after breast cancer treatment, especially to the group receiving radiotherapy to the axilla area and treatment might be introduced during radiotherapy; the conclusions are not directly based on the studied case series.

Physiotherapy during the first week post-surgery can lead to an increased drainage volume. (evidence level 1-)

- Chen and Chen (1999) reported a statistically significant difference in the amount of axilla fossa drainage volume at 14 days after surgery when the drain in the axilla were removed (559ml compared to 485 or 568ml) in randomised groups that received early, late or delayed (after drain removal) physiotherapy; the authors concluded upper arm exercise should start after drain removal.
- Van der Horst *et al.* (1985) reported a mean drainage volume of 935ml (range 210-3840) in a group randomised to what the authors call early exercises compared to 817ml (range 70-2600) in the group that started shoulder exercises on day seven with a mean drainage time of 8.3 versus 6.4 days; this result was not statistically significant in the small sample.
- Le Vu *et al.* (1997) found the most volume of drained lymph in a group randomised to receiving mobilisation exercises in comparison to a massage, no intervention or a combination of massage and mobilisation.
- In contrast, Johansson (2005) stated in an editorial that physiotherapy started six months post-operatively also improves shoulder functioning but that there is no rationale to postpone the start.

#### When during the year after surgery

The timing of exercises does not significantly affect effectiveness or adverse events. (evidence level 1+)

- Lauridsen *et al.* (2005) showed in a good quality RCT that patients receiving team instructed physiotherapy during the 6<sup>th</sup> to 8<sup>th</sup> post-operative week had no better results than physiotherapy after the 26<sup>th</sup> postoperative week – both

groups in this cross-over trial showed no differences once both groups had received physiotherapy.

- Sandel *et al.* (2005) found no training order effect when analysing patients randomised to a dance and movement programme or waiting list and later cross-over for range of motion measures, body image and SF-36 scores but this was evident for a breast cancer specific quality of life measure.

Physiotherapy offered early can result in higher compliance than when offered at a later date in the year post-surgery. (evidence level 1+)

- Lauridsen *et al.* (2005) showed in a good quality RCT that patients receiving team instructed physiotherapy during the 6<sup>th</sup> to 8<sup>th</sup> post-operative week had a 10% non-attendance rate, the groups receiving physiotherapy after the 26<sup>th</sup> postoperative week a 19% rate; no statistical significance test reported.
- In this context, Gosselink can be cited who conclude from their case series tracing the recovery of upper limb function after axillary dissection that a continuation of physiotherapy after three months post-operatively is warranted. This provides evidence that can be held against the opinion that physiotherapy is only effective shortly after surgery / recovery will come over time regardless of physiotherapy.

### **Setting and means of delivery**

Instructed physiotherapy shows better results regarding function compared to exercise instruction booklets or other self-exercise programmes. (evidence level 1+)

- Box *et al.* (2002) in a good quality RCT showed better results regarding function up to two years after surgery for an exercise programme outlined in a care plan than the controls that were provided with an exercise instruction booklet.
- Wang *et al.* (2005) found that a group randomised to a directed functional rehabilitation gymnastic programme showed better results regarding anterior, posterior and lateral elevation angles as well as internal and external rotation angles compared to a self-exercise group.
- The study by Gerber *et al.* (1992) is also marginally relevant in this context who speculated that the better functional outcomes of a group with axillary dissection compared to modified radical mastectomy could be because the range of motion was supervised during the entire radiation treatment for these patients.
- Na *et al.* (1999) found in a clinical trial that patients receiving an intensive course of physical therapy showed better results for flexion, abduction, internal rotation and external rotation at either discharge or one month after discharge compared to patients who had received written material of a self-exercise programme.

Instructed physiotherapy shows better results regarding compliance compared to exercise instruction booklets. (evidence level 1+)

- Box *et al.* (2002) showed in a good quality RCT better compliance at each of the six follow-up times for an exercise programme outlined in a care plan than the controls that were provided with an exercise instruction booklet.

Directed exercises are more effective for selected functional outcomes than free exercises and do not appear to increase adverse events. (evidence level 1-)

- Ferreira de Rezende *et al.* (2006) reported significant better results regarding the recovery of extension, flexion, external rotation and abduction 42 days post-surgery for a group randomised to directed exercises following a specific sequence and number of repetitions as compared to the free execution of exercises; there were no statistically significant differences for adduction and internal rotation and the difference was not statistically different for all previous follow-ups, the compliance was equal and differences in adverse events were also not observed.
- Also relevant here is Wang *et al.* (2005) who showed that a group randomised to a directed functional rehabilitation gymnastic programme showed better functional results and fewer incidences of oedemas one and two months post-operatively compared to a self-exercise group. Similarly, the physical therapy clinical trial by Na *et al.* (1990) could be cited here that did report better functional outcomes but not more adverse events such as oedema, wound breakdown, infection, motor weakness or adhesional band use in the instructed group compare to the self-exercise group; however more of the former reported sensory changes (clinical and statistical significance unclear).
- Beurskens *et al.* (2007) reported on a small RCT that investigated the efficacy of physiotherapy treatment of shoulder function, pain and the quality of life in patients who have undergone breast cancer surgery and axillary lymph node dissection compared to control intervention (where the (the treatment group began physiotherapy two weeks after surgery in a private practice of their choice for a total number of nine treatments and the control was a leaflet with advice and exercises for arm and shoulder for the first weeks following surgery). Functional shoulder impairments and pain in the shoulder/arm were significantly reduced following physiotherapy at three months as compared to the control group. There was no significant improvement in handgrip strength or in volume of the related arm between both groups at baseline and follow-up.
- Cinar *et al.* (2008) conducted a small RCT which evaluated the effects of early onset rehabilitation program on shoulder mobility, functional capacity, lymphoedema and postoperative complications in patients who underwent modified radical mastectomy. The trial investigated the effect of clinical variables on the recovery of shoulder mobility, functional capacity and development of lymphoedema. The intervention included a treatment group (directed physiotherapy) versus home group (exercises taught by physiotherapist and patients to perform them by themselves). The improvement in measurements of flexion, abduction, and adduction movements of the shoulder joint and the functional questionnaire scores were significantly improved in the treatment group. No statistically significant difference in the development of lymphoedema and postoperative complications in both groups was observed.

#### Relevant but problematic data

A programme including home visits from physiotherapists may be beneficial and efficient with regards to costs compared to group sessions. (evidence level 2-)

- Gordon *et al.* (2005a) compared patients taking part in a domiciliary Allied Health and Acute CARE Rehabilitation Team programme (DAART), a Strength Through Recreation Exercise Togetherness Care Health and a further programme that did not offer exercises; when adjusting for all confounders no differences between groups were significant but the authors are convinced that DAART programme patients receiving home visits from a physiotherapist had clinically significant better quality of life outcomes and that the cost-effectiveness analysis shows promoting DAART is an excellent public health investment.
- Similar problematic data stem from Lauridsen *et al.* (2000), an RCT comparing team instructions and individual treatment by a physiotherapist, which reported that improvement for a variety of physical findings was more pronounced in the individual treatment regime but failed to clearly demonstrate all available results.

#### **Miscellaneous, use unclear**

Zaltoprofen intake improves range of shoulder motions during physiotherapy. (evidence level 1)

- Hase *et al.* (2006) showed that a group randomised to zaltoprofen intake showed larger flexion and abduction movements than controls before and after physiotherapy exercises. The authors imply that it could boost patients' confidence of succeeding in achieving elevated arm positions, e.g. as required for radiotherapy.

The size of the effect of different surgical procedures and radiotherapy administration are likely to overpower any effects of strategies to reduce arm and shoulder mobility problems. (evidence level 3)

- Rietman *et al.* (2004) present a risk factor study that mentions the factor exercise and physical therapy but none of the prediction models of impairment, disability and health related quality of life include these factors (rather radiotherapy and chemotherapy predict impaired range of motion).

## Evidence Tables

Lauridsen MC, Christiansen P & Hesso I (2005). The effect of physiotherapy on shoulder function in patients surgically treated for breast cancer: A randomized study. *Acta Oncologica*, 44(5), 449-457.

**Design:** RCT, **evidence level:** 1+

**Country:** Denmark, **setting:** Secondary care

**Inclusion criteria** unilateral surgery planned according to Danish guidelines

**Exclusion criteria** reported illnesses affecting upper extremities preoperatively, unable to give consent

**Population** N=139 patients undergoing breast conserving therapy including axillary lymph node dissection and radiation therapy or undergoing modified radical mastectomy including axillary dissection; mean age in subgroups ranging between 49 – 63 years

**Interventions** standard treatment of the ward [presumably a short course of immediate physiotherapy, both groups were encouraged to perform the exercises on a regular basis at home]

Group A (n=72): team instructed physiotherapy, 12 sessions of 60 minutes, 2 sessions a week, during 6<sup>th</sup> to 8<sup>th</sup> postoperative week

Group B (n=67): same physiotherapy but offered after the 26<sup>th</sup> postoperative week

**Outcome note** Constant Shoulder Score (subjective parameters and objective measurements of active motion range and shoulder strength); exams by same physician

**Follow up** 6, 12, 26 and 56 weeks

### Results

Outcome	Result
Function and Strength	Directly after the treatment of Group A, these patients had better shoulder function and strength results (p=0.001) and 6 months postoperatively (p=0.001) compared to controls. After both groups had received the intervention, no differences were found These results were similar for the modified radical mastectomy patients but not the breast conserving therapy group (no difference between treatment and control). The results were not significantly different in patients with modified radical mastectomy regardless of radiation therapy treatment
Compliance	The median number of sessions missed was 1 or 3 in the early (A) subgroups and 2 or 3 in the later (B) subgroups, the number of patients not attending any session was 10% in Group A, 8 or 19% in the Group B subgroups
Adverse effects	The presence of axially strings was equally distributed in the treatment groups at all times and was not influenced by type of surgery or radiation therapy

Authors concluded team instructed physiotherapy improves shoulder function.

**General comments** computer generated randomisation sequence, allocation concealment by 3<sup>rd</sup> party, no blinding, withdrawals described; power calculation; ITT analysis

Box, Reul-Hirche, Bullock-Saxton & Furnival (2002). Shoulder movement after breast cancer surgery: results of a randomised controlled study of postoperative physiotherapy. Breast Cancer Research and Treatment 75[1], 35-50.

**Design:** RCT, **evidence level:** 1+

**Country:** Australia, **setting:** Secondary care

**Inclusion criteria** Women scheduled to undergo breast conserving surgery (complete local excision and axillary dissection) or modified radical mastectomy at two hospitals

**Exclusion criteria** Confused mental state or inability to follow the exercise guidelines, concurrent reconstructive surgery, residence beyond 50km radius and no monitoring as an outpatient, refusal of random allocation, insufficient time to obtain consent/perform preoperative assessment, absence of principal investigator at time of recruitment (n=5)

**Population** N = 65 patients, 49% with breast conserving surgery, no axillary radiotherapy but breast radiotherapy possible, mean age 56 years

**Interventions**

Intervention group: physiotherapy management care plan; exercise programme and lymphoedema awareness education which started preoperatively and continued post-operatively, postoperative reviews to monitor shoulder ROM, progress exercise programmes and individualised intervention as required, the care plan also included exercises when secondary lymphoedema was detected

Control group (n=33): exercise instruction booklet

**Outcome note** ROM assessed by blinded physiotherapist for some patients

**Follow up** 2 years, preoperative, prior to randomisation, Post-operatively at day 5, 1 month, 3 months, 6 months, 12 months and 24 months

**Results**

Outcome	Result
Function	Two years after surgery, 80% of all patients reported no residual shoulder stiffness or functional problems; the intervention group demonstrated greater abduction compared to the control group over time (p = 0.01), the intervention group at 3 months showed more abduction at 3 (p=0.05) and 24 months (p=0.01) but not at the other follow-ups The group allocation significantly influenced the tasks 'being able to hang out the washing', 'pulling a shirt on or off over head', and 'brushing or combing hair / fix wig or head scarf' no significant differences for flexion, internal rotation or external rotation were found between treatment groups
Compliance	The exercise compliance rates were better in the intervention group compared to controls at every follow up measurement (100% vs 94% at 1 month, 91% vs 61%, 73% vs 49%, 54% vs

	21%, 33% vs 22% at 2 years)
Adverse effects	Two years after surgery, 80% of all patients reported no residual problems with shoulder stiffness; the rate of residual problems at two years were not significantly different across groups: 14% vs 26% in controls

Authors concluded a physiotherapy management care plan provided in the early postoperative period is effective in facilitating and maintaining shoulder movement recovery over the first 2 years.

**General comments** Randomisation after informed consent, stratified by planned surgical procedure; participants blinded, physiotherpists not entirely; power calculation; all analyses controlled for age, number of lymph nodes excised, level of axillary dissection, history of previous shoulder problem, radiotherapy, chemotherapy and wound infection; ITT analysis: 3 controls received physiotherapy according to a rule set a priori due to poor recovery; drop-outs accounted for (59 out of 65 were fully evaluated); no significance tests for compliance data

Lee TS, Kilbreath SL, Refshauge KM et al. (2007). Pectoral stretching program for women undergoing radiotherapy for breast cancer. *Breast Cancer Res Treat*, 102, 313-321.

**Design:** RCT, **evidence level:** 1+

**Country:** Australia, **setting:** presumably secondary care

**Inclusion criteria** patients who underwent breast cancer surgery and received radiotherapy to the breast or chest wall in either 2 or 3 fields

**Exclusion criteria** radiotherapy to the axilla

**Population** N=64 consecutive patients; some conservative surgery, some mastectomy; some without axillary surgery, some sentinel node biopsy some axillary dissection, some with chemotherapy; some received tamoxifen or arimidex; some in both groups with shoulder pain at baseline; mean age in subgroups ranging between 55 (SD: 13) and 53 (SD: 12) years

**Interventions** usual care, physiotherapy course parallel to radiotherapy; pamphlet describing gentle shoulder range of motion exercises, patients seen by physiotherapist weekly; booklet to record use of medication, treatments and exercises performed during the radiotherapy course

Stretch group (n=31): pectoral muscle stretching programme on low-load, prolonged passive stretches of pectoralis major and minor while in supine lying, each stretch position held for up to 10 minutes twice per day, positions often adjusted, technique was reviewed weekly, patients encouraged to continue stretching until follow up; skin care and lymphoedema advice

Control (n=30): no exercise advice during weekly sessions with physiotherapist only skin care and lymphoedema info

**Outcome note** blind outcome assessor, pain measured on 11-point scale after 1<sup>st</sup> attempt of each movement

**Follow up** 6 weeks postoperatively, 8.5 months post-operatively (7 months after completion of radiotherapy and exercises), QoL: Quality of Life questionnaire Version 3 Breast Module BR23

**Results**

Outcome	Result
Function	No significant difference was found between groups for passive horizontal extension, forward flexion, external rotation or abduction and range of motion; A 6° difference was found between arms for horizontal extension and forward flexion (p<0.001) No differences were found between arms for external rotation or active abduction meaning both groups attained close to full range of motion at their affected shoulder 7 months post-radiotherapy
QoL	no differences were found between groups for QoL items
Compliance	28/31 patients complied with stretching exercise, 1 discontinued do to concurrent neck and jaw pain, 14/30 patients in the control group also exercised
Strength	There were no differences in strength between groups at all

	<p>follow-ups  Patients maintained normal arm strength throughout the study, strength measurements did not differ between arms at any measurement occasion</p>
Adverse effects	<p>4 new arm swelling cases in control group at 7 months follow up, 1 new case in the stretch group, breast symptoms increased for both groups during radiotherapy</p>

Authors concluded stretching did not influence outcomes because symptoms reported were not a consequence of contracture.

**General comments** computer generated randomisation sequence, allocation concealment through opaque envelopes, single-blind, withdrawals described (only 50 patients finally analysed), power calculation, ITT analysis, sophisticated analyses, arm dominance differentiated, it would be more convincing had the statistical significance test been reported for strengths and QoL and pain alone was not reported at all

Kilbreath S, Reshaug K, Beith J & Lee M (2006). Resistance and stretching shoulder exercises early following axillary surgery for breast cancer. *Rehabilitation Oncology*, 24(2), 9-14.

**Design:** RCT, **evidence level:** 1+ / 1-  
**Country:** Australia, **setting:** secondary care

**Inclusion criteria** patients undergoing surgery to the axilla for early stage breast cancer

**Exclusion criteria** -

**Population** N=22 patients, more than half with mastectomy, the others wide local excision, half with axillary node dissection, half sentinel node biopsy, most with radiotherapy, chemotherapy and tamoxifen; mean age 52 (SD=12) years

**Interventions** usual hospital care including breast care nurse visit, physiotherapist to review upper limb exercises possible and occupational therapist discussing lymphoedema prevention, patients discharged 2-7 days post-surgery

Treatment group (n=14): daily home programme of resistance and stretching shoulder exercises to increase shoulder ROM and strengthening shoulder muscles, supervised by physiotherapist once a week, stretches in supine included forward flexion, horizontal extension at 90° abduction and horizontal extension at 135° abduction, stretch was held passively for 5 minutes on day 1, progressing up to 15 minutes over 2 weeks time; Theraband was used for strengthening the shoulder flexors and abductors and external rotators, 2 sets of 8-12 repetitions daily, starting with low resistance grade of Theraband in week 1 up to a 'somewhat hard' on the Borg effort scale grade, strengthening exercises were progressed by either increasing resistance or number of repetitions

Controls (n=8): no extra resistance and stretching shoulder exercises

**Outcome note** European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Version 3 (QLQ-C30); lymphoedema = ≥ 2cm difference between arms; passive ROM and active abduction measured; inclinometer, dynamometer

**Follow up** immediately after intervention = 12 / 13 weeks post-surgery

**Results**

Outcome	Result
Function	The difference in forward flexion range of motion between the affected and unaffected arm was 1° (-1, 7.5) in the exercise group and 7° (2, 52) in the controls (n.s.)
Compliance	All women in the exercise group undertook resistance training and passively stretched for up to 15 minutes daily
Strength	difference in strength between affected and unaffected shoulder flexors was 0 (-5, 11) in the exercise group and 22 (14, 24) in the controls (n.s.)
QoL, Acceptability, Adverse	More controls had an interlimb difference ≥2cm than the treatment group (p=0.03) From questionnaire:

<p>effects, Pain</p>	<p>The exercise group had better scores regarding role, emotional, and cognitive functioning; no differences in QoL, physical or social functioning;</p> <p>The controls had less fatigue, but more pain, more appetite loss and more financial difficulties; there were no differences regarding nausea / vomiting, dyspnoea, insomnia, constipation or diarrhoea</p> <p>The exercise group had a better body image and sexual functioning; no differences regarding sexual enjoyment and future perspective</p> <p>The treatment group had fewer systemic therapy side effects, arm and breast symptoms and was less upset by hair loss than the controls (n.s.)</p>
--------------------------	--

Authors concluded the intervention seem to lead to better outcomes than usual care.

**General comments** computer generated randomisation sequence, allocation concealment by opaque envelopes; drop-outs explained; the objectively measured function results were only depicted in full in a confusing figure; sample probably far too small to show effects

Sandel, Judge, Landry, Faria, Ouellette & Majczak (2005). Dance and movement program improves quality-of-life measures in breast cancer survivors. *Cancer Nursing*, 28[4], 301-309.

**Design:** RCT (crossover), **evidence level:** 1- / 1+

**Country:** USA, **setting:** Community, multi-centre

**Inclusion criteria** Patients treated for breast cancer, having undergone surgery at least one month previous, but within the preceding 5 years

**Exclusion criteria** metastatic breast cancer, inability to stand unaided for 3 minutes

**Population** N=35 patients who had surgery on average 11 months ago, most with mastectomy or partial mastectomy, a few with lumpectomy, most with lymph node removal, some with breast reconstruction; mean age 61 years, range 38 to 82 years

**Interventions** cross-over at week 13

Dance group (n=19): 12 week dance exercise program of a planned 18 sessions, at week 14 patients resumed their normal activities; warm up, core exercises (to shoulder, elbow and wrist), dance movements and stretching; Lebed Method, Focus on Healing Through Movement and Dance, certified instructor

Controls (n=16): maintained normal activity until week 14, when they undertook the dance programme as above from weeks 14-25

**Outcomes note** questionnaires Functional Assessment of Cancer Therapy-Breast (FACT-B): physical, social, functional and emotional QoL domains plus 9 breast cancer specific items; SF-36; Body Image Scale; shoulder ROM = sum of ROM in all 5 directions); ROM and arm circumference measured by blinded physiotherapist

**Follow up** 13 and 26 weeks

### Results

Outcome	Result
Function	Shoulder ROM increased at 13 weeks in both groups (time effect $p=0.03$ ): $15^\circ$ in the intervention group, $8^\circ$ in controls
QoL	FACT-B improved in the intervention group at 13 weeks from 102.0 (SD: 15.8) to 116.7 (SD: 16.9), compared to controls 108.1 (SD: 16.4) to 106.1 (SD: 22.3), $p=0.008$ , large clinical improvement; The SF-36 showed no differences between groups
Adverse events	In all subjects, the summed arm circumference at baseline in the involved arm was greater than that on the non-operated side (118.6 (SD: 12.1) cm vs 116.2 (SD 9.8) cm, $p=0.004$ ) No changes in arm circumference in either group at 13 weeks or 26 weeks for either involved arm or non-involved arm 3 patients with lymphoedema [group unclear]
Other	Body image scores showed no differences between groups Timing: The training order effect for function and the SF-36 was not statistically significant but it was for FACT-B (QoL, $p=0.015$ )

Authors concluded that a dance movement programme improves breast cancer specific QoL.

**General comments** computer-generated random numbers, sequential sealed envelopes opened after baseline testing; multi-centre, problematic data (waiting list crossover design, unusual analysis method); there were several significant time effects but this abstract concentrated on differences between groups; withdrawals mentioned; ITT analysis (asked to complete measures regardless of compliance); short follow up

Jansen RFM, van Geel AN, de Groot HGW et al. (1990). Immediate versus delayed shoulder exercises after axillary lymph node dissection. American Journal of Surgery, 160(5), 481-484.

**Design:** RCT **evidence level:** 1-

**Country:** The Netherlands **setting:** 4 institutions, Secondary care and Cancer center

**Inclusion criteria** patients undergoing primary surgical treatment of breast carcinoma

**Exclusion criteria** grade 3 or 4 WHO Performance Status Scale, previous diseases or operations influencing ipsilateral shoulder movements, previous ipsilateral axillary operations or radiotherapy, immediate postoperative iridium implantation, simultaneous bilateral axillary lymph node dissection

**Population** N=168 patients; modified radical mastectomy (majority), axillary lymph node dissection with or without lumpectomy equally distributed amongst groups; mean age 59, range 28-81

**Interventions** physiotherapy, movements of the shoulder, performed actively once a day under supervision of physiotherapist, movements until pain barrier was reached; all spontaneous movements and use of arm during the day were allowed but no pain, supervision discontinued when shoulder function returned or at discharge; physiotherapy at home prescription depending on results

Early: physiotherapy starts at day 1

Late: 7 days of immobilisation, physiotherapy starts at day 8

**Outcome note** function measured by 1 or 2 physiotherapists (different ones for the institutions)

**Follow up** before surgery, 1<sup>st</sup> day of shoulder movements, discharge, 1 and 6 months post-operative

### Results

Outcome	Result
Function	The pattern of recovery and the final outcome showed no difference between the groups (sharp decrease in shoulder function which disappeared during the first 6 months but all shoulder functions slightly reduced 6 months after operation)
Adverse effects	The group with previous immobilisation had 14% less wound drainage volume (n.s.), axillary drainage time, number and volume of seroma aspirations, percentage of patients with serious shoulder restrictions, wound complications and lymphoedema were equal
Other	The number of days of physiotherapy at home was equal in the 2 groups

Authors concluded there was no significant difference between groups in any outcome.

**General comments** randomisation not described; withdrawals explained; study is inspired by Van der Horst (too small) and Dawson (incomplete

statistical analysis); the study is remarkable in directly testing an open question in the literature, however, it is unfortunate that more modern statistical analyses were not available

Bendz & Fagevik (2002). Evaluation of immediate versus delayed shoulder exercises after breast cancer surgery including lymph node dissection - A randomised controlled trial. *Breast*, 11[3], 241-248.

**Design:** RCT, **evidence level:** 1- (1+ possible but not all reported)

**Country:** Sweden, **setting:** Secondary care, outpatient clinic / home

**Inclusion criteria** Women undergoing radical mastectomy or quadrantectomy, including axillary dissection for breast cancer

**Exclusion criteria** >80 years, senility, bilateral surgery or co-morbidity affecting the outcome e.g. rheumatoid arthritis, stroke

**Population** N = 230 consecutive patients, half with radiotherapy (none to the axilla), mean age = 58 (SD:11) years

**Interventions** after 14 days patients in both groups received an exercise programme to perform, difference is in earlier treatment

Intervention (n=101): shoulder/arm exercise programme instructions preoperatively to be started on 1<sup>st</sup> post-operative day, intermittent hand contractions with ball, elbow flexion / extension, hand pro- and subination in supine position with arm resting on wedge pillow, from day 3 arm elevation and abduction to 90° with bent elbow in sitting position, from day 8 arm elevation and abduction to 90° with straight elbows, internal rotation with hand on back, supervised by physiotherapist

Controls (n=104): advice to use arm as much as comfortable but to avoid lifting/carrying/forced movements for 14 post-operative days

**Outcome note** Lymphoedema: water displacement volume measurement: lymphoedema = 10% volume increase in comparison to other arm, corrected for preoperative differences and the dominant arm; goniometer; vigorimeter; subjective estimation of pain, heaviness and tension on visual analogue scale (mild, moderate, severe)

**Follow up** 2 week (crucial, after this both groups receive intervention), 1 month, 6 months and 2 year post-operatively

### Results

Outcome	Result
Function	All measured movements in both groups were reduced at 2 weeks and 1 month post-operatively; at 2 weeks post-operatively arm elevation was 73% of its preoperative level in the intervention group compared to 55% in the control group ( $p < 0.001$ ); at 2 years follow up the intervention group had better movement than controls for flexion ( $167^\circ$ vs $164^\circ$ , $p < 0.05$ ) and abduction ( $154^\circ$ vs $145^\circ$ , $p < 0.05$ ) but no differences for internal and external rotation no differences due to radiotherapy status
Strength	There were no statistically significant differences between groups for hand grip strength at any follow up point
Pain	There were no differences in pain between groups
Adverse effects	no differences in arm volume changes between groups at any follow up point up to 2 years post-operatively at 2 years no difference between groups in lymphoedema (13% vs 12%),

	overall incidence of lymphoedema 6.5% at 6 months and 13.8% at 2 years no differences due to radiotherapy status There were no statistically significant differences between groups regarding heaviness and stiffness at any follow up point, all reported symptoms mild or moderate
--	---

Authors conclude that mobility recovered earlier in the early exercise group.

**General comments** randomisation not described, blinding unclear; withdrawals explained (49/230 lost), study took hand dominance into account, units of measurement not always reported: 'elevation' reported in results but not methods

Chen SC & Chen MF (1999). Timing of shoulder exercise after modified radical mastectomy: A prospective study. *Changgeng Yi Xue Za Zhi*, 22(1), 37-43.

**Design:** RCT, **evidence level:** 1-

**Country:** Taiwan, **setting:** Secondary care

**Inclusion criteria** patients undergoing modified radical mastectomy as primary surgical treatment for breast cancer

**Exclusion criteria** partial mastectomy, previous axillary operation or radiotherapy, bilateral breast cancer, persistent haematoma and serious infection of surgical wound

**Population** N=344 consecutive patients with axillary lymph node dissection with tissue removal in axillary veins, anterior edge of latissimus dorsi muscle, anterior serratus muscle and subscapular muscle; long thoracic nerve and thoracodorsal artery vein and nerve not removed; some with lymph node dissection, some with transected pectoralis minor; all with flat drain in axilla fossa and medial chest wall, dressing removed on 3<sup>rd</sup> day postoperative, drain removal varied; mean age 51 (SD: 13.6) or 48 (SD: 10.6 or 11.2) in the groups

**Interventions** 1<sup>st</sup> day after operation and on each additional day performed a hand squeezing exercise and elevation of the forearm not beyond 40° 4 times a day

Early exercises (n=116): upper arm exercises gradually increasing ROM until pain threshold starting on 3<sup>rd</sup> day; supervision by nurse, active and active-assisted exercise, pendulum exercise, wall climbing, pulley exercise (rope above), some exercised taught at home, patients instructed to continue exercises at home

Late exercises (n=115): started a 6<sup>th</sup> day postoperatively

Delayed exercises (n=113): started after drain was removed

**Outcome note** nurse who supervised exercises also performed measurements

**Follow up** 3<sup>rd</sup> day, 7<sup>th</sup> day, 1, 2, 6 months post-operative

### Results

Outcome	Result
Function	The delayed group had the lowest ROM values for anteflexion and abduction throughout the follow-up but there was no statistically significant effect; exo-rotation ROM was not different between groups at all follow-ups; Most patients returned to full function at 6 months post-surgery
Adverse effects	The drainage amount over axillary fossa was lower in the delayed group compared to the other groups (p=0.032) No differences in chest wall or aspiration drainage volume, duration of drain for axilla fossa, chest wall or number of aspirations between the 3 groups

Authors concluded exercises can start after drains are removed, delay doesn't limit function.

**General comments** randomisation and blinding not reported, no power calculation but big sample

Lauridsen MC, Torsleff KR, Husted H & Erichsen C. (2000). Physiotherapy treatment of late symptoms following surgical treatment of breast cancer. *Breast*, 9(1), 45-51.

**Design:** RCT, **evidence level:** 1-

**Country:** Denmark, **setting:** unclear (data came from national register)

**Inclusion criteria** women treated by surgery for breast cancer according to the Danish guidelines, without recurrence and no other malignant disease

**Exclusion criteria** -

**Population** N=55 patients, 82% with mastectomy, 18% with lumpectomy, a few ; these came from a pool of 110 patients who reported to suffer one or more late symptom and wished to receive physiotherapy; mean age 55 years, range 36-73

**Interventions** physiotherapy once a week for 10 weeks

Group 1 (n=28): team instruction with training in a warm swimming bath and subsequent training on the floor by a physiotherapist, excercises are based on extension and relaxation, strength training, vein pump therapy and balance training

Group 2 (n=27): individual treatment by a physiotherapist, excercises based on extension and relaxation, strength training, vein pump therapy and balance training; also treated with stretching of the scar tissue and treatment with the object of increasing mobility of the skin above the pectoralis major muscle and in the area of the axilla

**Outcome note** assessor of physical examination did not perform the training, rest patient questionnaire

**Follow up** ?, investigation duration was 12 month

### Results

Outcome	Result
Function	71% of group 1 showed an improvement in shoulder movement, 90% of group 2; 'significant'
Strength	86% of group 1 showed an improvement in strength, 83% of group 2; 'significant' 86% of group 1 showed an improvement in muscle tone, 83% of group 2
Adverse effects	50% of group 1 showed an improvement in traction, 84% of group 2; 'significant' 100% of group 1 showed an improvement in abnormal neural tension, 100% of group 2; 'significant' 67% of group 1 showed an improvement in winged scapula, 100% of group 2; 'significant' No statistical significance was observed in the frequency of lymphoedema before and after physiotherapy The improvement in late symptoms 'pain in the neck, ipsilateral arm or shoulder', 'pain in or around the operation scar' and 'a feeling of reduced strength in the ipsilateral arm' was more pronounced in group 2 but not statistically significant

Authors concluded physiotherapy can improve strength, movement and muscle tone and reduce the presence and severity of late symptoms.

**General comments** very unusual result presentation, highly selective; no details about the

randomisation; assessor blinding possible; withdrawals explained

Van der Horst CM, Kenter JA, de Jong MT & Keeman JN (1985). Shoulder function following early mobilization of the shoulder after mastectomy and axillary dissection. *Netherlands Journal of Surgery*, 37(4), 105-108.

**Design:** RCT, **evidence level:** 1-

**Country:** The Netherlands, **setting:** probably secondary care

**Inclusion criteria** patients undergoing axillary dissections for carcinoma of the breast

**Exclusion criteria** -

**Population** N=57 consecutive patients, majority with modified radical mastectomy, some Halsted radical mastectomy, some undergoing breast saving procedure; mean age 62, range 17-81 years

**Interventions**

Group A (n=31): Day 1-7: shoulder exercises started immediately following surgery under the guidance of a physiotherapist, intermittent isometric contractions of shoulder, arm and hand muscles, arms were bent and hands clasped together in front of the body, instructed to push hands together for 5 to 10 seconds then relax, number of isometric contractions determined by individual ability and pain elicited, various positions of ante flexion of both arms, ante flexion, abduction and rotation were allowed actively or with assistance from the other arm until pain barrier. Day 8-14: daily activities as before but not integrated in the exercised and patients were encouraged to use their involved arm as before the operation

Group B (n=28): Day 1-6: intermittent isometric contractions of shoulder, arm and hand muscles in zero position in the glenohumeral joint; external rotation was actively performed from zero position with elbow flexed to 90°. Day 7: ante flexion 45°, abduction 90°. Day 8: ante flexion 90°, abduction 110°, Day 12-13: ante flexion 110°, abduction 130°, full ante flexion and abduction allowed

**Outcome note** blind assessor

**Follow up** 6 months

**Results**

Outcome	Result
Function	81% with full range of motion in group A, 13% with minor restrictions, serious restriction 6%; respective values for group B: 79%, 11% and 11%; no statistically significant differences
Compliance	1 patient in group A was so depressed that she refused the rehabilitation programme
Adverse effects	2 cases of lymphoedema and 2 of necrosis of wound edges in both groups, superficial wound infection occurred 1x in group A and 6x in group B; The mean drainage volume was 935ml (range 210-3840) in group A and 817ml (range 70-2600) in group B, the mean drainage time including aspirations was 8.3 days versus 6.4 days, statistically n.s.

Authors concluded the disadvantageous effects of early mobilisation as mentioned in the literature was not found, neither was an advantageous effect of early active mobilisation.

**General comments** double blind, no info on randomisation; the authors summarise group A as 'early active mobilisation', B as 'shoulder exercises started on the 7<sup>th</sup> postoperative day'; Jansen et al. (1990) think this study is too small to show effects

Forchuk, Baruth, Prendergast, Holliday, Bareham, Brimner, Schulz, Chan & Yammine (2004). Postoperative arm massage: a support for women with lymph node dissection. *Cancer Nursing*, 27[1], 25-33.

**Design:** RCT, **evidence level:** 1-  
**Country:** Canada, **setting:** Secondary care

**Inclusion criteria** 18 years or older, diagnosed with breast cancer scheduled for lymph node dissection, planning on having their significant other present (within 1 hour of leaving post anaesthesia care) after surgery, and both patient and significant other needed to consent to participate and be fluent in English

**Exclusion criteria** Organic brain disease; pre-existing disorder affecting arm function or the lymphatic system

**Population** N = 59 patients, age range 21 to 78 years, mean age 56

**Interventions**

Intervention group (n=30): Massage; patients' significant others were taught distal to proximal arm massage in circular pattern and encouraged to do so from the immediate post-operative period, no set parameters for frequency and duration of massage, a 10 minute duration was suggested and use as needed, a nurse checked a demonstration of the massage and patients received a handout

Controls (n=29): standard post-operative care

**Outcome note** questionnaires for self report including physician visits etc to estimate costs, tests, medication; diary for pain and massage, shoulder range of motion (ROM) measured by trained individuals, arm volume, estimated by circumferential measurements at 4 inch intervals

**Follow up** 24 hours, 10-14 days and 4 months post-operatively, pain and frequency of massage recorded daily

**Results**

Outcome	Result
Function	At 10-14 days post-surgery the intervention group reported less difficulty than the controls with washing their back, putting on a shirt, placing objects on a high shelf, placing objects in a back pocket (all p<0.05); There was no significant difference between groups for ROM 10-14 days and 4 months post-operative
Compliance	mean number of massages performed on day 1, 2 and 3 post-operatively was 1.72, 2.28 and 2.44 with a peak on day 4 with an average of 2.69 (range 0-10), 1 participant never received massage, after day 4 less massages
Pain	On 1 <sup>st</sup> day postoperatively intervention group reported more achieved pain control than the controls (p<0.05), on 2 <sup>nd</sup> and 3 <sup>rd</sup> day intervention group reported lower pain when pain was at its least (p<0.05), after the 3 <sup>rd</sup> day no differences in pain control
Adverse effects	The intervention group experienced more swelling at the 10-14 day post-operative follow-up point (e.g. proximal girth measurements 16.95 versus 16.20 respectively, p<0.05) and

	also the 4 month follow up point (no statistics reported); statistical significance ceased when outliers were removed
Cost	no significant differences between groups in health utilisation related costs, (e.g. nurse consultations, post-operative tests, medication)

Authors concluded arm massage decrease pain and discomfort and promotes a sense of closeness and support with significant other.

**General comments** no details on randomisation; power calculation; withdrawals explained; family stress and strengths not extracted due to baseline differences and incomplete results; especially pain data were selectively reported

Ferreira de Rezende L, Laier Franco R, Ferreira de Rezende M et al. (2006). Two exercise schemes in postoperative breast cancer: comparison of effects on shoulder movement and lymphatic disturbance. *Tumori*, 92(1), 55-61.

**Design:** RCT, **evidence level:** 1-

**Country:** Brazil, **setting:** physiotherapy outpatient centre

**Inclusion criteria** patients undergoing first surgery for invasive breast cancer, either modified radical mastectomy or quadrantectomy with axillary dissection

**Exclusion criteria** immediate breast reconstruction, bilateral surgery, difference of >2cm in arm circumference before surgery, limitation of movement in ipsilateral limb before surgery, >20° difference in flexion and abduction before surgery, unable to understand the proposed exercises

**Population** N = 60 women a few with chemotherapy, mean age 55 or 54 in the groups

**Interventions** 3 exercises started on 1<sup>st</sup> day after surgery, further exercises 48 hours after surgery in outpatient centre, 40 minute sessions, 3 times a week for 42 days, advice to maintain free activity with compromised limb in daily activities

Treatment group (n=30): directed exercises, kinesiotherapy based on spontaneous exercises including movements for flexion, extension, abduction, adduction and internal and external rotation of the shoulder, isolated or combined; 19 exercises performed 10 times with 60 second interval between exercises

Control group (n=30): free exercises, exercises following the biomechanical physiological movements of the shoulder including flexion, extension, abduction, adduction and internal and external rotation, either isolated or combined without a previously defined sequence or number of repetitions, executed to the rhythm of music, adapted to physiotherapy ability and experience

**Outcome note** adverse events from hospital records; goniometer; tape measure for circumference

**Follow up** 42 days postoperative

### Results

Outcome	Result
Function	ROM for adduction, extension and internal rotation did not show differences between preoperative and 42 <sup>nd</sup> day postoperative Flexion, abduction and external rotational movements showed reduced function at follow up The directed exercises showed better results regarding recovery of extension at day 42 than the free exercise group (47.6 (SD: 6.6) vs 42.9 (SD: 10.1), p=0.0447), also for flexion on day 28 (143.5 (SD: 21.1) vs 132.1 (SD:19.4), p=0.0391) and day 42 (155.4 (SD: 18.7) vs 142, SD17.7, p=0.0087), for external rotation on day 42 (66.1 (SD: 25.5) vs 50.4, SD 30.5, 0.0403) and for abduction at day 28 (122.4 (SD: 25.3) vs 108.2 (SD: 23.3), p=0.0322) and day 42 (139.7 (SD: 26.3) vs 121.2, (SD: 23.4), p=0.0077) There were no differences for adduction or internal rotation between groups
Compliance	Number of sessions performed was similar in both groups (13.8 (SD: 3.06) vs 13.2 (SD: 1.9))
Adverse	Incidence of infection similar in both groups

effects	Lymphatic disturbance showed no statistically significant difference between treatment groups with regard to average drainage volume, seroma incidences, time of drain removal or differences in arm circumference
<p>Authors concluded the directed group had better effectiveness outcomes and the lymphatic disturbance occurrences were equal among the groups.</p>	
<p><b>General comments</b> no description of randomisation process or blinding; power calculation; sketches of all exercises</p>	

Dawson I, Stam L Heslinga JM & Kalsbeek HL (1989). Effect of shoulder immobilization on wound seroma and shoulder dysfunction following modified radical mastectomy: a randomized prospective clinical trial. *British Journal of Surgery*, 76(3), 311-312.

**Design:** RCT, **evidence level:** 1-

**Country:** The Netherlands, **setting:** Secondary Care

**Inclusion criteria** women undergoing modified radical mastectomy

**Exclusion criteria** -

**Population** N = 100 women, mean age 64 (SD: 12) and 65 (SD: 14) in both groups

**Interventions**

Exercise group (n=51): group started to exercise on first postoperative day

Immobilized group (n=49): ipsilateral arm immobilized in sling for 5 days, then same shoulder exercises

**Outcome note** when suction drain was removed on 5<sup>th</sup> day, drainage volume was recorded, shoulder function assessed by same individual

**Follow up** 5 days postoperatively, wound inspection daily after day 5

**Results**

Outcome	Result
Function	The exercise group showed a 7° (SD: 9) anteflexion decrease, the immobilised group 10° (SD: 9), n.s. The exercise group showed a 10° (SD: 11) abduction decrease, the immobilised group 11° (SD: 10), n.s. Limitations of >15°antflexion occurred in 14% of patients in the exercise group and in 22% of immobilised patients, n.s. Limitations of >15°abduction occurred in 22% of patients in the exercise group and in 29% of immobilised patients, n.s.
Adverse events	Seromas developed more often in the exercise group but no significant difference in volume, duration or number of aspirations; 8% of the exercise and 2% of the immobilised group exhibited delayed wound healing, infections (6%) requiring either antibiotics or open drainage occurred only in the exercise group haemorrhage occurred in 2% of both groups The drainage volume for the exercise group was 15% more than for the immobilised group

Authors conclude shoulder exercises before the 5<sup>th</sup> postoperative day should be abandoned.

**General comments** randomisation not described, blinding not mentioned; statistical analysis missing for adverse events; Jansen et al. (1990) think this study presents an incomplete statistical analysis; published as a short notice

Sprod LK, Scott MS, Drum MS et al. (2005). The effects of walking poles on shoulder function in breast cancer survivors. *Integrative cancer therapies*, 4(4), 287-293.

**Design:** RCT, **evidence level:** 1-

**Country:** USA, **setting:** Cancer Rehabilitation Institute

**Inclusion criteria** women who had undergone primary breast cancer treatment

**Exclusion criteria** -

**Population** N = 16 women with mastectomy, some breast conservation therapy, some with axillary lymph node dissection, most with chemotherapy, half with radiation therapy, mean age 59 (SE: 4.6) and 55 (SE: 2.7) in both groups

**Interventions** aerobic conditioning, total body resistance training, flexibility training, bench press, shoulder press, latissimus dorsi pull down, 8 weeks

Treatment group (n=6): use of walking poles during aerobic exercises, demonstration, supervision, 20 min aerobic activity, 2 days per week, pole working usually took place outdoors, >18 months between treatment and exercise intervention

Controls (n=6): without walking poles

**Outcome note** muscular endurance measure: patients asked to perform as many repetitions as possible before volitional muscular fatigue

**Follow up** ?, probably immediately after exercise course

### Results

Outcome	Result
Function	All participants began the study with normal shoulder ROM values, hence no differences over time
Compliance	13.17 workouts (SE: 1.04) vs 12.50 (SE: 1.41) in experimental and control group, n.s.
Strength	The difference from pre-exercise to post-exercise was with 6.83 repetitions significantly better in the experimental group for bench press, the difference was -0.8 for the controls The difference from pre-exercise to post-exercise was 1.17 repetitions in the experimental group for shoulder press, the differences was -0.4 for the controls (both n.s. improvement) The difference from pre-exercise to post-exercise was with 13 repetitions significantly better in the experimental group for latissimus dorsi pull down, the difference was 5.2 for the controls

Authors conclude using poles improves muscular endurance.

**General comments** randomisation not described, blinding not mentioned, withdrawals explained, sample extremely small, difference between treatment and control group not tested for significance, only pre-post measurements

Wang BG, Yuan XY, Wang QT et al. (2005). Functional rehabilitation gymnastics for the oedema of upper limbs and the activity of shoulder joint in postoperative patients with breast cancer. Zhongguo Linchuang Kangfu, 9(30), 16-19.

**Design:** RCT, **evidence level:** 1- (due to translation issue, 1+ possible)

**Country:** China, **setting:** Department of Mammary Surgery

**Inclusion criteria** women with breast cancer

**Exclusion criteria** -

**Population** N = 200 women, it is possible that the age range varied from 28-72 and 30-74 in the groups

**Interventions**

Rehabilitation: functional rehabilitation gymnastics assisted with music, 5 sessions, offered at week 1,2,3,4 and 1 month postoperatively, each session had 4 parts

Control: self-exercise

**Outcome note** -

**Follow up** 1, 2, 3 months after treatment

**Results**

Outcome	Result
Function	3 months postoperatively anterior (106°, SD:1.0° vs 48°, SD:2.0), posterior (49°, SD: 2.0 vs 46°, SD: 1.0) and lateral elevation angles (85°, SD: 1.0 vs 60°, SD: 4.0) and internal (61°, SD: 1.0 vs 58, SD: 1.0) and external rotation angles (83°, SD: 1.0 vs 49°, SD: 1.0) of upper limbs were bigger in the rehabilitation group than the control group; p<0.05*
Adverse events	The rehabilitation group had fewer incidences of oedemas at 1 month postoperatively (7% vs 32% p<0.05) and at 2 months postoperatively (2% vs 15%, p<0.05)

Authors concluded gymnastics improve muscles, promote blood circulation and lymphatic return, alleviate oedema and improve shoulder joint activity and functional impairment.

**General comments** Japanese publication, data taken from abstract and tables, the quality of the RCT could be higher than 1-; randomisation not described in abstract; ITT analysis, sketch for every exercise; \* the significance test is a t-test so presumably all 5 differences were significant on the 0.05 level but it is not clear from the abstract

Le Vu B, Dumortier A, Guillaume M et al. (1997). Physiotherapy after surgery for breast cancer. Bulletin Cancer, 84(10), 957-961.

**Design:** RCT, **evidence level:** 1-

**Country:** France, **setting:** probably secondary care

**Inclusion criteria** surgically treated breast cancer patients

**Exclusion criteria** bilateral breast cancer, previous surgical or chemotherapy treatment, non French speaking, psychological problems, treatment allocation problems

**Population** N=264 patients with axillary clearance, 1/3 with mastectomy, some with tumorectomy, later breast reconstruction, mean age 55 (SD:11.3), 56 (SD:11.8), 57 (SD:12.5) or 58 (SD:12.5) years in the groups

**Interventions** intervention started the day after surgery for 7 days, all patients received 5 sessions of physiotherapy; after the 7<sup>th</sup> day all patients received massages and mobility training

Massage (n=65): massage in reclining position, gentle touch and firm gliding pressure, aiming to ease pain and at circulation

Mobilisation (n=65): shoulder movement, active, gradual, without resistance, symmetric, antepulsion, abduction and rotation

Combination (n=64): massage and mobilisation

No rehabilitation (n=63):

**Outcome note** 7 day data stem from hospital records, 3 months questionnaire, last follow up data from medical records; degree of motion was only assessed at day 7

**Follow up** 7 days (crucial), 3 months, 8-24 months

### Results

Outcome	Result
Function	The degree of abduction differed between groups on day 7 (p=0.0005) with 144° for the combination, 129° for mobilisation and massage and the control group had a value of 126° The degree of forward lifting? (antepulsion) differed between groups on day 7 (p=0.002) with 143° for the combination, 131° for mobilisation, 130 for massage and 126° in the control group After all patients received massages and mobility training, there were no differences between groups at the 3 months and the last follow-up There were no differences between groups in self reported abnormalities of amplitude at 3 months nor where there differences at the last follow up
Adverse effects	The volume of lymph drained on day 7 was lowest in the massage group (336cm <sup>3</sup> ) and highest in the mobilisation group (436cm <sup>3</sup> ), the combination had a volume value of 366, the controls 389; (p=0.03) All other adverse effects including pain showed no differences at the 3 and the last follow up (8-24 months)

Authors concluded that an early treatment including both physiotherapy and shoulder movement seems advisable.

**General comments** published in French, the intervention description has to be regarded with

caution due to possible translation mistakes, the authors translated the massage intervention as physiotherapy, the mobilisation intervention as shoulder movement; the text and tables differ for the 7 day data; no details about randomisation / blinding, ITT analysis (257 finally analysed), withdrawals descibed

Hase K, Kamisako M, Fujiwara T et al. (2006). The effect of Zaltprofen on physiotherapy for limited shoulder movement in breast cancer patients: A single-blinded before-after trial. Arch Phys Med Rehabil, 87, 1618-1622.

**Design:** Controlled before-after trial, **evidence level:** 1-

**Country:** Japan **setting:** Rehabilitation department

**Inclusion criteria** women with limited shoulder movement after breast cancer surgery

**Exclusion criteria** preoperative shoulder dysfunction, taking other NSAIDs, history of intestinal ulcer

**Population** N = 40 patients with surgery 10 to 223 days ago, all with pain at the end of maximum ROM, some with spontaneous dull pain, mean age 51, range 37-72

**Interventions** physiotherapy, pasive stretching for full ROM in flexion, abduction, and external rotation, physiotherapist supporting arm with muscular relaxation, use of a wooden stick or wall, supine, seated or standing position, 20 min, instructions for exercises at home  
Zaltprofen group: single 80mg tablet  
Controls: no treatment

**Outcome note** examiner and physiotherapist blinded, steps to ensure allocation concealment; goniometer; ROM estimated by physiatrist

**Follow up** post-exercise

#### Results

Outcome	Result
Function	The zaltoprofen group showed larger flexion and abduction movements than the controls before ( $p < 0.05$ ) and after ( $p < 0.01$ ) the exercises
Pain	Pain scores decreased after ROM exercises in the control and the zaltoprofen group, 2 controls had increased pain after ROM exercises, group comparison n.s.

Authors concluded oral zaltoprofen before ROM exercises may enhance the effect of physiotherapy.

**General comments** randomisation not further described, only patients not blind; the study gist is that painkiller lets you lift your arm higher but the authors mention that the immediate effect gave some patients an expectation of succeeding in achieving the elevated-arm position required for radiotherapy

Gerber L, Lampert M, Wood C et al. (1992). Comparison of pain, motion, and edema after modified radical mastectomy vs. local excision with axillary dissection and radiation. Breast Cancer Research and Treatment, 21, 139-145.

**Design:** RCT (case series regarding physiotherapy), **evidence level:** 1-  
**Country:** USA, **setting:** Department of Rehabilitation Medicine

**Inclusion criteria ?**

**Exclusion criteria -**

**Population** N=165 patients for whom pre- and postoperative ROM data was available, randomised to axillary dissection with radiation or modified radical mastectomy

**Interventions** heat, cold, massage and transcutaneous nerve stimulators for pain and to promote motion, use based on clinical judgement; day 1-2 postoperatively 40° flexion and abduction, day 3 45°, day 4-6 45-90° flexion and 45° abduction, day 7 / when drains removed flexion and abduction to tolerance, internal / external rotation throughout to tolerance of pain; home maintenance programme after achieving at least 110° flexion, 90° abduction and 55° external rotation of the shoulder, use of overhead pulley recommended; education about preventing arm oedema

**Outcome note** goniometer for ROM, manual muscle test, tenderness by examiner / utterance of pain palpitation

**Follow up** year 1, 2, 3, 4 and 5

**Results**

Outcome	Result
Function	The average number of days when post-operative ROM was reached was 172 (axillary dissection with radiation) and 195 (modified radical mastectomy), p=0.043 There was no significant loss in ROM over the first year in flexion, abduction or internal or external rotation, regardless of the surgery type
strength	The serratus anterior muscle was most frequently found to be weak, followed by the pectoralis major and latissimus dorsi (incidences in 4 to 12 patients), full strength returned within 1 year, regardless of the surgery groups
Pain	The number of participants with chest wall tenderness was 43, 44, 56, 58 and 46 in the first 5 years after surgery
Adverse events	79/131 patients had a circumferential measurement of <2, 35 had values 2-3.9, 13 4-5.9 and 4 had 6cm or more; Cosmetic differences were found in 22/121 patients; Skin elasticity was reduced to <3mm in 6 patients

Authors concluded that the axillary dissection group may have reached better ROM results because ROM was supervised during the entire radiation treatment.

**General comments** only marginally relevant, it is impossible to separate the effects of surgery and mobility strategy; randomisation and blinding not described, loss to follow up explained (165 or less of 247 finally analysed)

Wingate L, Croghan I, Natarajan N, Michalek M & Jordan J (1989). Rehabilitation of the mastectomy patient: A randomized, blind, prospective study. Arch Phys Med Rehabil, 70, 21-24.

**Design:** RCT combined with non-randomised data, **evidence level:** 2++  
**Country:** USA, **setting:** physical therapy department

**Inclusion criteria** patients scheduled for a modified radical mastectomy

**Exclusion criteria** -

**Population** N = 115 patients, these included patients from a non-randomised pilot study, mean age 56 and 58 in both groups

**Interventions**

Treatment (n=61): physical therapy, 30 minutes twice a day, beginning on the first postoperative day active hand, wrist, elbow, and postural exercises were initiated, active and active-assisted shoulder exercises were started in conjunction with functional activities and proprioceptive neuromuscular facilitation patterning (PNF); after removal of the drain, treatment included progressive resistive exercise and PNF, exercises were made progressively more difficult; instructions with printed materials were provided for a home exercise program to be continued for at least 8 weeks, info about prostheses was given along with hand and arm care instructions  
 Controls (n=54): no physical therapy

**Outcome note** assessor blind; psychological status (self-) assessed with SCL-90-R; goniometer; functional outcome probably observation

**Follow up** 5 days postoperatively and between 1-3 months (mean 2.5 months) postoperatively

**Results**

Outcome	Result
Function	Both groups lost range of motion but shoulder abduction and flexion was better for treated patients than controls (p<0.001) at 5 days; both groups showed improvement at the late follow up but the intervention group showed better improvement than controls (p<0.001); Controls had more difficulties with the tasks 'bring your arm behind you to wash your upper back on that side' (p=0.005), 'bring your arm across the front to wash your upper back on the opposite side' (p=0.001) and 'carry a bag with 10pounds groceries' (p=0.02) than the treatment group 5/6 tasks were more difficult for the control group at the late follow-up including zip up a back fastening zipper (p=0.02) and 'make a double bed' (p=0.05), the other mentioned tasks remained significantly more difficult for the control group
Adverse effects	Postoperative complications or lengths of hospital were not different across groups; No difference at 5 day follow up in circumferential measurements, three measurements different at late follow up but not greater than 0.2cm
Other	There were no differences in psychological status across groups

Authors concluded early physical therapy is significant for returning to normal function without

increasing postoperative complications or hospital stay.

**General comments** randomised sample and non-randomised pilot study combined therefore classified as cohort study; randomisation procedure not described; assessors blinded

Na YM, Lee JS Par JS et al. (1999). Early rehabilitation program in postmastectomy patients: A prospective clinical trial. Yonsei Medical Journal, 40(1), 1-8.

**Design:** Clinical trial, **evidence level:** 2-

**Country:** Korea, **setting:** presumably secondary care

**Inclusion criteria** patients scheduled for mastectomy with biopsy confirmed breast cancer

**Exclusion criteria** no consent

**Population** N = 33, majority with modified radical mastectomy, minority with partial mastectomy / axillary dissection, some with history of neck and shoulder pain; mean age 44 (SD: 2.1) and 47 (SD: 9.8) years in both groups

**Interventions**

Rehabilitation (n=20): 40 minutes physical therapy, 30 minutes exercise 4 times a day with protocol, beginning on 1<sup>st</sup> post-operative day postural exercise, assisted ROM exercise of the shoulder, elbow, wrist; active use of involved arm for light functional activities, physical modalities for pain relief or muscle spasm and therapeutic exercise including ROM exercise from 3<sup>rd</sup> post-operative day on, patients encouraged to elevate the arm as often as possible, using an elastic bandage, massaging the extremity from distal to proximal along the length, isometric and isotonic pumping exercises of the distal muscles; stretching exercises of neck or shoulder muscles after pain relief; after drain removal progressive-resistive exercises of the upper extremities, number of ordinary functional activities (e.g. dressing) progressively increased; encouraged to continue exercises after discharge for at least 4 weeks

Controls (n=13): printed material about self-exercise programme, proper positioning by physiatrist

**Outcome note** SCL-90-R (self report) for psychological assessment; goniometric measurement, functional evaluation using Wingate's system (questionnaire for activities of daily living) and upper extremity circumferential measurements by physiatrist

**Follow up** 3 days postoperatively, at discharge, 1 month after discharge

**Results**

Outcome	Result
Function	<p>ROM for flexion was not higher 3 days postoperative but at discharge (161 vs 150, p&lt;0.05) and 1 month after discharge (179 vs 167, p&lt;0.05) in the rehabilitation group compared to controls</p> <p>ROM for abduction was not higher 3 days postoperative but at discharge (129 vs 110, p&lt;0.05) and 1 month after discharge (167 vs 119, p&lt;0.01) in the rehabilitation group compared to controls</p> <p>ROM shoulder internal rotation was not higher 3 days postoperative or at discharge but higher 1 month after discharge (69 vs 65, p&lt;0.05) in the rehabilitation group compared to controls</p> <p>ROM shoulder external rotation was not higher 3 days postoperative or 1 month after discharge but higher at discharge (84 vs 69, p&lt;0.05) in the rehabilitation group compared to controls</p>
Adverse	45% of rehabilitation patients reported sensory changes, 39% of

effects	<p>the controls; oedema, wound breakdown, infection, motor weakness or adhesional bands did either not occur or only in 1 to 3 patients in both groups</p> <p>1 patient in the rehabilitation group showed an increment of circumference &gt;1cm compared to preoperative</p> <p>Circumferential measurements did not differ between groups</p>
<p>Authors concluded that instructed rehabilitation is beneficial and does not increase complications.</p>	
<p><b>General comments</b> very small control group, it is not entirely clear whether there were treatment elements that were shared between the groups; the results for the functional items were not extracted as figures indicated no differences or mixed results while the text stated statistically significant differences; the psychological variables were not compared between groups</p>	

Gordon, Battistutta, Scuffham, Tweeddale & Newman (2005a). The impact of rehabilitation support services on health-related quality of life for women with breast cancer. *Breast Cancer Research and Treatment*, 93[3], 217-226.

Gordon, LG, Scuffham P, Battistutta D et al. (2005). A cost-effectiveness analysis of two rehabilitation support services for women with breast cancer. *Breast Cancer Research and Treatment*, 94, 123-133.

**Design:** Prospective comparative study, Cost-effectiveness analysis **evidence level:** 2-  
**Country:** Australia, **setting:** Community/secondary care

**Inclusion criteria** Intervention groups: women attending 2 rehabilitation programmes, diagnosed with primary, unilateral breast cancer, spoke English, had no cognitive problems, were aged 25-74 years; Control group: women from a different project

**Exclusion criteria** 'too ill', had attended the programmes previously; in one rehabilitation group, women who were recruited in a known trial of sentinel node biopsy

**Population** N = 275 women (about 50% of eligible patients), mean age 56 years

**Interventions**

DAART (n=36): Domiciliary Allied Health and Acute Care Rehabilitation Team, 6 week programme commencing 4-5 days post-surgery; home visits from physiotherapists aiming at 90% recovery of shoulder ROM and emotional support, education, tailored exercise prescription for self-management  
 STRETCH (n=31): Strength Through Recreation Exercise Togetherness Care Health; 8 week programme commencing 8 weeks post-operatively, group sessions, exercise physiologist, aiming at peer support, recovery of preoperative strength and shoulder ROM and alleviating psychosocial concerns

Controls (n=208): patients from the same locality, no exercises

**Outcomes note** mailed questionnaire, health related QoL and functional assessment self-report; Functional Assessment of Cancer Therapy including a breast cancer subscale (FACT-B); Functional Assessment of Cancer Therapy (FACT-G, = general), which excludes the breast cancer specific subscale; Extended Functional Assessment of Cancer Therapy with a specific arm morbidity subscale (FACT-B+4); Disability of the Arm, Shoulder or Hand (DASH) scale, a scale based on performing daily activities

Cost: the analysis took costs for the programme (personnel, overheads, capital equipment, other), clients (leisure forgone, travel, other expenses, health services expenditure) and the community (volunteers, lost productivity) into account; the incremental calculations were increments of the intervention over the non-intervention group; Monte-Carlo simulations

**Follow up** post-intervention (3-8 weeks post-diagnosis, timing varied in groups), 6 and 12 months post-diagnosis, compared to post-surgery data

**Results**

Outcome	Result
Function	The authors stated that DAART patients showed clinically significant improvements in arm function and upper body function Overall scores suggested relatively little disability Adjusting for known confounders there were no statistically significant differences between the three treatment groups compared for any subscale of any instrument

QoL	<p>DAART patients showed clinically significant improvements in functional well-being</p> <p>Adjusting for known confounders there were no statistically significant differences between the 3 treatment groups for any subscale</p> <p>20-40% of women at 12 months post-diagnosis had declining health related QoL scores</p> <p>According to the authors the control group had clinically important higher scores than the intervention groups for the functional, breast cancer, FACT-G and FACT-B subscales</p>
Cost	<p>The DAART intervention was most efficient with an incremental cost of \$1344 per QALY gained, the corresponding value for the STRETCH programme was \$14.478</p> <p>The cost-effectiveness acceptability curves did not cross (hence the probability that DAART is cost-effective is always higher compared to STRETCH at the same level of societal willingness to pay)</p>

Authors concluded that early physiotherapy after surgery has the potential for short-term functional, physical and overall health related QoL benefits.

**General comments** the 3 samples differed considerably, not just regarding the intervention (more statistically significant differences in sample characteristics than for the outcomes of interest, several variables were significant confounders); considerable conceptual overlap between the subscales and for most of the many scales it was unclear what exactly they assessed; the authors' belief in significant clinical improvements despite any statistically significant results is controversial; the effectiveness and the cost-effectiveness publications were extracted together

Christodoulakis M, Sanidas E, de Bree E et al. (2003). Axillary lymphadenectomy for breast cancer – the influence of shoulder mobilisation on lymphatic drainage. *EJSO*, 29, 303-305

**Design:** Cohort study with historic controls, **evidence level:** 2-

**Country:** Greece, **setting:** Department of Surgical Oncology

**Inclusion criteria** women undergoing wide local tumour excision and axillary lymph node dissection level I and II for cytologically or histologically proven invasive breast cancer

**Exclusion criteria** WHO performance status >2, history of disease or treatment affecting the axilla or shoulder

**Population** N = 100 consecutive women plus N = 60 historic controls; mean age 58 (31-81) and 58 (37-79) in both groups

#### **Interventions**

Intervention: drainage tube in axilla without restricting arm movement

Controls: external compression dressing, arm immobilised by bandage around chest and in an adduction position with the elbow in flexion and the underarm over the anterior chest wall for 4 days

**Outcome note** hospital records

**Follow up** at least 9 days; drainage recorded each day for 4 days

#### **Results**

Outcome	Result
Adverse effects	No difference between post-operative complications, only a trend towards higher drain obstruction rate in the free shoulder movement group There was no difference in drainage volume or the number of days with drain in both groups
Other	The non-restricted group had a shorter hospital stay than the immobilised historic controls (5.7 (SD: 2.3) vs 6.7 (SD: 2.2) days, p=0.009

Authors concluded external compression dressing with immobilisation has no impact on the drainage volume and duration but it is associated with adverse effects such as discomfort, prolonged hospital stay and shoulder stiffness.

**General comments** the difference in hospital stay between the current and the historic control can have many reasons; the conclusions regarding the adverse events is not documented in the result section apart from the length of stay

Johansson K, Ingvar C, Albertsson M & Ekdahl (2001). Arm Lymphoedema, shoulder mobility and muscle strength after breast cancer treatment – A prospective 2-year study. *Advances in Physiotherapy*, 3, 55-66.

**Design:** Case series, **evidence level:** 3

**Country:** Sweden **setting:** Departments of Physical Therapy and Surgery

**Inclusion criteria** women undergoing axillary dissection combined with mastectomy or segmental resection for breast cancer

**Exclusion criteria** previous contralateral breast disease, recurrent cancer, muscle or joint disorder, difficulties in participating such as dementia, personal reasons, too short notice

**Population** N = 61 (out of 90 eligible) patients, half with radiotherapy with some to the breast and axilla, mean age 56 (SD: 10)

**Interventions** daily home exercise programme and oedema-prevention programme, verbal and written, experienced physiotherapist; shoulder flexion and abduction in supine position, internal and external rotation sitting, 5 times, 3 times a day, at least for 6 months, to pain limit without stretching; oedema prevention: high arm position, hand pumping exercise; advice to avoid heavy or monotonous work and infections

**Outcome note** strength only evaluated +6 months; goniometer; Jamar dynamometer; test-retest reliability of measures assessed in pilot study; lymphoedema defined as 10% volume increase compared to non-operated arm

**Follow up** every month for 6 months postoperatively, at 1 and 2 years

**Results**

Outcome	Result
Function	Reduction of ROM for shoulder abduction was observed on 48% of patients at 5 months, at 6 months reduced internal rotation occurred in 61% of patients, abduction 41%, external rotation 34% and flexion 33%; at 2 years the corresponding values were 63, 43, 30 and 27% None of the patients returned to their preoperative values for internal rotation The patients who received radiotherapy to the breast and the axilla showed continuous impairment of ROM
Strength	A significant decrease in isometric muscle strength was found at 6 months, 1 and 2 years for flexors, adductors and internal rotators of the shoulder but no change in gripping force At 2 years there were no differences between radiotherapy and other groups
Adverse events	Arm oedema incidence 12% during 2 years

The authors concluded postoperative physiotherapeutic management needs to pay special attention to early impairments after breast cancer treatment, especially patients receiving radiotherapy to the axilla area; treatment might be introduced during radiotherapy.

**General comments** clearly reported; drop-outs explained; the conclusion is based on logical considerations as the study does not investigate the effect of physiotherapy alone

Rietman JS, Dijkstra PU, Debreczeni R et al. (2004). Impairments, disabilities and health related quality of life after treatment for breast cancer: A follow-up study 2.7 years after surgery. *Disability and Rehabilitation*, 26(2), 78-84.

**Design:** Case series, **evidence level:** 3

**Country:** The Netherlands, **setting:** unclear

**Inclusion criteria** patients undergoing modified radical mastectomy or segmental mastectomy with axillary lymph node dissection

**Exclusion criteria** mastectomy on both sides, metastases, patients with recurrences

**Population** N = 55 patients, mean age 57 (SD: 13.3) years

**Interventions** exercises, physical therapy

**Outcome note** this risk factor study assessed exercise compliance and the number of patients who had physical therapy

**Follow up** 2.7 years post-operatively

**Results**

Outcome	Result
Other	The prediction models of impairment, disability and health related quality of life did not include the factors exercise compliance or physical therapy

Authors concluded radiotherapy and chemotherapy predict impaired range of motion, pain predicts disability and health related QoL.

**General comments** withdrawals described (55 of 156 asked finally analysed); it is not certain that the relevant outcomes were included in the analyses in the first place but the data seemed to be theoretically available

Gosseling R, Rouffaer L, Vanhelden P et al. (2003). Recovery of upper limb function after axillary dissection. Journal of Surgical Oncology, 83, 204-211.

**Design:** Case series, **evidence level:** 3

**Country:** Belgium **setting** Department of Physiotherapy

**Inclusion criteria** patients undergoing at least a level I and II axillary dissection

**Exclusion criteria** -

**Population** N = 76 patients with modified radical mastectomy or breast-conserving procedure with axillary dissection, patients with mastectomy more likely to undergo irradiation of the axilla; mean age 56 (SD: 12)

**Interventions** Shoulder mobilisation under supervision of physiotherapist, started 2<sup>nd</sup> postoperative day to the 5<sup>th</sup> day after surgery; written and verbal instruction for lymphoedema prevention; subscription for further supervised shoulder mobilisation during 6 weeks

**Outcome note** active ROM; goniometer; tapemeasure for inward and outward rotation with patient standing; arm circumference with tape measure; pain visual analogue scale (0-10); questionnaire for activities of daily living, general questions regarding impairment

**Follow up** day 4, 3 weeks, 3 months post-surgery

### Results

Outcome	Result
Function	At 4 days a significant impairment of shoulder flexion was measured, flexion improved 37° in breast-conserving and 18° in mastectomy patients after 3 months, the pattern for shoulder abduction was similar (50° and 20°) Inward rotation improved after 3 months (p=0.04), 72% of patients had a normal inward rotation, Outward rotation improved by 5 and 3 com in the two groups, 22% reached normal values 96% of patients noticed a difference in upper limb function during activities of daily living at 3 weeks
Compliance	At 3 months, the patients have had on average 25 sessions of physiotherapy (SD: 10)
Pain	The score for pain at 4 days and at 3 weeks was 3.3, after 3 months it improved to 2.6 (p=0.01)
Adverse events	5% of patients had lymphoedema at day 4, 2.5% at 3 months

Authors concluded that results warrant considering continuation of physiotherapy after 3 months post-operatively.

**General comments** hand dominance was considered; only marginally relevant, it is impossible to trace the results back to the mobility strategy

Johansson K (2005). Is physiotherapy useful to the breast cancer patient?  
Acta Oncologica, 44, 423-424.

**Design:** Editorial, **evidence level:** 4

**Country:** Sweden, **setting:** -

**Inclusion criteria** -

**Exclusion criteria** -

**Population** whole review relevant

**Interventions** Physiotherapy, physical activity

**Outcome note** -

**Follow up** -

**Results**

Outcome	Result
Function	In order to prevent reduced shoulder mobility, active arm exercises are important; patients without physiotherapy postoperatively show significant limitation in range of motion and function in the shoulder (Wingate et al., 1989 cited), physiotherapy started 6 months postoperatively also improves shoulder functioning (Lauridsen et al., 2005 cited) but there is no rationale to postpone the start
Strength, Adverse events	To maintain the muscle strength of the ipsilateral arm it is important to continue on the same activity level as soon as possible postoperatively; patients are sometimes advised 'to be careful' with the affected arm to prevent lymphoedema but there is no empirical evidence to back this up

Author concluded "Yes, indeed!", physiotherapy is useful, it is worthwhile even if started after 6 months but there is no rationale to postpone the start.

**General comments**

Anon. (2000). Arm oedema following breast cancer treatment. Drug & Therapeutics Bulletin, 38(6), 41-43.	
<b>Design:</b> Non-systematic review <b>evidence level:</b> 4 <b>Country:</b> UK <b>setting:</b> - <b>Inclusion criteria</b> - <b>Exclusion criteria</b> - <b>Population</b> 1 relevant sentence <b>Interventions</b> exercise <b>Outcome note</b> - <b>Follow up</b> - <b>Results</b>	
Outcome	Result
Function, strength	Exercise has the advantage of promoting recovery of arm strength and mobility, and of capacity to pursue normal daily activities
The authors do not mention strategies to reduce arm and shoulder mobility problems in the conclusion.	
<b>General comments</b> no empirical study cited for the relevant sentence	

Beurskens, C., van Uden, C., Strobbe, L., Oostendorp, R., Wobbes, T. (2007) The efficacy of physiotherapy upon shoulder function following axillary dissection in breast cancer, a randomised controlled study <i>BMC Cancer</i> 7;166.	
<b>Design:</b> Randomised Controlled Trial <b>Evidence Level:</b> 1+  <b>Country:</b> The Netherlands  <b>Aim:</b> To investigate the efficacy of physiotherapy treatment of shoulder function, pain and the quality of life in patients who have undergone breast cancer surgery and axillary lymph node dissection.  Beurskens <i>et al.</i> (2007) reported on a small RCT that investigated the efficacy of physiotherapy treatment of shoulder function, pain and the quality of life in patients who have undergone breast cancer surgery and axillary lymph node dissection. Functional shoulder impairments and pain in the shoulder/arm were significantly reduced following physiotherapy at three months as compared to the control group. There was no significant improvement in handgrip strength or in volume of the related arm between both groups at baseline and follow-up.	
<b>Inclusion criteria:</b> 18 years or older with an ALND following breast cancer A Visual Analogue Scale (VAS; 0-10) pain score of 1 or more Moderate shoulder disabilities in daily life	

<p><b>Exclusion criteria</b>  Previous contralateral breast cancer surgery  Insufficient knowledge of the Dutch language to fill in the questionnaire</p>
<p><b>Population:</b> N=30</p>
<p><b>Interventions:</b> Specific physiotherapy treatment vs. no physiotherapy  The control group (no physiotherapy) were given a leaflet with advice and exercises for arm and shoulder for the first weeks following surgery.  Patients in the treatment group began physiotherapy two weeks after surgery in a private practice of their choice for a total number of nine treatments.</p>
<p><b>Outcomes:</b>  The primary outcomes were; Pain in the shoulder or arm, measured using the VAS score (0=no pain to 10=unbearable pain), shoulder mobility and abduction.  Secondary outcomes included disabilities in daily life measured by DASH (Disabilities in Arm, Shoulder and Hand) questionnaire, edema, grip strength and quality of life.</p>
<p><b>Results</b>  Functional shoulder impairments and pain in the shoulder/arm were significantly reduced following physiotherapy (<math>p &lt; 0.001</math> at three months as compared to the control group).   Pain decreased by 3.4 points on the VAS in the treatment group compared with a 0.5 point decrease in the control group.   Shoulder flexion and abduction increased by 45 degrees and 70 degrees respectively in the treatment group compared with 11 and 13 degrees respectively in the control group (<math>p = 0.003</math> and <math>p = 0.005</math> respectively).   There was no significant improvement in handgrip strength or in volume of the related arm between both groups at baseline and follow-up.</p>
<p><b>General comments</b>  Lymphoedema is a secondary outcome of this trial and so there is indirect applicability to the PICO.   The length of follow-up for this study is not likely to have been sufficient to provide information on lymphatic edema following ALND as there is evidence to suggest that lymphoedema can commence anywhere between 1 month and 28 years following ALND.</p>

<p>Cinar, N., Seckin, U., Keskin, D., Bodur, H., Bozkurt, B., Cengiz, O. (2008) The effectiveness of Early rehabilitation in patients with modified radical mastectomy <i>Cancer Nursing</i> 31;2:2008</p>	
<p><b>Design:</b> Randomised Trial</p>	<p><b>Evidence Level:</b> 1-</p>
<p><b>Country:</b></p>	

**Aim:** To evaluate the effects of early onset rehabilitation program on shoulder mobility, functional capacity, lymphoedema and postoperative complications in patients who underwent modified radical mastectomy.

To determine the effect of clinical variables on the recovery of shoulder mobility, functional capacity and development of lymphoedema.

Cinar *et al.* (2008) conducted a small RCT which evaluated the effects of early onset rehabilitation program on shoulder mobility, functional capacity, lymphoedema and postoperative complications in patients who underwent modified radical mastectomy. The trial investigated the effect of clinical variables on the recovery of shoulder mobility, functional capacity and development of lymphoedema. The intervention included a treatment group (directed physiotherapy) versus home group (exercises taught by physiotherapist and patients to perform them by themselves). The improvement in measurements of flexion, abduction, and adduction movements of the shoulder joint and the functional questionnaire scores were significantly improved in the treatment group. No statistically significant difference in the development of lymphoedema and postoperative complications in both groups was observed.

**Inclusion criteria:** None Given

**Exclusion criteria:** None Given

**Population:** N=57

**Interventions:** Treatment Group (directed physiotherapy) versus Home Group (Exercises taught by physiotherapist and patients to perform them by themselves).

**Outcomes:** Range of Movement (ROM) including flexion, extension, and internal and external rotation  
Circumferential measurements of both arms to assess lymphoedema  
Upper extremity function (assessed via a functional questionnaire)

**Results:**

There was no statistically significant difference in the demographic properties of the patients between the groups.

There was no significant difference in preoperative ROM of the shoulder joint or upper extremity questionnaire between the operated and unoperated arms in both groups.

There were statistically significant time-related changes in all ROM and functional questionnaire scores in both groups. Flexion, abduction and adduction movements were significantly better in the treatment group compared with the home group ( $p < 0.01$ ,  $p < 0.001$ , and  $p < 0.005$  respectively).

The recovery of upper extremity functional questionnaire was significantly better in the treatment group compared with the home group ( $p < 0.05$ ).

Clinical Variables

Treatment Group

- Previous Shoulder problems resulted in limited flexion ( $p = 0.048$ ) and abduction

( $p=0.019$ ) movements at six month assessment in the treatment group. Adduction was also limited throughout the whole follow-up period.

- Age was negatively correlated with shoulder flexion at 3 ( $r = -0.415, p<0.05$ ) and 6 ( $r = -0.487, p<0.001$ ) month assessment.
- Age was negatively correlated with abduction at 1 ( $r = -0.510, p<0.001$ ), 3 ( $r = -0.590, p<0.001$ ) and 6 ( $r = -0.505, p<0.01$ ) month assessments.
- Body Mass Index was negatively correlated with flexion at month 3 ( $r = -0.448, p<0.05$ ) and with abduction at month 3 ( $r = -0.543, p<0.05$ ) and month 6 ( $r = -0.456, p<0.05$ ).
- Body Mass Index was correlated with functional questionnaire scores at first month ( $r = 0.387, P<0.05$ ).
- Education year was negatively correlated with first month functional questionnaire scores ( $r = -0.382, p<0.05$ ).

#### Home Group

- Education year was negatively correlated with functional questionnaire scores at first month ( $r = -0.400, p<0.05$ ).
- Education year was correlated with flexion at month 3 ( $r = 0.013, p<0.05$ ) and extension at month 3 ( $r = 0.044, p<0.05$ ) and month 6 ( $r = 0.368, p<0.05$ ).
- The number of metastatic axillary lymph nodes was negatively correlated with abduction at month 1 ( $r = -0.474, p<0.001$ ) and month 3 ( $r = -0.396, p<0.05$ ); internal rotation at month 1 ( $r = -0.452, p<0.05$ ) and adduction at 5<sup>th</sup> day ( $r = -0.462, p<0.05$ ), month 1 ( $r = -0.413, p<0.05$ ), month 3 ( $r = -0.381, p<0.05$ ) and month 6 ( $r = -0.383, p<0.05$ ).
- Patients who had radiotherapy had decreased shoulder abduction at six month assessment ( $p=0.002$ ).

There was no significant time-related circumferential difference in the treatment group and a statistically significant circumferential increase in the home group ( $p=0.015$ ) but no significant difference between the two groups.

Two patients in the treatment group and 2 patient in the home group had mild lymphoedema and 3 in the treatment group and 4 in the home group had moderate lymphoedema. In the treatment group the duration ( $r = 0.586$ ) and amount ( $r = 0.470$ ) of lymphoedema was correlated with the number of dissected lymph nodes

#### **General comments:**

This is not a controlled trial and there is a high potential for bias, particularly in relation to the functional questionnaire. The numbers in the study are small and no information is given as to the level of compliance with the treatment programs. The results of this study should be considered with caution.

Patients that received early postoperative rehabilitation obtained better shoulder mobility than the home group suggesting the efficacy of early rehabilitation following surgery. Recovery of functional capacity was better in the treatment group over the whole follow-up period and the six month functional questionnaire scores were better than at baseline.

Upper extremity lymphoedema following breast cancer surgery is a well known complication with reported incidence between 6% and 83%; this study recorded incidence of 19.2% for mild or moderate lymphoedema.

In the treatment group, negative correlation with age may indicate younger patients understand and apply the rehabilitation program more easily than older patients or may be indicative of the physiological decrease in mobility with age. Negative correlations with body mass index could be indicative of the difficulties obese patients may have with performing the exercises and negative correlations with education suggest that higher levels of education may lead to higher compliance with the exercise program.

### **8.3 What treatments are effective and safe for use to treat patients with menopausal symptoms and invasive breast cancer or DCIS?**

#### **Short Summary**

Many different types of intervention were identified including pharmacological (for example, endocrine therapies), alternatives to endocrine therapies, (for example antidepressants and other prescribed medications), complementary therapies, (for example isoflavones and herbal remedies), psychological support and group activities, (for example relaxation and exercise). The majority of the evidence was drawn from systematic reviews some of which included studies of women without breast cancer. (Antoine *et al.* 2007; Bordeleau *et al.* 2007; Carpenter *et al.* 2007; Col *et al.* 2005; Deng *et al.* 2007; Ganz *et al.* 2000; Goodwin *et al.* 2008; Hickey *et al.* 2005; Kenemans *et al.* 2005; Kimmick *et al.* 2006; Kroiss *et al.* 2005; Loprinzi *et al.* 2007; MacLennan *et al.* 2004; Modelska *et al.* 2002; Mom *et al.* 2006; Nedrow *et al.* 2006; Nelson *et al.* 2006; Pritchard *et al.* 2002; Royal College of Obstetricians and Gynaecologists *et al.* 2006; Thompson *et al.* 2008; Tremblay *et al.* 2008; von Schoultz *et al.* 2005; Walji *et al.* 2007)

There was inconsistency in the findings of RCTs of Hormone Replacement Therapies (HRT) and progestational agents regarding breast cancer recurrence, several trials were ongoing. All RCTs of selective serotonin reuptake inhibitors (SSRIs) and selective norepinephrine/noradrenaline reuptake inhibitors (SNRIs) were consistent in reporting a moderate effect in reducing hot flush frequency and severity. A reduction in menopausal symptoms was also reported from RCTs of clonidine and gabapentin, although the latter was only effective at high doses. A comparison of venlafaxine with clonidine found that daily hot flush frequency was reduced more effectively by venlafaxine than clonidine. The synthetic steroid, tibolone, produced a reduction in hot flushes comparable to HRT, improved sexual function and possibly mood. However there were longer term safety considerations since the drug increased blood lipids and clotting factors. There was no effect of red clover on menopausal symptoms however there were no studies of women with breast cancer. Soy extracts provided conflicting effects with a possible weak effect for women without breast cancer. There were no significant effects on hot flushes for black cohosh, vitamin E or magnetic therapy in women with breast cancer. There may be a risk of hepatic disorders with black cohosh and its safety remains under review by the Medicines and Healthcare products Regulatory Agency (MHRA). A comprehensive menopausal assessment programme found significant improvements in the menopausal symptom scale with reduced symptoms in the intervention group and an improvement in sexual functioning. Another systematic review found some effect of relaxation on hot flushes for women with breast cancer however the study quality was poor. There was no significant effect on hot flush frequency of acupuncture for women with breast cancer from one RCT.

## PICO

POPULATION	INTERVENTION	COMPARISON	OUTCOME

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

## **Evidence Summary**

A large volume of literature was available for the time period searched between 1968 and 2007. Many different types of intervention were identified including pharmacological e.g. hormone therapies, alternatives to hormone therapies, e.g. antidepressants and other prescribed medications, complementary therapies, e.g. isoflavones and herbal remedies, psychological support, group activities, e.g. relaxation and exercise. Since studies of psychosocial support tended to be concerned with the experience of having breast cancer rather than the relief of symptoms these were not included in this section of the review. The majority of the evidence was drawn from systematic reviews and it was not possible to differentiate between patients with invasive breast cancer or DCIS as suggested in the PICO table. Some trials in the systematic reviews included a healthy population of women with menopausal symptoms. The RCT populations were sometimes heterogeneous, some women were recruited after breast cancer treatment whilst others were still undergoing treatment.

There was inconsistency in the findings of RCTs of Hormone Replacement Therapies (HRT) and progestational agents regarding breast cancer recurrence, several trials were ongoing. All RCTs of SSRI/SNRIs were consistent in reporting a moderate effect in reducing hot flush frequency and severity. A reduction in menopausal symptoms was also reported from RCTs of clonidine and gabapentin, although the latter was only effective at high doses. A comparison of venlafaxine with clonidine found that daily hot flash frequency was reduced more effectively by venlafaxine than clonidine. The synthetic steroid, tibolone, produced a reduction in hot flashes comparable to HRT, improved sexual function and possibly mood. However there were longer term safety considerations since the drug increased blood lipids and clotting factors. There was no effect of red clover on menopausal symptoms however there were no studies of women with breast cancer. Soy extracts provided conflicting effects with a possible weak effect for women without breast cancer. There were no significant effects on hot flushes for black cohosh, vitamin E or magnetic therapy in women with breast cancer. A comprehensive menopausal assessment programme found significant improvements in the menopausal symptom scale with reduced symptoms in the intervention group and an improvement in sexual functioning. Another systematic review found some effect of relaxation on hot flashes for women with breast cancer however study quality was poor. There was no significant effect on hot flash frequency of acupuncture for women with breast cancer.

## **Hormone Replacement Therapy**

One good quality systematic review and meta-analysis comparing the findings of RCTs and non-randomized studies (NRS) of the use of HRT in breast cancer survivors reported that results of observational studies are discrepant to those of RCTs (Col *et al* 2005, 1++). The pooled RR of the two randomized trials was 3.41 (95% CI 1.59–7.33) for any breast cancer recurrence favouring no treatment with HRT. The largest contribution to this effect was from the Swedish HABITS trial (Holmberg & Anderson 2004) which was stopped early due to the increased incidence of new breast cancer events in the HRT arm. A third RCT (von Schoultz *et al* 2005) conducted since the meta-analysis

provided conflicting findings of no increase in risk with HRT (RR=0.82, 95% CI 0.35-1.9) and suggested that the choice of hormone regimen may modify the recurrence risk. However caution in the use of HRT is recommended whilst trials are ongoing. The Cochrane review (MacLennan *et al* 2004, 1++) provided evidence of the effectiveness of HRT vs. placebo in a non-breast cancer population, with a 75% reduction in hot flush frequency provided by the treatment.

An update search identified another systematic review (Antoine *et al* 2007, 1+) including two RCTs (Holmberg & Anderson 2004, von Schoultz *et al* 2005) which reported the conflicting findings of these two trials.

### **Epidemiological evidence**

An update search identified one review of the use of hormone therapy in women without a diagnosis of breast cancer (Shapiro 2007) from recent analyses of the Million Women Study (MWS) and the Women's Health Initiative (WHI). The WHI data suggested that oestrogen therapy reduced the overall risk of breast cancer especially of ductal and localized breast cancers. The MWS suggested that the increased risk of breast cancer in women on HRT was greatest for lobular and tubular tumours, whilst the risk for ductal carcinoma was raised but to a lesser extent.

### **Progestational agents**

A fair quality review of progestational agents (Mom *et al* 2006, 2+) reported the effectiveness of oral and intramuscular progestins in reducing hot flush frequency. Despite this, caution was recommended for women with breast cancer because of an additional increased risk of breast cancer in women using estrogen-progestagen combinations compared to estrogen only, suggesting an influence of progestagens on cancer growth.

An update search identified an RCT (Goodwin *et al* 2008, 1+) which reported that a 20mg dose of oral megestrol acetate significantly reduced hot flush frequency with little effect on other menopausal symptoms.

### **Antidepressants (SSRI and SNRI)**

One good quality systematic review (Nelson *et al* 2006, 1++) and 2 recent good quality RCTs (Carpenter *et al* 2007, 1+; Kimmick *et al* 2006, 1+) compared the effectiveness of paroxetine, venlafaxine, fluoxetine or sertraline with placebo in women with breast cancer. The systematic review reported a combined estimate which indicated a reduction of approximately 1 hot flash/day for paroxetine, venlafaxine, fluoxetine and citalopram in 6 trials. This compares with a reduction of 2.5-3 /day on oestrogen. Different doses of paroxetine did not produce a differential effect, whilst higher doses of venlafaxine were more effective (from 1 trial). Fluoxetine was not statistically different from placebo. Citalopram was not used in studies of women with breast cancer.

A recent crossover RCT of high and low dose venlafaxine vs. placebo used a monitor to measure physiological hot flashes as well as self reports. Both doses

moderately reduced the frequency of hot flashes, but only the higher dose reduced hot flash interference (Carpenter *et al* 2007, 1+).

Another recent small crossover RCT (Kimmick *et al* 2006, 1+) reported no differences in hot flash frequency or score for sertraline vs. placebo. However the crossover analysis revealed a reduction in hot flashes of -0.9 and -1.7 at 6 and 12 weeks when changing from placebo to sertraline which was significant when compared with an increase in frequency when crossing from sertraline to placebo ( $p = 0.03$  and  $0.03$ ). Measures of depression and quality of life were within normal ranges and did not change significantly within treatment groups.

One recent RCT (Loibl *et al* 2007, 1++) compared venlafaxine directly with clonidine. Venlafaxine was significantly more effective in reducing daily hot flash frequency (decrease of 7.6 / day) than clonidine (decrease of 4.9 / day). However patients taking venlafaxine had significantly more symptoms of nausea.

In an update search an RCT comparing sertraline with placebo in healthy peri- and post-menopausal women found that sertraline was ineffective and associated with bothersome symptoms (Grady *et al* 2007).

### **Clonidine**

The good quality systematic review (Nelson *et al* 2006, 1++) of non-hormonal therapies for menopausal symptoms identified 2 RCTs of clonidine vs. placebo for women with breast cancer.

- Goldberg (1994) found a decrease in mean difference of hot flush frequency of -0.79 (95% CI -1.55 to -0.04) and a composite score (frequency x severity) of 56% vs. 30% ( $P < 0.04$ ) in comparison to placebo.
- Pandya (2000) found a decrease in mean difference of hot flush frequency of -1.17 (95% CI -1.87 to -0.47) and reduced frequency of 24% vs. 14%  $P = 0.09$  in comparison to placebo.

Both studies were of fair quality and show a moderate decrease in the frequency of hot flushes in comparison to placebo for women with breast cancer.

### **Gabapentin**

The good quality systematic review (Nelson *et al* 2006, 1++) of non-hormonal therapies for menopausal symptoms identified 1 RCT of gabapentin vs. placebo for women with breast cancer (Pandya *et al* 2005). The severity and frequency of hot flushes was significantly reduced on the high dose of 900 mg, but not on the low dose of 300 mg (45% vs. 15%,  $P < 0.001$ ).

An update search identified one RCT of women using antidepressants for menopausal symptoms which compared existing treatment plus gabapentin (900mg) with gabapentin alone (Loprinzi *et al* 2007, 1+). Eighty one percent of

participants had a history of breast cancer. There was a median reduction of 50% in hot flash frequencies and scores regardless of whether the patients continued on antidepressants.

### **Levetiracetam**

An update search identified a pilot Phase II study (Thompson *et al* 2008; Level 3) on the use of levetiracetam to reduce hot flashes. A significant reduction in hot flash scores and frequency was reported. However further evaluation is required.

### **Tibolone (synthetic steroid)**

A systematic review of tibolone assessed the effects over a range of outcomes including hot flush frequency, mood, sexual function and serum lipids (Modelska & Cummings 2002, 1+). Of the 8 RCTs identified most reported a significant reduction in hot flushes and sweating in women taking tibolone compared with placebo. Two trials reported improvements in mood for women taking tibolone. Three trials reported a beneficial effect of tibolone on fatigability, frequency of headaches, psychological instability, and insomnia.

Two randomized and double-blind trials assessed the effects of tibolone on sexual function compared with placebo. In the first trial by Nevinny-Stickel (1983), there was no significant improvement in libido in women taking tibolone. In contrast, the recent double blind, placebo-controlled trial by Laan (2001) has shown that treatment with tibolone significantly improved the physiological aspects of sexual function in postmenopausal women, such as vaginal blood flow and lubrication, and subjective measures, such as sexual desire and arousability.

Seven trials assessed the effects of tibolone on lipids and the clotting factors compared with those of placebo. Tibolone reduced HDL-C by approximately 34% and decreased triglycerides by approximately 25%, but had no effect on LDL-C and lipoprotein(a).

Compared with placebo, tibolone caused increases in hemoglobin, antithrombin III, plasminogen, and platelet count. Conclusions about risks for cardiovascular disease or venous thromboembolism cannot be drawn from these trials.

A recent RCT (Kroiss *et al* 2005, 1+) comparing tibolone with placebo found no change in the daily number of hot flushes with either tibolone or placebo ( $P = 0.219$ ) after three months. There was a significant reduction in the severity of flushes with tibolone compared with placebo (-0.4 vs 0.2,  $P = 0.031$ ). At 12 months there was a decrease of 30% in frequency of hot flushes and sweats in the tibolone group, and an increase of 30% in the placebo group. A significant decrease in triglycerides (-23% vs. 1.4%) and HDL (-12% vs. 19%) was observed after 12 months of treatment on tibolone.

### **Isoflavone extracts (red clover and soy)**

A high quality systematic review assessed the effects of non-hormonal agents on hot flushes (Nelson *et al* 2006, 1++). The RCTs of red clover extracts did not include women with breast cancer. One poor quality RCT (Jeri 2002) found a reduction in hot flash frequency vs. placebo (48.5% reduction vs 0%,  $P < 0.001$ ). However the other 5 did not show a significant difference of red clover vs. placebo. The overall effect on combining the trials was a small reduction that was not significant, weighted mean difference  $-0.44$  (95% CI,  $-1.47$  to  $0.58$ ).

Soy isoflavone extracts were compared with placebo in 11 trials (4 of women with breast cancer). Effects from individual trials were conflicting with 3 studies finding that severity scores improved for soy isoflavone users, and no difference between soy and placebo in severity scores for other studies. There was a significant effect of soy isoflavones in reducing hot flash frequency on 50-70 mg/day for 4-6 weeks, 12-16 weeks and 6 months. These trials did not include breast cancer patients. The effect at 4-6 weeks was not significant when the one trial of breast cancer patients using SERM and a higher dose of soy isoflavones was included (Quella *et al* 2000). The combined weighted mean difference in number of daily hot flashes for soy isoflavones compared with placebo was  $-1.15$  (95% CI,  $-2.33$  to  $0.03$ ) after 4 to 6 weeks in 5 trials;  $-1.48$  (95% CI,  $-2.49$  to  $-0.48$ ) after 4 to 6 weeks in 4 trials when the study of women with breast cancer was removed;  $-0.97$  (95% CI,  $-1.82$  to  $-0.12$ ) after 12 to 16 weeks use in 4 trials; and  $-1.22$  (95% CI,  $-2.02$  to  $-0.42$ ) after 6 months in 2 trials.

An update search identified another systematic review (Bordeleau *et al* 2007, 1+) which also assessed soy isoflavones. One additional study in breast cancer patients was included in the review, however there was no significant difference between placebo (40% reduction) and soy beverage (30% reduction) groups (Van Patten *et al* 2002).

### **Black cohosh**

Four RCTs analysed in two systematic reviews found conflicting evidence of effectiveness of black cohosh for women with breast cancer (Nelson *et al* 2006, 1++; Walji *et al* 2007, 1+).

### **Vitamin E**

One fair quality crossover trial of women with breast cancer (Barton 1998, N=125, 4 weeks/phase) compared 800IU/day of vitamin E with placebo. There were no significant differences between groups in hot flash frequency or severity.

### **Psycho-educational interventions**

A systematic review of psycho-educational interventions to relieve hot flashes was identified in an update search (Tremblay *et al* 2008, 1+). Three of the RCTs involved women with breast cancer, including the study by Ganz *et al* (2000) of the Comprehensive Menopausal Assessment programme described below, which was identified previously. There was some effect of relaxation on hot flash frequency in two RCTs however both studies were poor in quality.

### **Comprehensive Menopausal Assessment (CMA)**

This was delivered by a nurse practitioner and focused on symptom assessment, education, counselling and, as appropriate, specific pharmacologic and behavioural interventions for each of the three target symptoms (hot flashes, vaginal dryness, stress urinary incontinence). Change scores for the menopausal symptom scale differed significantly between groups ( $P=0.0004$ ) with reduced symptoms in the intervention group. There was a statistically significant improvement in sexual functioning for the intervention group on the CARES scale ( $P=0.04$ ) (Ganz *et al* 2000, fair).

### **Magnetic therapy**

One small crossover placebo controlled trial of 15 women with breast cancer evaluated magnetic devices placed over 6 Chinese acupressure points corresponding to hot-flash relief (Carpenter & Andrykowski 2002, poor). The device was only applied for 72 hours. Results from 11 survivors of breast cancer showed that magnetic therapy and placebo reduced hot flash frequency and bothersome hot flashes. There was significantly more effect in the placebo group ( $p=0.02$ ). There were no differences between groups in hot flash severity, interference with daily activities, and overall quality of life.

### **Acupuncture**

An update search identified one RCT of acupuncture to treat hot flashes for women with breast cancer (Deng *et al* 2007, 1+). There were no significant differences between groups after four weeks of treatment.

An update search identified a further systematic review of therapeutic options for hot flashes in breast cancer survivors (Bordeleau *et al* 2007, Level 1+). This included another RCT of an open-label study of venlafaxine (Barton *et al* 2002). The randomised phase found a reduction in hot flashes with no changes in toxicity over time. The review authors suggest that the optimal starting dose of venlafaxine is 37.5 mg/day with a doubling of the dose if no effect within 3 to 7 days.

The systematic review (Bordeleau *et al* 2007) also commented further on the paroxetine RCT of breast cancer patients (Stearns *et al* 2005). More patients favoured paroxetine 10 and 20 mg (71%-72%) than placebo (25%); and patients were less likely to discontinue treatment on 10 mg paroxetine than 20 mg (5% vs. 17%;  $p=0.02$ ).

Bordeleau (2007) made some general comments about the use of SSRIs and SNRIs in breast cancer patients noting that as well as reducing hot flashes there were improvements in other associated symptoms such as sleeplessness, loss of libido, depression and anxiety. The adverse effects associated with use were nausea, decreased appetite, dry mouth, somnolence/insomnia and headache which may lead to discontinued treatment in 10-15% of women with breast cancer. In addition SSRIs may inhibit cytochrome P450 reducing the amount of active tamoxifen metabolites available in women with a particular genotype (CYP2D6 variant). This effect is

associated primarily with paroxetine, moderately with fluoxetine and sertraline, but not with venlafaxine.

One recent RCT of sertraline for women with breast cancer was identified and is included in the next table. In an update search a further RCT of sertraline compared with placebo in healthy perimenopausal and postmenopausal women was identified. Sertraline was found to be ineffective and associated with bothersome symptoms. (Grady D, Cohen B, Tice J, Krisof M, Olyaie A, Sawaya GF. Ineffectiveness of sertraline for treatment of menopausal hot flushes - A Randomized controlled trial. *Obstet Gynecol* 2007;109(4):823-30).

## Evidence table

### Intervention: Hormone replacement therapy (HRT)

#### Meta-analysis of RCTs

Col NF, Kim JA, Chlebowski RT. Menopausal hormone therapy after breast cancer: a meta-analysis and critical appraisal of the evidence. *Breast Cancer Research* 2005;7(4):R535-R540.

Aim: To estimate the impact HRT has on recurrence risk from observational and randomised studies, and to examine the reliability of these estimates.

Design: Systematic review  
analysis of RCTs only)

Level 1++ (for the meta-

Country: Multinational

**Inclusion criteria** Studies of women with invasive breast cancer receiving oral HRT, a defined comparison group and reporting of breast cancer recurrence.

**Exclusion criteria** Studies reporting overlapping or redundant data, those not describing control groups, topical hormones.

**Population** 2 RCTs (Holmberg & Anderson 2004, Marsden *et al* 2000)

N=445 patients

Mean age 55.5 years

Mean disease free interval (DFI) 33.2 months (Median 38 months Holmberg 2004; median 31.8 Marsden 2000)

Duration of HRT 19.9 months (Mean 24 months Holmberg 2004; mean 6 months Marsden 2000)

Node status not reported

ER/PR status not reported

#### Interventions

Oral HRT

#### Outcomes

Recurrence –defined as any second breast cancer event (local, regional or distant recurrence or invasive cancer in either breast)

Deaths

**Follow up** - Mean follow-up after HRT 25.2 months (Holmberg & Anderson 2004)

Follow-up not reported in (Marsden *et al* 2000)

#### Results

Study characteristics and results from the 2 trials are reported in the following table.

Study	N participants	Mean duration of HT	Mean follow-up	Recurrences	Deaths – all cause	Deaths – primary tumour
Holmberg & Anderson 2004	345	24 months	24	HT 26 No HT 7	HT 5 No HT 4	HT 3 No HT 4
Marsden <i>et al</i>	100	6	NR	HT 2	NR	NR

al 2000		months		No HT 1	NR	NR
Total	445			HT 28 No HT 8	9	7

Key:  
HT = Hormone Therapy  
NR = not reported

A total of 36 recurrences and 9 deaths occurred during the study period the largest contribution of these events occurred in the Holmberg (2004) trial with longer follow-up and greater recruitment. This trial was stopped early because of the increased breast cancer recurrences in participants taking hormonal therapy.

The pooled risk ratio (RR) for the two randomized trials was 3.41 (95% CI 1.59–7.33)  $p=0.0016$  favouring no HT, significant statistical heterogeneity was present.

The RCT by Holmberg (2004) provided the best available data on the impact of HRT in breast cancer survivors. Col commented that the unblinded design and lack of a placebo group could lead to selective attrition, but the follow-up rates were comparable between arms.

A further RCT was reported since this analysis (The Stockholm Trial, von Schoultz *et al* 2005) that used cyclical hormone treatment for younger patients (<55 years) and a spaced regime for older women to minimize the use of progestogen combined with oestrogen. At a median follow-up of 4.1 years, the risk of breast cancer recurrence was not associated with menopausal hormone therapy (RR = 0.82, 95% CI = 0.35 to 1.9). The authors concluded that doses of oestrogen and progestogen and treatment regimens for menopausal hormone therapy may be associated with the recurrence of breast cancer.

A further comment was that statistically significant heterogeneity in the rate of recurrence was observed ( $P = .02$ ; two-sided likelihood-ratio test) between the two studies (HABITS vs. Stockholm), indicating that chance may not be the only explanation for the conflicting findings.

**Author conclusions:**

Observational studies of HRT use in breast cancer survivors have design limitations that cannot be controlled for using standard statistical methods and hence should be considered essentially uninformative with respect to the safety of HRT use in breast cancer survivors. Only randomized clinical trials are likely to provide reliable estimates of the effect of HRT use in this setting.

**RCTs included:**

Holmberg L, Anderson H, for the HABITS steering and data monitoring committees: HABITS (hormonal replacement therapy after breast cancer – is it safe?), a randomised comparison: trial stopped. *Lancet* 2004, 363:453-455.

Marsden J, Whitehead M, A'Hern R, Baum M, Sacks N: Are randomized trials of hormone replacement therapy in symptomatic women with breast cancer feasible? *Fertil Steril* 2000, 73:292-299.

Added: von Schoultz E, Rutqvist LE, Stockholm Breast Cancer Study Group. Menopausal hormone therapy after breast cancer: the Stockholm randomized trial. Journal of the National Cancer Institute 2005;97(7):533-5.

**General comments** –The review also included observational studies (n=8) which have been omitted from this table.

An updated search identified another systematic review of hormone therapy in breast cancer patients and is included below.

Antoine C, Liebens F, Carly B, Pastijn A, Neusy S, Rozenberg S. Safety of hormone therapy after breast cancer: a qualitative systematic review. *Hum Reprod* 2007;22(2):616-22.

Design: Systematic review

Level 1+

Country: Belgium

Aim: To analyze the safety of hormone therapy (HT) in breast cancer patients.

**Inclusion criteria** Articles in English or French languages, safety data of HT or oestrogen therapy (ET) on breast cancer recurrence and survival in women with invasive breast cancer.

Search dates not reported.

**Exclusion criteria** Not reported

**Population** 2 RCTs (Holmberg & Anderson 2004, von Schoultz *et al* 2005)

18 non-randomized studies were also identified but not included in this table.

*Holmberg & Anderson 2004*: HABITS trial 434 postmenopausal patients with early stage breast cancer (1997-2003); duration HT 2.1 years (0.1-5.3), follow-up 2.1 years (0.1-5.5)

Node positive 24% (69/292)

HR positive 52% (159/305)

Tamoxifen 21% (72/345)

*von Schoultz et al 2005*: Stockholm trial 359 postmenopausal patients with early stage breast cancer (1997-2003), HT duration 4.1 years (0.2-7), follow-up 4.1 years (0.2-3.3)

Node positive 18% (65/355)

ER positive 60% (216/359)

Tamoxifen 53% (189/359)

### Interventions

Intervention arm received HT in both RCTs.

*Holmberg & Anderson 2004*:

HT compared with controls on at least one other therapy of either clonidine, sotalol, psychological help, exercise or acupuncture.

*von Schoultz et al 2005*:

The treatment if any in the comparison arm was not reported.

Both trials unblinded.

### Outcomes

Relapses (locoregional and contralateral breast cancer recurrences)

Recurrences

Contralateral breast cancer

Deaths

Distant metastases

### Follow up –

Holmberg & Anderson 2004 follow-up 2.1 years (0.1-5.5)

von Schoultz *et al* 2005 4.1 years (0.2-3.3)

### Results

The trials were not combined because of heterogeneity in the trial methods and population

characteristics.

Results reported in the review are shown in the following table:

<b>Outcome</b>	<b>Holmberg 2004</b>	<b>Von Schoultz 2005</b>
Total recurrences: HR Control		11 13
Locoregional recurrences: HR Control	11 2	5 5
Distant recurrence: HR Control	10 5	3 5
Contralateral breast recurrence: HR Control	5 1	3 3
Breast cancer deaths: HR Control	3 4	2 4
All cause (deaths): HR Control	5 4	4 9

Relative Hazard of breast cancer recurrence for women taking HT:

Holmberg & Anderson 2004: At a median of 2.1 years RH = 3.3 (95% CI 1.5-7.4) – trial stopped early

von Schoultz *et al* 2005. At a median of 4.1 years RH = 0.82 (95% CI 0.35-1.9)

The same conclusions apply as in the previous systematic review by Col.

**Author conclusions:** There are no data to indicate an absence of a harmful effect of HT. Further studies should analyze the safety of different regimens and there is a need for RCTs to assess the safety of these regimens.

**General comments –**

This systematic review was identified during an update search.

MacLennan AH, Broadbent JL, Lester S, Moore V. Oral oestrogen and combined oestrogen/progestogen therapy versus placebo for hot flushes. Cochrane Database of Systematic Reviews: Reviews. Cochrane Database of Systematic Reviews 2004 Issue 4. Chichester (UK): John Wiley & Sons, Ltd; 2004

Design: Cochrane systematic review

Level 1++

Country: Multi-national

Aim: To examine the effect of oral HRT compared to placebo on these vasomotor symptoms and the risk of early onset side-effects.

### **Inclusion criteria**

Double-blind, randomised, placebo-controlled trials of oral HT for at least three months duration.

### **Exclusion criteria**

Un-blinded or single-blinded trials, non-identical HT and placebo packaging, participants not randomised, no placebo.

Non-menopausal women, major intercurrent disease, previous HT within 1 month of commencement of study.

### **Population**

Menopausal women recruited from any health care setting or a population based sample with either spontaneous menopause or bilateral oophorectomy (removal of both ovaries).

Peri-menopausal women were defined as women with spontaneous menopause and irregular menstruation over the last 12 months. Post-menopausal women were defined as women with surgical menopause or spontaneous menopause and amenorrhea for more than 12 months.

### **Interventions**

All oral oestrogens with or without concomitant progestogens (administered as sequential or continuous progestogen therapy) for a minimum treatment period of three months.

### **Outcomes**

The primary outcome was hot flushes which includes the symptoms of night sweats and was defined as any otherwise unexplained sensation of flushing/sweating experienced by the woman being studied.

### **Follow up -**

### **Results**

115 abstracts were identified, 24 trials met the selection criteria.

Study participants = 3,329.

Trial duration ranged from three months to three years.

There was a significant reduction in the weekly hot flush frequency for HT when compared to placebo (WMD -17.92, 95% CI -22.86 to -12.99). HT reduced hot flush frequency by 75% (95% CI 64.3 to 82.3) relative to placebo. Symptom severity was also significantly reduced compared to placebo (OR 0.13, 95% CI 0.07 to 0.23).

No adverse effects were found but the trials were only short term.

### **Author conclusions:**

Oral HT is highly effective in alleviating hot flushes and night sweats. Therapies should

only be assessed in blinded trials against a placebo or a validated therapy because of the large placebo effect seen in well conducted RCTs, and because during menopause symptoms may fluctuate then after menopause symptoms decline.

**General comments –**

No breast cancer studies were included in this high quality systematic review. It is reported in this table to show the magnitude of effect achieved by HT on menopausal hot flushes.

## Registered RCTs

Bliss J. Randomized Study of Hormone Replacement Therapy for Relieving Menopausal Symptoms in Postmenopausal Women With Prior Stage I or II Breast Cancer. 2004.

Cochrane Central Register of Controlled Trials.

Rageth C. Phase III randomised study of hormone replacement therapy in menopausal or perimenopausal women with prior stage 0-II breast cancer. 1999. Cochrane Central Register of Controlled Trials.

Cobleigh MA. Phase III randomized study of hormone replacement therapy for hot flashes and/or vaginal symptoms in postmenopausal women with a history of node-negative invasive carcinoma or ductal carcinoma in situ of the breast who are receiving adjuvant Tamoxifen. 2001. Cochrane Central Register of Controlled Trials.

## Guidelines

Pritchard KI, Khan H, Levine M. Clinical practice guidelines for the care and treatment of breast cancer: 14. The role of hormone replacement therapy in women with a previous diagnosis of breast cancer. *Can Med Assoc J* 2002;166(8):1017-1022.

### Recommendations:

#### Safety of HRT for women with a history of breast cancer

- Routine use of HRT (either oestrogen alone or oestrogen plus progesterone) is not recommended for women diagnosed with breast cancer because of the risk of recurrence and contralateral breast cancer. Randomized controlled trials are required to guide recommendations. The effect of HRT on recurrence and contralateral breast cancer has not been determined in methodologically sound studies. However animal and in vitro studies have shown the development and growth of breast cancer to be oestrogen dependent. Since there is an increased risk of breast cancer associated with HRT in women without a diagnosis of breast cancer, this risk could be of a similar magnitude for women with breast cancer
- Postmenopausal women with a previous diagnosis of breast cancer who request HRT should be encouraged to consider alternatives. If menopausal symptoms are troublesome and unresponsive to alternative approaches, then HRT may be used after discussion of the risks with her physician. Both the dose and duration of treatment should be minimized.

Validation: Internal validation within the Steering Committee on Clinical Practice Guidelines for the Care and Treatment of Breast Cancer.

Although this guideline is now out-of-date the recommendations still stand in the light of the findings from more recent RCTs of women with breast cancer.

An update search identified another guideline on the role of local vaginal oestrogens for vaginal atrophy:

Hickey M, Saunders CM, Stuckey BGA. Non-hormonal treatments for menopausal symptoms. *Maturitas* 2007;57(1):85-9.

One recommendation relevant to cancer patients was that for women with a non-hormone dependent cancer, management of vaginal atrophy is similar to women with no history of cancer. For women with a history of hormone-dependent cancer then management recommendations are for each woman's preference in consultation with her oncologist.

**Intervention: Progestational agents (progestins)**  
**Systematic review**

Mom CH, Buijs C, Willemse PH, Mourits MJ, de Vries EG. Hot flushes in breast cancer patients. [Review] [94 refs]. *Critical Reviews in Oncology-Hematology* 2006 Jan;57(1):63-77.

Aim: A literature search was conducted to gather information concerning the pathophysiologic mechanisms leading to hot flushes, their prevalence and severity in breast cancer patients, their influence on quality of life, and the best therapeutic option.

Design: Systematic review Level 2+ (includes non-randomized studies)  
 Country: Multinational

**Inclusion criteria** Primary studies and relevant reviews including all types of intervention. Large randomized, double-blind, placebo controlled trials were preferable, but non-randomized studies were included where no randomized studies were available.

**Exclusion criteria** Case reports

**Population** Women with a history of breast cancer

**Interventions**

A range of interventions were assessed, progestational agents are the focus in this section.

**Outcomes**

Frequency of hot flushes.

**Follow up -**

**Results**

Studies identified:

Author	Design	Agent
N		
Loprinzi (1994) 163 (97 BrCa/66 men)	RCT (cross over)	Megestrol acetate vs. placebo prostate ca)
Barton (2002) 15 BrCa	Case series	Medroxyprogesterone (intra muscular)
Bertelli (2002) 71	RCT	Medroxyprogesterone (im) vs. oral

Loprinzi (1994)

After four weeks of treatment there was a reduction in hot flashes of 21 percent in the group receiving placebo first, and 85 percent in the group receiving megestrol acetate first (P < 0.001). An analysis of eligible treated patients found a 50 percent or more decrease in hot flash frequency over the first 4 weeks in 74 percent of the megestrol acetate group compared with 20 percent of the placebo group (P < 0.001). Efficacy was similar in men and women. The cessation of menstrual bleeding in women was the only side effect, usually occurring one to two weeks after discontinuation of megestrol acetate.

Barton (2002)

Treatment with megestrolprogesterone produced a 90% decrease in hot flashes (95% CI 82-97%). Daily hot flash frequency decreased from a mean of 10.9 on the first day of treatment (95% CI 8.0-13.8 hot flashes per day) to a mean of 1.1 hot flashes after 6 weeks (95% CI 0.5-1.8 hot flashes), and to a mean of 0.7 hot flashes at 12 weeks (95% CI 0.1-1.2). The reduction in hot flash frequency was maintained for some months after discontinuation of injections in many patients. Minimal side effects reported were reported.

Bertelli (2002)

At six weeks hot flashes were reduced by 86% for all patients with no significant differences between the two progestins. A response was achieved in 75 and 67% of patients receiving MPA or megestrol, respectively ( $P = 0.5$ ). When responders were followed to assess whether the response was maintained (without further treatment), this was significantly greater in the i.m. MPA: group (89% of responders showed a benefit at week 24 compared with 45% in the megestrol group,  $P = 0.03$ ).

Bertelli G, Venturini M, Del ML, Bergaglio M, Sismondi P, Biglia N, et al. Intramuscular depot medroxyprogesterone versus oral megestrol for the control of postmenopausal hot flashes in breast cancer patients: a randomized study. *Ann Oncol* 2002 Jun;13(6):883-8.

Loprinzi CL, Michalak JC, Quella SK, O'Fallon JR, Hatfield AK, Nelimark RA, et al. Megestrol acetate for the prevention of hot flashes. *The New England journal of medicine* 1994;331(6):347-52.

### **Author conclusions**

Despite the effectiveness of progestagens for the treatment of hot flushes, there is a hesitation to use hormonal agents in breast cancer patients. The Million Women Study (Beral 2003), of a million healthy women aged 50-64 years found an additional increased risk of breast cancer in women using oestrogen-progestagen combinations compared to oestrogen only, suggesting an influence of progestagens on cancer growth.

### **General comments –**

These findings have also been confirmed in two Women's Health Initiative RCTs (Rossouw 2002, Anderson 2004).

## Randomized controlled trial Megestrol acetate

An update search identified another RCT of oral megestrol acetate for menopausal symptoms in breast cancer patients, this is included below:

Goodwin JW, Green SJ, Moinpour CM, Bearden JD 3rd, Giguere JK, Jiang CS, Lippman SM, Martino S, Albain KS. Phase III randomized placebo-controlled trial of two doses of megestrol acetate as treatment for menopausal symptoms in women with breast cancer: Southwest Oncology Group Study 9626. *Journal of Clinical Oncology* 2008 Apr 1;26(10):1650-6.

Design: RCT (1998-2000)

Level 1+

Country: USA, setting: Multi-centre

Aim: To test the progestin megestrol acetate (MA) at two doses versus placebo over 6 months for the treatment of hot flashes in women with breast cancer

### Inclusion criteria

Patients with T1-3, N0-1, M0 infiltrating breast cancer after completion of surgery and chemotherapy and at least 4 months of tamoxifen (if prescribed). Women with at least 10 hot flashes of any severity or at least five severe episodes per week. Previous hormones and steroid treatments were discontinued but other ongoing medications for hot flashes were allowed.

### Exclusion criteria

Pregnancy, lactating, history of deep vein thrombosis, vaginal bleeding if postmenopausal, previous malignancies.

**Population** number of patients =288 randomized, 286 eligible

Age range 38-82 years

On tamoxifen 80%

75% experienced hot flashes over 6 months

40% had over 63 hot flashes / week

### Interventions

Randomized to:

Placebo (n=101)

20 mg megestrol acetate (MA20) (n=92)

40 mg megestrol acetate (MA40) (n=93)

Stratification was by:

Tamoxifen status – not taking tamoxifen vs. > 4 months

Number of hot flashes per week - 5 – 34; 35 – 63; > 63

Duration of hot flashes (<6 months vs. >6 months)

Drugs were administered for an initial period of 6 months and the response measured. Those that achieved a successful response continued in the blinded study for a further 3 months. Patients not achieving a response were placed on open label MA 20 for a further 3 months in addition to the blinded study drug.

Primary outcomes were measured at 3 months.

### Outcomes

Patient Report of Menopausal Symptoms: Number and severity of hot flashes recorded daily for 1 week, from mild to very severe in 4 categories

Daily log of hot flashes (frequency only)

Symptom log

Common Toxicity Criteria (CTC) for depression (Grade 1 to 3 – representing mild to severe and interfering with daily living activities in the latter) and fatigue (Grade 1 to 3 – representing mild to severe-related to ECOG performance status)

**Follow up** Daily log of hot flashes evaluated after initial 6 month period. Failure defined as less than 75% reduction in hot flash episodes compared with baseline or discontinuation of treatment before 3 months. Patients were re-registered after evaluating the response. Those considered a success continued on the blinded study drug for an additional 3 months. Patients not successful received one open-label MA20 tablet in addition to blinded study drug for an additional 3 months. A final response evaluation was conducted at 6 months (initial period + 3 month extension).

### Results

3 month assessment of Hot Flash Log (N=244).

241/286 (84%) of patients were re-registered at 3 months for the second part of the trial, 225 were eligible to continue.

206/286 (72%) completed 6 months of treatments and completed a Hot Flash Log

Treatment	Eligible at start (n=286)	Completed 3 months (n=225)	Completed 6 months (n=206)
Placebo	101	78	67
MA20	92	77	71
MA40	93	70	68

Primary outcomes at 3 months:

Treatment	% completing treatment	Success (≥75% reduction in hot flash frequency from baseline)	P value (reference placebo)
Placebo	83	14%	
MA20	90	65%	<0.001
MA40	83	48%	<0.001

After 6 months the % successful in reducing hot flashes (by ≥75% from baseline):

Placebo (also given MA20 if not successful after 3 months): 64%

MA20	77%
MA40	81%

The response to treatment at 3 months by age, tamoxifen use, or number and duration of hot flashes was not associated with the overall response (p values were not reported).

*Physician rated toxicity at 3 months*

Most reported toxicities were grade 1 and included: oedema, and weight gain in placebo arm;

fatigue for MA20 arm; depression, fatigue, nausea and weight gain for MA40 arm. No significant differences between treatment arms were found (data not reported). More patients taking MA had vaginal bleeding than the placebo arm. Toxicity scores ranged from 0.4 to 2.3 (scale 0 “not at all” to 4 “extremely bothersome”). The difference in scores from baseline was not reported. There were some small differences in scores at 6 months, differences and significance were not assessed.

**Author conclusions:** MA significantly reduced vasomotor symptoms with durable benefit over 6 months. MA 20 mg/d is the preferred dose. There was no significant impact on other menopausal symptoms.

**General comments –**

The results of this study were not presented very clearly. The change in symptom scores pre and post intervention were not reported and no statistical tests were applied to measure the significance of changes in symptoms other than hot flash frequency.

## **Guidelines**

Hickey M, Saunders CM, Stuckey BGA. Management of menopausal symptoms in patients with breast cancer: an evidence-based approach. *Lancet Oncology* 2005;6(9):687-95.

Alternatives to HRT for management of symptoms of the menopause. Royal College of Obstetricians and Gynaecologists (2006). Scientific Advisory Committee Opinion Paper 6.

Both of these guidelines note that the safety of progestagens is uncertain with potential risk to the breast.

**Intervention: Antidepressants (SSRI and SNRI)**  
**Systematic review of RCTs**

Nelson HD, Vesco KK, Haney E, Fu RW, Nedrow A, Miller J, et al. Nonhormonal therapies for menopausal hot flashes - Systematic review and meta-analysis. *Jama-Journal of the American Medical Association* 2006;295(17):2057-71.

Aim: To compare the efficacy and adverse effects of therapies other than those primarily composed of oestrogen, progestin or progesterone, or androgen for menopausal hot flashes from published RCTs.

Design: Systematic review (1966-2005)

Level 1++

Country: Multinational

**Inclusion criteria**

Published English-language, randomized, double-blind, placebo-controlled trials providing data on treatment of menopausal hot flashes using 1 or more non-hormonal therapies

**Exclusion criteria**

Head-to-head trials without a placebo group that compared non-hormonal therapies with oestrogen or other medications were excluded because of difficulty interpreting results without a placebo.

Trials of women with other major diseases or oestrogen use within 1 month of commencement of the study.

**Population**

Women experiencing menopausal hot flashes recruited from health care settings or the general population. Trials of women with breast cancer were included and additional data, such as use of tamoxifen or other selective oestrogen receptor modulators (SERMs), were obtained.

**Interventions**

Antidepressants including Selective Serotonin Reuptake Inhibitors (SSRIs) and Selective Norepinephrine/Noradrenaline Reuptake Inhibitors (SNRIs).

**Outcomes**

Frequency or severity of hot flashes. (Frequency obtained by self-report using symptom diaries).

Severity measures also self-reported using a graded scale or a composite measure (frequency x severity). Hot flash frequency and composite measures have demonstrated validity and reliability, and are highly correlated.

Outcomes were determined by the differences in hot flashes measured at baseline and the end of the trial. Treatment effects were defined as the differences in outcomes between the treatment and placebo groups at the end of the trial.

**Follow up -**

**Results**

Ten trials of antidepressant medications met the inclusion criteria:

6 trials of selective serotonin reuptake inhibitors (SSRIs) or serotonin norepinephrine reuptake inhibitors (SNRIs) [paroxetine (2), venlafaxine (2), fluoxetine (2) and

citalopram (1)]. The citalopram study was not conducted in breast cancer patients.

Three trials of the antidopaminergic drug veralipride and 1 trial of a selective monoamine oxidase-A inhibitor moclobemide were also identified. These former 3 trials were conducted in the 1980s and were of poor quality, the more recent trial of moclobemide was also poor in quality. None were conducted in breast cancer patients. These agents have not been commented on in the evidence table.

Results of hot flash frequency in studies in breast cancer patients are shown in the following table:

<b>Study</b>	<b>Duration</b>	<b>Antidepressant dose</b>	<b>Comparison</b>	<b>Hot flash frequency</b>
Stearns 2003 (not br ca but good quality) N=165	6 weeks	Paroxetine 12.5 or 25 mg/day	Placebo	3.2-3.3 vs. 1.8 fewer episodes, P=0.01
Stearns 2005 (Br Ca patients on Tamoxifen) Cross over trial. Fair quality. N=151	4 weeks / phase	Paroxetine 10 or 20 mg/day	Placebo	50-51% vs. 15% P<0.001
Loprinzi 2000 (Br ca or high risk). Good quality. N=221	4 weeks	Venlafaxine 37.5, 75 or 150 mg/day	Placebo	30-58% vs. 19% P<0.001
Loprinzi 2002 (Br ca or high risk) Cross over trial. Fair quality. N=81	4 weeks / phase	Fluoxetine 20 mg/day	Placebo	No difference

Both paroxetine and venlafaxine were significantly effective in reducing hot flash frequency compared with placebo. There was no difference in effect between fluoxetine and placebo.

Results of the meta-analysis are reported in the following table. Only the findings from the breast cancer trials are reported as individual studies.

<b>Study / quality</b>	<b>Participants</b>	<b>Antidepressant dose</b>	<b>Mean difference (95% CI) in number of hot flashes / day</b>
Stearns 2005 fair	151	Paroxetine 10 or 20 mg/day	-2.43 (-4.43 to -0.42)
Loprinzi 2000 good	167	Venlafaxine 37.5, 75 mg/day (Excludes 150mg/day dose)	-1.09 (-1.99 to -0.18)
Loprinzi 2002 fair	81	Fluoxetine 20 mg/day	-0.90 (-3.78 to 1.98)
<b>Trials with SERM</b>	<b>564</b>	<b>4 comparisons</b>	<b>-1.40 (-1.97 to -0.82)</b>

use combined		(includes the 3 breast cancer trials) (paroxetine, venlafaxine, fluoxetine, citalopram)	
Trials of SERM use in women without breast cancer	180	2 comparisons (venlafaxine and citalopram)	-0.17 (-1.41 to 1.07)
All trials combined	844	7 comparisons	-1.13 (-1.70 to -0.57)

SSRI/SNRIs significantly reduced hot flash frequency by 1 hot flash / day overall trials. This compares with a reduction of 2.5-3 /day on oestrogen. The effect was slightly stronger in SERM users overall (includes the 3 trials of women with breast cancer). There was no significant effect in SERM users who did not have breast cancer. Different doses of paroxetine did not produce a differential effect, whilst higher doses of venlafaxine were more effective (from 1 trial).

**Author conclusions:**

The SSRIs or SNRIs trials provide evidence for efficacy based on a small number of fair to good quality studies; however, effects are less than for oestrogen, few trials have been published and most have methodological deficiencies, generalizability is limited, and adverse effects and cost may restrict use for many women. These therapies may be most useful for highly symptomatic women who cannot take oestrogen but are not optimal choices for most women.

*RCTs of breast cancer patients included in the table and meta-analysis:*

Loprinzi CL, Kugler JW, Sloan JA, Mailliard JA, LaVasseur BI, Barton DL, et al. Venlafaxine in management of hot flashes in survivors of breast cancer: a randomised controlled trial. *Lancet* 2000;356(9247):2059-63.

Stearns V, Beebe KL, Iyengar M, Dube E. Paroxetine controlled release in the treatment of menopausal hot flashes - A randomized controlled trial. *Jama-Journal of the American Medical Association* 2003;289(21):2827-34. (not breast cancer)

Stearns V, Slack R, Greep N, Henry-Tilman R, Osborne M, Bunnell C, et al. Paroxetine is an effective treatment for hot flashes: results from a prospective randomized clinical trial. *Journal of clinical oncology : official journal of the American Society of Clinical Oncology* 2005;23(28):6919-30.

**General comments –**

Some trials use cumulative symptoms scores (e.g. Kupperman Index and Greene Climacteric Scale) to assess hot flashes and other menopausal symptoms. Use of these scores is problematic because some have not been validated, different components are measured which cannot be compared directly, and measures of vasomotor symptoms may not be specific.

The authors report a significant level of heterogeneity in the meta-analyses the degree of heterogeneity is not reported or commented on in the findings. Other non-hormonal

interventions were assessed and these are reported in appropriate sections of the evidence table.

## **Randomized controlled trial Venlafaxine**

One recently published RCT comparing venlafaxine with placebo, and another comparing venlafaxine with clonidine were identified:

Carpenter JS, Storniolo AM, Johns S, Monahan PO, Azzouz F, Elam JL, et al. Randomized, double-blind, placebo-controlled crossover trials of venlafaxine for hot flashes after breast cancer. *Oncologist* 2007 Jan;12(1):124-35.

Design: 2 RCTs (2000-2004)

Level 1+

Double-blind, cross-over, placebo controlled

Country: USA, setting: Multicentre Cancer Centre clinics

Aim: To evaluate the efficacy of venlafaxine for self-reported and physiological hot flashes.

### **Inclusion criteria**

Adult women with a history of breast cancer

No other cancer

Disease-free and functioning independently at the time of study enrollment

At least 4 weeks after completion of local therapy (chemotherapy or radiation)

Experiencing daily hot flashes (1 per day)

Desiring treatment for hot flashes but not currently using any other hot flash treatments

Postmenopausal or using a clinically acceptable method of birth control throughout the study to prevent pregnancy

Within 60 miles of study site to access the hot flash monitor

Verified as non-depressed by study psychologist through structured clinical interview.

### **Exclusion criteria**

On tamoxifen or aromatase inhibitor for 6 weeks

On antidepressants

Receiving hot flash treatment within the past 4 weeks (e.g., soy supplements, botanicals, vitamin E, and prescription medications)

Pregnant or lactating.

**Population** number of patients :

N= 64 low dose arm

N=20 high dose arm

### **Interventions**

Two randomized, double-blind, placebo-controlled crossover trials of 14-weeks duration.

Low-dose study = 6 weeks of 37.5 mg venlafaxine daily (n =64)

High-dose treatment = 1 week of 37.5 mg venlafaxine daily, then 4 weeks of 75 mg venlafaxine daily, then 1 week of 37.5 mg venlafaxine daily (n = 20).

Extended release formulations were used.

No washout periods because of the short half-life of the drug (5 hours) and the major metabolite (11 hours).

### **Outcomes**

Hot flash frequency using diaries and monitors during one 24 hour period per week, evaluated using the validated Hot Flash-Related Daily Interference Scale

Psychological outcomes:

Negative affect index was calculated as the combination of standardized scores on four questionnaires:

Profile of Mood States Short Form total mood disturbance score (excluding fatigue)

Positive and Negative Affect Scale - the negative affect subscale only

Centre for Epidemiological Studies Depression Scale

Hamilton Rating Scale-Depression (Ham-D).

**Follow up** 14 weekly visits.

Weeks 1 and 2 provided baseline information (B1 and B2), and weeks 3 to 14 included 6 weeks of treatment (T1–T6) and 6 weeks of placebo (P1–P6).

In the high dose arm patients received 75 mg per day during weeks T2–T5 and 37.5 mg at T1 and T6 to taper on and off the drug.

Patients were telephoned 1, 6, and 12 months after completing the weekly visits to assess continued venlafaxine use.

## Results

### *Low dose hot flash frequency*

When compared with placebo the physiological hot flash frequency, self-reported frequency (diary and event marker), hot flash severity and bother were reduced. Findings are reported in the following table:

Low dose outcomes:

Hot flashes/24 hr	Mean (% change from baseline)			P value	Effect size (95% CI)
	Baseline	Placebo	Low dose		
Monitor frequency	7.46	7.49 (0)	5.80 (-22)	<0.001	0.16 (0.09 – 0.23)
Diary frequency	6.02	4.96 (-18)	3.50 (-42)	<0.001	0.22 (0.16 – 0.29)
Event marker frequency	7.72	6.02 (-22)	4.52 (-41)	<0.001	0.20 (0.14 – 0.26)
Diary severity	4.27	4.54 (6)	3.95 (-7)	<0.001	0.21 (0.14 – 0.27)
Diary distress	3.86	4.27 (10)	3.71 (-4)	<0.001	0.20 (0.13 – 0.28)
interference	2.33	1.52 (-35)	1.42 (-39)	0.47	0.05 (-0.09 – 0.20)

On low dose treatment physiological hot flashes decreased by 1.7/day (22%) compared with baseline.

Diary hot flashes decreased by: 1.46/day (24%) compared with placebo

2.52/day (42%) compared with baseline.

There was no significant difference overall in psychological outcomes when compared to placebo (negative affect, fatigue, sleep quality, quality of life).

The reported side effects that were significantly more severe compared with placebo were headaches, constipation and dry mouth during the venlafaxine treatment period.

*High dose hot flash frequency*

When compared with placebo the physiological hot flash frequency, self-reported frequency (diary and event marker), hot flash severity, bother and interference were reduced. Findings are reported in the following table:

High dose outcomes:

Hot flashes/24 hr	Mean (% change from baseline)			P value	Effect size (95% CI)
	Baseline	Placebo	High dose		
Monitor frequency	7.46	8.44 (13)	6.43 (-14)	0.013	0.22 (0.05 – 0.39)
Diary frequency	6.02	5.78 (-4)	4.53 (-25)	0.001	0.24 (0.10 – 0.38)
Event marker frequency	7.72	9.42 (22)	7.44 (-4)	<0.001	0.19 (0.10 – 0.29)
Diary severity	4.27	4.05 (-5)	3.12 (-27)	<0.001	0.39 (0.24 – 0.53)
Diary distress	3.86	4.10 (6)	3.15 (-19)	<0.001	0.39 (0.24 – 0.54)
interference	2.33	1.97 (-36)	1.23 (-47)	0.003	0.50 (0.18 – 0.82)

On high dose treatment physiological hot flashes decreased by 1.03/day (14%) compared with baseline.

Diary hot flashes decreased by: 1.49/day (25%) compared with baseline

Again there was no significant difference overall in psychological outcomes when compared to placebo (negative affect, fatigue, sleep quality, quality of life). Significantly less trouble sleeping but more severe constipation and dry mouth were reported when taking venlafaxine at the high dose.

There was no placebo effect for the physiological hot flash monitor in the low-dose study (p = 0.52). However, there was a placebo effect for self-reported hot flashes. In the high dose study there was no placebo effect for physiological hot flashes (p = 0.71), but again there was a placebo effect for self-reported hot flashes.

The trials found a modest reduction in physiological and self-reported hot flashes in patients on venlafaxine compared with placebo. Both doses of venlafaxine reduced physiological and subjective hot flash frequency, hot flash severity and bother. However, hot flash interference improved only at the higher dose of 75-mg. The effects on physiological hot flashes were greatest at 1 week of treatment on the 37.5mg daily dose, and at 5 weeks on the 75mg daily dose.

#### *Limitations*

The authors reported the main study limitations as (a) racially and ethnically homogeneous samples, (b) small sample sizes, (c) limited treatment time, and (d) lack of pharmacogenetic data. Because of the lack of sample diversity and lack of a non-cancer comparison group the findings may not be generalizable to a broader population.

#### *Summary*

The subjective hot flash measures showed placebo effects in comparison to the physiological measurements. There were modest decreases in hot flash frequency, severity and distress on venlafaxine, but only hot flash interference improved at the higher dose. The timing of the effects on hot flashes varied by dose. A subgroup of women with  $\geq 50\%$  decrease in physiological hot flashes also experienced significant improvements in fatigue, sleep quality, and quality of life. Side effects were mild, but most patients discontinued venlafaxine in the long-term.

**Author conclusions:** Although venlafaxine resulted in modest and acute reductions in hot flashes with few side effects, it may not be tolerable to some patients long-term. At least 50% relief in physiological hot flashes may be needed for patients to demonstrate improvement in other outcomes, including decreased fatigue, improved sleep, and improved quality of life.

#### **General comments –**

The quality of life outcomes were only significantly improved in a small subgroup of patients who obtained at least a 50% reduction in monitor hot flashes, and have not been reported in the table.

### **Randomized clinical trial Venlafaxine vs. clonidine**

Loibl S, Schwedler K, von MG, Strohmeier R, Mehta K, Kaufmann M. Venlafaxine is superior to clonidine as treatment of hot flashes in breast cancer patients--a double-blind, randomized study. *Ann Oncol* 2007 Apr;18(4):689-93.

Design: RCT (2002-2004)  
Level 1 ++  
Country: Germany, setting: Single university hospital  
Aim: To compare venlafaxine to another non-hormonal agent in the treatment of hot flashes of breast cancer patients.

**Inclusion criteria**

Women aged over 18 years with primary breast cancer experiencing hot flashes at least 14 times per week or seeking help for hot flashes.

Hot flashes for at least 4 weeks.

A predefined menopausal status was not required.

ECOG performance status 0 to 1.

**Exclusion criteria**

Previous treatment with venlafaxine, clonidine, oestrogens, progestogens, or androgens for hot flashes.

Current treatment with hypertensive or antidepressant agents or other non-hormonal agents for hot flashes such as black cohosh, isoflavone, and vitamin E.

Patients with hypertension, hypotension, peripheral or cardiovascular diseases, symptomatic cardiac diseases or metastatic disease.

**Population** number of patients = 80 recruited, 64 evaluable

**Interventions**

Stratification was by:

Age ( $\leq 50$  years versus  $> 50$  years)

Adjuvant therapy (endocrine versus no endocrine therapy).

Randomization was double-blind to receive **twice** daily 0.075 mg clonidine (total 0.15mg) or 37.5 mg venlafaxine (total 75mg) in tablet form over 4 weeks.

In the original plan patients were to cross-over treatments after 4 weeks, but this was abandoned because of missing data.

Clonidine n=40, with 33 evaluable

Venlafaxine n=40, with 31 evaluable

**Outcomes**

Frequency of hot flashes (number of hot flashes/week)

Severity of hot flashes (hot flash severity score obtained by scoring mild =1 to severe =4)

Hot flash severity score = Sum of (severity score X frequency) per day

Toxicity

Symptoms

**Follow up** Four weeks

**Results**

Most patients (n = 55; 69%) had taken an endocrine treatment for breast cancer concurrently (85% treated if not intention to treat analysis):

Treatment	N =55	%
Tamoxifen	42	76
Tamoxifen and goserelin	6	11
Aromatase inhibitor (ARI)	5	9
ARI with goserelin	2	4

Data related to hot flash frequency for each drug are reported in the following

table:

<b>Outcome</b>	<b>Clonidine (n=33)</b>	<b>Venlafaxine (n=31)</b>
Decrease in median hot flash frequency from baseline (100%)	37% (SE 4.7)	57% (SE 7.4) P=0.025
Decrease in daily median hot flash frequency	4.85 / day	7.6 / day
Increase in hot flash frequency from baseline (>100%)	6% (n=2)	10% (n=3)
Decrease in hot flash frequency from baseline		
0-24%	12% (n=4)	29% (n=9)
25-49%	24% (n=8)	26% (n=8)
50-74%	33% (n=11)	19% (n=6)
75-100%	24% (n=8)	16% (n=5)
>100%	6% (n=2)	10% (n=3)
Decrease in hot flash score	8.9 units /day [57% SE 6.2]	11.4 units /day [39% SE 5.4] P=0.043

Most of the outcomes favoured venlafaxine which produced a larger decrease in hot flash frequency over the 4 week period and on a daily basis.

#### *Toxicity*

Toxicity was evaluated weekly. There was no difference in the frequency of symptoms before treatment between groups and the most common symptoms were dry mouth, restless sleep and tiredness.

After treatment there was no difference between groups for the following outcomes measured:

- Loss of appetite
- Sleeplessness
- Drowsiness
- Tiredness
- Sweating
- Constipation
- Restless sleep
- Nervousness
- Moodiness
- Mouth dryness

Nausea was significantly increased in the venlafaxine group (n=6; 19%) compared to the clonidine group (n=2; 6%; p=0.05). During the first week 39% of patients on venlafaxine had nausea.

**Author conclusions:** Venlafaxine is significantly more effective in reducing the frequency of hot flashes in breast cancer patients than clonidine

**General comments -**

## Randomized controlled trials

### Sertraline

Kimmick GG, Lovato J, McQuellon R, Robinson E, Muss HB. Randomized, double-blind, placebo-controlled, crossover study of sertraline (Zoloft) for the treatment of hot flashes in women with early stage breast cancer taking tamoxifen. *The breast journal* 2006;12(2):114-22.

Design: RCT (1996-2000)

Level 1+

Double-blind, cross-over, placebo controlled

Country: USA, setting: Oncology Clinic

Aim: To determine if sertraline is effective in decreasing the frequency and severity of hot flashes in breast cancer survivors taking adjuvant tamoxifen.

#### Inclusion criteria

Women aged  $\geq 18$  years with localized breast cancer (stages 0–IIIB) receiving adjuvant tamoxifen therapy and had at least one hot flash per day (or more than seven hot flashes per week).

Menopausal status determined by patient self-report.

#### Exclusion criteria

Pregnancy or breast-feeding, a history of seizure disorder, or hepatic or renal insufficiency.

Oestrogen, progestagen, corticosteroids, androgens or other antidepressant therapy.

**Population** number of patients = 62 women enrolled

Median age 53.9 years (36.6–77.1)

Postmenopausal = 89%

Breast cancer survivors on adjuvant tamoxifen reporting bothersome hot flashes.

Baseline hot flash frequency/ day 5.8 (SD 4.1)

Baseline hot flash score (SD 12.1)

#### Interventions

Randomized, double-blind, placebo-controlled, crossover study of a 50 mg dose of sertraline (each morning) for 6 weeks followed by placebo for 6 weeks or vice versa.

Stratification was by menopausal status and average number of hot flashes/day.

#### Outcomes

Daily hot flash diary recording hot flash frequency and severity, then hot flash scores (frequency x severity) were calculated.

Centre for Epidemiologic Studies depression scale to assess mood (at baseline, 6 weeks, and 12 weeks).

Functional Assessment of Cancer Therapy--Breast (FACT-B) (at baseline, 6 weeks, and 12 weeks) to assess quality of life.

#### Follow up

Baseline week n=54

First 6 weeks n=47

All 12 weeks n=39

## Results

At 6 weeks there were no statistically significant differences in hot flash frequency or scores between groups. After 6 weeks a 50% reduction in the frequency of hot flashes was seen in 36% of women taking sertraline (n = 25) compared with 27% taking placebo (n = 22) (p = 0.7) which was also not significant.

At 12 weeks, patients initially on sertraline and had crossed over to placebo had a 1% change in hot flash frequency compared to the level at 6 weeks. No statistically significant differences were found in hot flash frequency or scores when compared to baseline.

However, the crossover analysis found sertraline to be significantly more effective in controlling hot flashes than placebo:

A comparison of hot flash frequency and score at 6 and 12 weeks, found women crossing from placebo to sertraline had a decrease ( -0.9 [SD = 3.7] and -1.7 [SD = 8.4] respectively) whilst women crossing from sertraline to placebo had an increase (1.5 [SD = 2.6] and 3.4 [SD = 5.2], respectively) (p = 0.03 and 0.03).

The hot flash frequencies and scores reported in the paper are shown in the following table:

	<b>Placebo then sertraline</b>	<b>Sertraline then placebo</b>	<b>P value</b>
<b>Baseline</b>	n=25	n=29	
Frequency (SD)	5.5 (4.4)	6.1 (3.9)	0.6
Score (SD)	11.2 (13.6)	12.8 (16.1)	0.7
<b>Week 6</b>	n=22	n=25	
Frequency (SD)	4.4 (3.8)	4.9 (5.7)	0.8
Score (SD)	7.6 (7.9)	10.8 (22.7)	0.5
<b>Change at 6 weeks vs baseline</b>	n=22	n=25	
Frequency (SD)	-1.5 (3.9)	-1.6 (3.0)	0.9
Score (SD)	-4.6 (13.0)	-3.2 (8.1)	0.7
50% reduction in hot flash frequency at 6 weeks	27%	36%	0.7
<b>Week 12</b>	n=19	n=20	
Frequency (SD)	3.9 (5.3)	4.9 (2.9)	0.4
Score (SD)	6.5 (11.2)	8.6 (7.5)	0.5
<b>Change at 6 weeks vs baseline</b>	n=19	n=20	
Frequency (SD)	-0.9 (3.7)	1.5 (2.6)	0.03
Score (SD)	-1.7 (8.4)	3.4 (5.2)	0.03

There was no carry-over effect, period effect, week effect or treatment effect detected.

Forty-eight percent preferred the sertraline period, 11% preferred the placebo

period, and 41% had no preference ( $p = 0.006$ ).

#### *Side effects*

During the first 6 weeks of the study the most frequent side effects reported were:

	Sertraline (n=25)	Placebo (n=22)
Total	14 (44%)	7 (25%)
Nausea	7 (28%)	2 (9%)
Fatigue/malaise	3 (12%)	0
Diarrhoea	5 (20%)	0
Anxiety/nervousness	3 (12%)	0

#### *Quality of life*

There were no significant differences between placebo and sertraline arms on the CES-D scale at baseline, 6 weeks and 12 weeks. The mean scores decreased sequentially over time on placebo. However mean scores decreased at 6 weeks then increased to more than baseline at 12 weeks in the sertraline arm. More than 30% of patients had dropped out by 12 weeks. Mean scores on the CES-D were below the recognized clinical cut-off point ( $\geq 17$ ) for depression at all time points and in both treatment arms.

Similarly quality of life scores (FACT-B) did not differ significantly between the placebo and sertraline groups. The scores remained similar to the baseline level. In summary the depression and quality of life scores were within the normal range and did not change significantly within treatment groups.

#### **Author conclusions**

There was no significant change in hot flash frequency or score with sertraline versus placebo. Women who completed all 12 weeks of treatment preferred sertraline to placebo. Presently venlafaxine is the treatment of choice to alleviate hot flashes, as it has no effect on tamoxifen metabolites. Sertraline, a related SSRI/ SNRI, may also have efficacy and may be an alternative in women who do not tolerate venlafaxine.

#### **General comments –**

A small crossover study, questionable whether there was sufficient power to detect changes.

## **Guidelines**

Hickey M, Saunders CM, Stuckey BGA. Management of menopausal symptoms in patients with breast cancer: an evidence-based approach. *Lancet Oncology* 2005;6(9):687-95.

Alternatives to HRT for management of symptoms of the menopause. Royal College of Obstetricians and Gynaecologists (2006). Scientific Advisory Committee Opinion Paper 6.

Both guidelines predate the recent trial evidence. However RCOG suggest that venlafaxine is the most effective SNRI for vasomotor symptoms.

## Intervention: Other prescribed medications

**Clonidine ( $\alpha$ -adrenergic agonist antihypertensive)**

**Gabapentin ( $\gamma$ -aminobutyric acid analogue anticonvulsive)**

**Levetiracetam (a pyrrolidine with antiepileptic activity)**

**Tibolone (a synthetic steroid)**

## Systematic review of RCTs

Nelson HD, Vesco KK, Haney E, Fu RW, Nedrow A, Miller J, et al. Non-hormonal therapies for menopausal hot flashes - Systematic review and meta-analysis. *Jama-Journal of the American Medical Association* 2006;295(17):2057-71.

Aim: To compare the efficacy and adverse effects of therapies other than those primarily composed of oestrogen, progestin or progesterone, or androgen for menopausal hot flashes from published RCTs.

Design: Systematic review (1966-2005)

Level 1++

Country: Multinational

### Inclusion criteria

Published English-language, randomized, double-blind, placebo-controlled trials providing data on treatment of menopausal hot flashes using 1 or more non-hormonal therapies

### Exclusion criteria

Head-to-head trials without a placebo group that compared non-hormonal therapies with oestrogen or other medications were excluded because of difficulty interpreting results without a placebo.

Trials of women with other major diseases or oestrogen use within 1 month of commencement of the study.

### Population

Women experiencing menopausal hot flashes recruited from health care settings or the general population. Trials of women with breast cancer were included and additional data, such as use of tamoxifen or other selective oestrogen receptor modulators (SERMs), were obtained.

### Interventions

Clonidine – a centrally active  $\alpha$ -adrenergic agonist antihypertensive.

Gabapentin –  $\gamma$ -aminobutyric acid analogue anticonvulsive

### Outcomes

Frequency or severity of hot flashes. (Frequency obtained by self-report using symptom diaries).

Severity measures also self-reported using a graded scale or a composite measure (frequency x severity). Hot flash frequency and composite measures have demonstrated validity and reliability, and are highly correlated.

Outcomes were determined by the differences in hot flashes measured at baseline and the end of the trial. Treatment effects were defined as the

differences in outcomes between the treatment and placebo groups at the end of the trial.

**Follow up -**

**Results**

Ten RCTs of clonidine were identified, two of these included women with breast cancer and were of fair quality.

Two RCTs of gabapentin were identified, one good quality trial included women with breast cancer.

**Clonidine**

*Placebo-controlled trials of Clonidine for women with breast cancer*

Results of hot flash frequency in studies of breast cancer patients are shown in the following table.

Study	Duration	Antihypertensive dose	Comparison	Hot flash frequency
Goldberg 1994 (Br Ca patients on Tamoxifen) Cross over trial. Fair quality. N=116	4 weeks / phase	Clonidine 0.1 mg/day transdermal	Placebo	44% vs. 27% P<0.04
Pandya 2000 (Br ca patients on Tamoxifen). Fair quality. N=198	8 weeks treatment 4 week follow-up	Clonidine 0.1 mg/day	Placebo	24% vs. 14% P<0.09

Both trials reported a reduction in hot flash frequency, reduced severity and composite scores were also reported. Women in these two trials were also taking tamoxifen (SERM use). Adverse effects of clonidine were dry mouth, insomnia or drowsiness.

A meta-analysis of 6 of the 10 clonidine trials (N=672) was conducted which included both of the breast cancer studies. The mean differences of hot flash frequency / day of relevant studies are shown in the following table:

Study / quality	Participants	Clonidine dose	Mean difference (95% CI) in number of hot flashes / day
Goldberg 1994 Fair quality	116	0.1 mg/day 4 weeks	-0.79 (-1.55 to -0.04)
Pandya 2000 Fair quality	198	0.1 mg/day At 4 weeks	-1.17 (-1.87 to -0.47)

Trials with SERM use combined	314	2 comparisons (includes the 2 breast cancer trials at 4 weeks)	-1.00 (-1.51 to -0.49)
All 4 week studies combined (4 trials)	444	4 comparisons	-0.95 (-1.44 to -0.47)
Pandya 2000 Fair quality	198	0.1 mg/day At 8 weeks	-1.70 (-2.91 to -0.49)
All 8 week trials combined (2 trials)	228	2 comparisons	-1.63 (-2.76 to -0.50)

There was a significant reduction in mean difference of hot flash frequency in both breast cancer trials compared to placebo. Reduced severity and composite score was also reported by Goldberg (1994). A significant reduction was also obtained when combining all trials at 4 weeks. When the 4 week trials without SERM use were combined in the meta-analysis a weaker non-significant effect was obtained [-0.53 (-2.09 to 1.04)]. The combination of 2 trials after 8 weeks of treatment produced a stronger effect than the combination at 4 weeks.

The 10 clonidine trials reported inconsistent results, with approximately half of the trials reducing hot flash frequency and severity significantly. The estimate for the 3 fair quality trials combined was a reduction of approximately 1 hot flash/day. Clonidine may relieve hot flashes by reducing peripheral vascular activity.

### Gabapentin

#### *Placebo-controlled trials of Gabapentin*

Results of hot flash frequency in two studies are shown in the following table. One good quality study involved breast cancer patients.

Study	Duration	Gabapentin dose	Comparison	Hot flash frequency
Guttuso 2003 Fair quality. N=59	12 weeks	300 mg 3 times daily	Placebo	45% vs. 29% P=0.02
Pandya 2005 (Breast cancer 71% patients on Tamoxifen). Good quality. N=420	4 weeks and 8 weeks	100 mg 3 times daily 300 mg 3 times daily	Placebo	44% vs. 15% P<0.001 900mg dose Severity 46% vs. 15% P<0.001 900mg 300mg/d no difference

#### **Meta-analysis**

2 trials	N=479	Weighted mean difference vs. placebo in number of daily hot flashes. -2.05 (-2.80 to -1.30)
----------	-------	--

Both trials reported a reduction in hot flash frequency and severity compared to placebo. Only the 900 mg/day dose was effective in reducing hot flashes. The meta-analysis reported a combined mean difference of both trials. Mean differences of individual studies was not reported. Side effects reported were somnolence, fatigue, dizziness, rash, heart palpitations and peripheral oedema.

**Author conclusions:**

Same comments as for SSRIs. Clonidine and gabapentin trials were effective in reducing the frequency and severity of menopausal hot flashes based on a small number of fair to good quality trials (gabapentin) or poor to fair quality trials (clonidine); however, effects are less than for oestrogen, few trials have been published and most have methodological deficiencies, generalizability is limited, and adverse effects and cost may restrict use for many women. These therapies may be most useful for highly symptomatic women who cannot take oestrogen but are not optimal choices for most women.

*RCTs of breast cancer patients included in the tables and meta-analysis:*

*Clonidine*

Goldberg RM, Loprinzi CL, O'Fallon JR, Veeder MH, Miser AW, Mailliard JA, et al. Transdermal clonidine for ameliorating tamoxifen-induced hot flashes. *Journal of clinical oncology: official journal of the American Society of Clinical Oncology* 1994;12(1):155-8.

Pandya KJ, Raubertas RF, Flynn PJ, Hynes HE, Rosenbluth RJ, Kirshner JJ, et al. Oral clonidine in postmenopausal patients with breast cancer experiencing tamoxifen-induced hot flashes: a University of Rochester Cancer Center Community Clinical Oncology Program study. *Annals of internal medicine* 2000;132(10):788-93.

*Gabapentin*

Pandya KJ, Morrow GR, Roscoe JA, Zhao H, Hickok JT, Pajon E, et al. Gabapentin for hot flashes in 420 women with breast cancer: a randomised double-blind placebo-controlled trial. *Lancet* 2005;366(9488):818-24.

**General comments –**

Some trials use cumulative symptoms scores (e.g. Kupperman Index and Greene Climacteric Scale) to assess hot flashes and other menopausal symptoms. Use of these scores is problematic because some have not been validated, different components are measured which cannot be compared directly, and measures of vasomotor symptoms may not be specific. The authors report a significant level of heterogeneity in the meta-analyses but this is not commented on in the findings.

## Randomized Controlled Trials

### Gabapentin

An update search identified one RCT comparing gabapentin alone with gabapentin whilst taking an antidepressant.

Loprinzi CL, Kugler JW, Barton DL, Dueck AC, Tschetter LK, Nelimark RA, et al. Phase III trial of gabapentin alone or in conjunction with an antidepressant in the management of hot flashes in women who have inadequate control with an antidepressant alone: NCCTG N03C5. J Clin Oncol 2007;25(3):308-12.

Design: RCT (Nov 2004 –July 2005)

Level 1+

Country: USA, setting: Multi-centre

Aim: To address the use of gabapentin in women with inadequate control of hot flashes on an antidepressant.

#### Inclusion criteria

Women receiving antidepressants for hot flashes with at least 14 severe hot flashes / week.

History of breast cancer or concern about taking hormones.

No current evidence of disease.

#### Exclusion criteria

Women taking a monoamine oxidase inhibitor, a tricyclic antidepressant, clonidine.

**Population** number of patients = 113 eligible

Age = median 54 years (range 39-81)

Venlafaxine treatment 78%

Paroxetine treatment 7%

Tamoxifen treatment 37%

Aromatase inhibitor 30%

Breast cancer history 81%

#### Interventions

Randomization was stratified by duration of treatment (<9 vs ≥ 9 months), frequency of hot flashes/day (2-3 v 4-9 v >9), antidepressant (venlafaxine v paroxetine v other).

Week 1: continue taking antidepressant already prescribed

Following 3 weeks: gabapentin 300mg for 3 days; twice daily for 3 days; 3 times daily for 22 days.

Patients in one arm continued with the prescribed antidepressant.

Patients in the other arm were weaned off the antidepressant over 7-10 days

#### Outcomes

Daily hot flash diary to record frequency and severity of hot flashes (1=mild, 2=moderate, 3=severe, 4=very severe)

Weekly symptom diary – scored 0-10

Weekly quality of life (QoL) questionnaire

**Follow up** 4 weeks

#### Results

Data available for:  
 Hot flash frequency n=101 (89%)  
 Week 4 frequencies n=91 (81%)  
 Baseline hot flash scores n= 99 (88%)  
 Week 4 scores n=88 (78%)

*Hot flashes*

No significant differences between arms at week 4 in changes from baseline of hot flash scores (p=0.37) or hot flash frequencies (p=0.61).

<b>Week 4 findings</b>	<b>Gabapentin</b>	<b>Gabapentin + antidepressant</b>	<b>P value</b>
Median reduction hot flash score	60% (95%CI 33-73%)	56% (95%CI 26-71%)	P=0.37
Median reduction hot flash frequency	49% (95%CI 26-58%)	54% (95%CI 34-70%)	P=0.61

*Toxicity*

No significant differences between arms in changes from baseline at each treatment week for the 17 toxicity items (from self-reports). A trend of more dizziness was noted in patients receiving gabapentin alone in week 1, which reduced over the course of treatment. A slight increase in nervousness was also noted in the gabapentin only arm.

*Quality of life*

No significant differences between arms in changes from baseline to week 4 in self-assessments of QoL:  
 Overall QoL (p=0.98)  
 Mental well-being (p=0.27)  
 Physical well-being (p=0.23)  
 Emotional well-being (p=0.45)  
 Social activity (p=0.82)  
 Spiritual well-being (p=0.77)

**Author conclusions:** Gabapentin decreased hot flashes by approximately 50% in women with inadequate control taking antidepressants. There was no significant additional hot flash reduction from continuation of antidepressant.

**General comments -**

## Levetiracetam

### Phase II study

An update search identified a recent phase II study of another centrally acting agent levetiracetam which is briefly described in the next table.

Thompson S, Bardia A, Tan A, Barton DL, Kottschade L, Sloan JA, et al. Levetiracetam for the treatment of hot flashes: a phase II study. Support Care Cancer 2008 Jan;16(1):75-82.

Design: Phase II study (5/12/2005 – 23/8/2006)

Level 3

Country: USA, setting: Single Centre

Aim: To demonstrate efficacy of levetiracetam in reducing hot flashes.

**Inclusion criteria** Women aged over 18 years with a history of breast cancer, or women without breast cancer who wanted to avoid oestrogen therapy.

Bothersome hot flashes of sufficient severity to seek treatment ( $\geq 14$  per week)

ECOG performance status of 0 or 1

Alternative treatments for hot flashes provided commenced  $> 30$  days before the study period

Women receiving tamoxifen, raloxifene, aromatase inhibitors or vitamin E also included.

#### **Exclusion criteria**

Adverse reaction to levetiracetam

Pregnancy or nursing mothers

Seizure disorders

Raised creatinine

Women on evening primrose oil, ginkgo biloba, chemotherapy, androgens, oestrogens, progestational agents, or gabapentin.

**Population** number of patients = 28 (19 evaluable)

5 had breast cancer

3 were on tamoxifen

1 was on an aromatase inhibitor

#### **Interventions**

Week 1 (baseline) no study medication

Week 2: 1 tablet once daily at night (500 mg)

Week 3: 1 tablet in morning and 1 at night

Week 4: 2 tablets in morning and 2 at night

#### **Outcomes**

Hot flash frequency- average number of hot flashes / day each week

Hot flash score = sum of (n of mild hot flashes + 2n of moderate hot flashes + 3n of severe hot flashes + 4n of very severe hot flashes) = (frequency X severity)

Adverse effects – mean change from baseline after 4 weeks of treatment

**Follow up** After 4 weeks of treatment

#### **Results**

Eight (29%) patients withdrew because of side effects

Changes in scores and frequency are shown in the following table:

Variable	Baseline	Week 4	Difference	P value
Hot flash score	11.9	4.6	-7.3	0.0004
Median	13.6	5.9	-7.7	
Hot flash frequency	7.6	4.1	-3.1	<0.0001
Median	8.3	3.8	-4.5	
N of severe/very severe hot flashes	0.1 0.5	0.0 0.5	0 0	0.14
Mean				

There were significant reductions in hot flash scores and frequency. The number of very severe hot flashes was low in this group initially and the change was not significant.

The most frequent adverse events were somnolence, fatigue and dizziness of mild to moderate intensity.

15/20 (75%) of participants were satisfied with hot flash control.

8/15 (53%) would continue with levetiracetam.

**Author conclusions:** The results suggest that levetiracetam may be an effective therapy for the treatment of hot flashes. Further data is needed to evaluate efficacy and toxicity.

**General comments –**

Levetiracetam does not interfere with tamoxifen metabolism.

Hot flash score obtained from hot flash diary of number and severity.

No comparison group in this pilot study.

The recent Evidence-based systematic review of therapeutic options for women with breast cancer (Bordeleau *et al* 2007) concludes that newer antidepressants and gabapentin appear to be the most promising non-hormonal agents for the treatment of hot flashes in women with breast cancer.

### **Guidelines**

Hickey M, Saunders CM, Stuckey BGA. Management of menopausal symptoms in patients with breast cancer: an evidence-based approach. *Lancet Oncology* 2005;6(9):687-95.

Alternatives to HRT for management of symptoms of the menopause. Royal College of Obstetricians and Gynaecologists (2006). Scientific Advisory Committee Opinion Paper 6.

These guidelines were not sufficiently up to date and omitted recent trial data.

**Intervention: Tibolone (synthetic steroid with oestrogenic, androgenic and progestagenic properties)**

**Systematic review of RCTs**

Modelska K, Cummings S. Tibolone for postmenopausal women: systematic review of randomized trials. J Clin Endocrinol Metab 2002;87:16-23.

Design: Systematic review

Level 1+

Country: Multinational

Aim: To summarize the results from the randomized, controlled, and double blind trials (RCTs) of tibolone with respect to its effects on climacteric symptoms, sexual function, endometrial and breast tissue, lipid metabolism, and bone mineral density (BMD).

**Inclusion criteria**

Randomized, controlled, and double blind trials (RCTs) of tibolone use for postmenopausal women. Cross-over trials also included.

**Exclusion criteria**

Trials involving premenopausal women, retrospective analyses, nonrandomized and open label studies, and trials in which the use of a placebo was not specifically stated.

**Population**

Women aged from 27 to > 65 years (younger patients in one trial had oophorectomy)

**Interventions**

Tibolone (2.5 mg/day) compared with either placebo (6 RCTs), or oestradiol valerate (E2V) (1 RCT) or the combination of oestradiol and norethisterone (E2/NETA) (3 RCTs) in postmenopausal women.

**Outcomes**

Hot flushes

Mood

Sexual function

Vaginal bleeding

Lipids

**Follow up -**

**Results**

Comprehensive search between 1981 and 2001.

Number of participants in trials ranged from 20 to 437.

Duration of trials ranged from 6 to 48 weeks.

Eight RCTs assessed the effects of tibolone on climacteric symptoms.

*Hot flushes*

Six RCTs (305 women) comparing tibolone with placebo reported a significant reduction in hot flushes and sweating in women taking tibolone. The magnitude of the changes was not always reported. A comparison of tibolone with hormonal replacement therapy found a similar reduction in hot flushes,

however the magnitude of the effect could not be determined.

#### *Mood*

One small trial of young women who had undergone oophorectomy and hysterectomy (N=20, Crona *et al* 1988) compared tibolone with E2 valerate. A similar reduction in hot flushes and improved mood were reported. Another small trial (N=30, Genazzani *et al* 1987) reported that tibolone increased  $\beta$ -endorphin concentration and suggested this may contribute to improved mood in postmenopausal women, although mood was not directly assessed in this trial.

#### *Other postmenopausal symptoms*

Three trials reported a beneficial effect of tibolone on fatigability, frequency of headaches, psychological instability, and insomnia. Another trial (Genazzani *et al* 1987) reported that relief of hot flushes from the second month of treatment was also associated with an improvement in mood and insomnia. The reported changes in postmenopausal symptoms varied among trials and may be due to the heterogeneity of study duration, multicultural samples, and differences in scoring systems.

#### *Sexual function*

Two randomized, double-blind trials compared the effects of tibolone with placebo on sexual function. In one trial (Nevinny-Stickel 1983) there was no significant improvement in libido in women taking tibolone. In contrast, a more recent trial (Laan & van Lunsen 2001) found that tibolone significantly improved the physiological aspects of sexual function in postmenopausal women in comparison to placebo including vaginal blood flow and lubrication, and subjective measures e.g., sexual desire and arousability. However there were no differences in sexual practices e.g., frequency of intercourse, non-penetrative sexual activity, initiation or rejection of sexual activity. The authors comment that the small sample size of subgroups may have reduced the power to detect statistical differences.

One RCT (Doren *et al* 2001) comparing tibolone with E2/NETA reported a doubling in free testosterone levels in the tibolone group. Another trial (Nathorst-Boos & Hammar 1997) reported significant improvements in sexual satisfaction in the tibolone arm compared with E2/NETA, however there was a large drop out rate (28%).

#### *Effects on lipids and clotting*

In postmenopausal women there is a tendency for total cholesterol and triglycerides to increase, mainly caused by increases in low density lipoprotein cholesterol (LDL-C). High density lipoprotein cholesterol (HDL-C) tends to remain unchanged. Seven trials assessed the effects of tibolone on lipids and clotting factors compared with placebo. Two trials assessed the effects of tibolone vs. E2/NETA. When compared with placebo, tibolone reduced HDL-C by approximately 34% (3 RCTs), decreased triglycerides by approximately 25%, but had no effect on LDL-C and lipoprotein(a) (4 RCTs). The reduction in HDL-C by tibolone may be due to an androgenic effect. In comparison with E2/NETA tibolone decreased HDL-C and triglycerides to a lesser extent

(17%) and had no effect on LDL-C and lipoprotein(a) (1 RCT).

Compared with placebo, tibolone increased hemoglobin, antithrombin III, plasminogen, and platelet count (3 RCTs). A further 2 trials also reported significant increases in plasminogen, one trial was a comparison of tibolone with E2/NETA.

*Breast cancer*

In vitro studies of breast cancer cells have shown that tibolone metabolites inhibit the formation of active oestrogens in the breast. A small RCT found that tibolone did not increase breast density when compared with placebo and HRT groups.

**Author conclusions**

A few RCTs have shown the oestrogenic effects of tibolone in reducing hot flushes and sweating in postmenopausal women. Tibolone also may have beneficial, androgenic effects on sexual function. Other effects of tibolone in postmenopausal women, such as its influence on lipid metabolism, hemostasis, and sexual function, are less certain. The long-term effects of tibolone, particularly in reducing fractures, breast cancer, and cardiovascular disease are still unknown.

**General comments –**

The studies cited in this review were not specific to breast cancer patients.

## Randomized Controlled Trial Tibolone

Kroiss R, Fentiman IS, Helmond FA, Rymer J, Foidart JM, Bundred N, et al. The effect of tibolone in postmenopausal women receiving tamoxifen after surgery for breast cancer: a randomised, double-blind, placebo-controlled trial. *BJOG : an international journal of obstetrics and gynaecology* 2005;112(2):228-33

Design: RCT (1996-2000)

Level 1+

Country: Multicentre, setting: Hospital outpatients

Aim: A double-blind, placebo-controlled study was conducted to assess whether tibolone could prevent, relieve or delay the occurrence of climacteric symptoms in postmenopausal women treated with tamoxifen following breast cancer surgery.

### Inclusion criteria

Postmenopausal women (hospital outpatients; age  $\leq$  75 years)

Newly diagnosed, histologically confirmed invasive or non-invasive early stage breast cancer ( $\leq$  stage IIb)

Last natural menstrual period  $\geq$  1 year before diagnosis of breast cancer

Serum oestradiol concentration  $\leq$  30 pg/mL.

### Exclusion criteria

Other malignancies, prior hysterectomy and/or bilateral oophorectomy, endometrial hyperplasia/adenocarcinoma, abnormal cervical smear, cardiovascular, cerebrovascular or thromboembolic disorders, uterine bleeding of unknown cause, severe liver disorders, drug or alcohol abuse in the previous 12 months, requirement for cancer therapy (exceptions were tamoxifen or radiotherapy) or medication that might affect the metabolism of tibolone, and use of steroids or tamoxifen in the 6 weeks before the study, hormonal implants at any time.

**Population** number of patients = 70 randomized.

Mean age 59 (SD 6) years

Tibolone group exposure was 35.1 woman years

Placebo group exposure 32.9 woman years

### Interventions

Women received surgical treatment (BCS or MRM) followed by tamoxifen therapy.

Randomized to 20 mg/day oral tamoxifen plus either 2.5 mg/ day oral tibolone (Livial;NV Organon) or matching placebo.

33/35 on tibolone baseline and final visit data analysed

31/35 on placebo baseline and final visit data analysed

### Outcomes

Frequency and severity of hot flushes at 3 and 12 months.

Average daily severity of hot flushes used a weighted average score [(N of mild hot flushes X1) + (N of moderate hot flushes X2) + (N of severe hot flushes X3) / Total hot flushes]

Serum lipids.

**Follow up**

Medication was started within three days of baseline assessment (performed within 12 weeks of breast surgery) and continued for 12 months.

**Results***Baseline*

There were differences at baseline in the number of women experiencing hot flushes:

tibolone (78.6%) vs placebo (50%).

Results for hot flash frequency, sweating and intensity are reported in the following table:

<b>Outcome</b>	<b>Tibolone</b>	<b>Placebo</b>	<b>P value</b>
<b>3 months</b>			
Daily n of hot flushes	-0.1	0.9	0.22
Severity of flushes	-0.4	0.2	0.03
<b>12 months (from baseline)</b>			
Mean change n of hot flushes	-0.6	+1.1	0.02
Mean change n of sweats	-0.6	1.2	0.22
Mean change intensity of hot flushes	-0.2	+0.2	0.09
Mean change intensity of sweats	-0.2	+0.3	0.15

*3 months*

There was no change in the daily number of hot flushes with either tibolone or placebo at three months, however there was a significant decrease in the severity of hot flushes with tibolone compared with placebo.

*12 months*

At 12 months there was a decrease of 30% in frequency of hot flushes and sweats in the tibolone group, and an increase of 30% in the placebo group.

*Serum lipids*

At 12 months there were significant decreases of triglycerides (-23% vs. 1.4%) and HDL (-12% vs. 19%) in the tibolone group compared with placebo.

**Author conclusions**

This study demonstrated that tibolone prevented the increase in the occurrence, severity and intensity of hot flushes and sweats associated with tamoxifen treatment following surgical treatment for breast cancer. There was also a trend for tibolone to reduce the impact of hot flushes and sweats on normal daily life. None of the patients had a breast cancer recurrence.

At present, there are no approved effective compounds to treat postmenopausal women with a history of breast cancer and climacteric symptoms. The findings from this pilot study are promising, but only a large, long term clinical trial can provide confirmatory data regarding the effects of tibolone on recurrence in breast cancer patients.

**General comments –**

The effect of tibolone on breast recurrence rate in women with a history of breast cancer is currently being assessed in a large double-blind, randomised, placebo-controlled, five-year clinical trial (LIBERATE).

**Limitations:**

Since a higher proportion of women in the tibolone group experienced hot flushes and sweats at baseline, any reduction in effects due to tibolone may be exaggerated in comparison to the placebo group.

## Guidelines

The only guideline retrieved that was specific to tibolone is reported below:

Kenemans P, Speroff L. Tibolone: Clinical recommendations and practical guidelines: A report of the International Tibolone Consensus Group. *Maturitas* 2005;51(1):21-8.

### *Summary*

The consensus was that tibolone is a valuable treatment option for women with menopausal symptoms. Its effects include relieving vasomotor symptoms, with positive effects on sexual well-being and mood, and an improvement in vaginal atrophy and urogenital symptoms. The prevention of bone loss with tibolone is comparable to that seen with oestrogen therapy (ET) and oestrogen/progestogen therapy (EPT). Endometrial proliferation is rare and no additional progestogen is required. It is well tolerated with a low incidence of vaginal bleeding and breast pain. There is no increase in mammographic density. The absolute numbers of women at increased breast cancer risk are estimated to be low with both tibolone and ET, and the risk with tibolone should be lower than that with EPT. Tibolone may be preferable to EPT in women who have not had a hysterectomy. Based on the available evidence, the panel proposed a number of subgroups of postmenopausal women with vasomotor symptoms for whom tibolone may be useful; these included women with sexual dysfunction, mood disorders, fibroids and urogenital complaints, also those with breast tenderness or high mammographic breast density with EPT use.

### *Breast safety*

Randomized controlled clinical trials have shown that tibolone has a different clinical effect on the breast to that of EPT. In contrast to EPT, tibolone does not increase breast tissue proliferation.

No increased breast cancer risk was observed compared with placebo from pooled data of all phase III/IV trials of tibolone (relative risk (RR) 0.50; 95% confidence interval 0.11–2.54) [Helmond 2002]. The Million Women Study (MWS) reported an increased relative risk of breast cancer with tibolone (RR = 1.45; 95% CI 1.25–1.67), although this was significantly ( $p < 0.0001$ ) less than with EPT [MWS]. Another epidemiological study using the UK General Practice Research Database (GPRD) showed no increased risk with tibolone (RR = 1.02; 95% CI 0.78–1.33) [Allen 2002]. However, this study was published only as an abstract, not as a full paper. The best evidence currently available for the effect of tibolone on breast cancer is from the observational Million Women Study, the risks reported may be overestimated [Shapiro 2004, Whitehead 2004]. Recent prospective trial data [Anderson 2004, Chlebowski 2003] found that the absolute increase in risk for breast cancer was lower than reported in the MWS, and that the risks with tibolone and ET were probably lower than that with EPT.

- Consensus: randomised controlled trials investigating breast cancer incidence with tibolone are awaited before firm conclusions may be made regarding tibolone and breast cancer.

Level of evidence inconclusive.

## **Intervention: Alternative and complementary therapies**

### **Isoflavone extracts (Red clover and soy)**

#### **Systematic review of RCTs**

Nelson HD, Vesco KK, Haney E, Fu RW, Nedrow A, Miller J, et al. Nonhormonal therapies for menopausal hot flashes - Systematic review and meta-analysis. *Jama-Journal of the American Medical Association* 2006;295(17):2057-71.

Aim: To compare the efficacy and adverse effects of therapies other than agents primarily composed of oestrogen, progestin or progesterone, or androgen for menopausal hot flashes from published RCTs.

Design: Systematic review (1966-2005)

Level 1++

Country: Multinational

#### **Inclusion criteria**

Published English-language, randomized, double-blind, placebo-controlled trials providing data for the treatment of menopausal hot flashes with one or more non-hormonal therapies. Trials of women with breast cancer.

#### **Exclusion criteria**

Head to head comparisons with no placebo arm. Non-menopausal women, other major diseases, previous oestrogen use within 1 month of commencement of study.

Dietary sources of isoflavones were excluded.

#### **Population**

Women experiencing menopausal hot flashes recruited from health care settings or the general population. Trials of women with breast cancer required additional data such as concomitant use of tamoxifen or other selective oestrogen receptor modulators (SERMs).

#### **Interventions**

Trials evaluating red clover isoflavones, which contained genistein, daidzein, formononetin and biochanin, and soy isoflavones containing predominantly daidzein, genistein, and their glucoconjugates.

Seventeen RCTs of isoflavone extracts met inclusion criteria.

The type of red clover isoflavone extracts used were promensil (40 mg, 80-82 mg, or 160 mg daily) and one trial also used rimostil (57 mg/d).

#### **Outcomes**

Frequency or severity of hot flashes. (Frequency obtained by self-report using symptom diaries).

Severity measures also self-reported using a graded scale or a composite measure (frequency x severity). Hot flash frequency and composite measures have demonstrated validity and reliability, and are highly correlated.

Outcomes were determined by the differences in hot flashes measured at baseline and the end of the trial. Treatment effects were defined as the differences in outcomes between the treatment and placebo groups at the end of the trial.

#### **Follow up –**

## Results

### *Red Clover*

Red clover isoflavones were compared with placebo in 6 trials. (Quality ratings were good (1 trial), fair (3 trials), and poor (2 trials). No trials included women with breast cancer.

All 6 trials used promensil, which contained a higher proportion of biochanin and genistein.

One trial also used rimostil, which contained a higher proportion of formononetin and daidzein.

Doses were 40, 80 or 160 mg/day of promensil; 57 mg/day of rimostil.

N=605 participants.

Four of the trials had  $\leq 51$  participants.

The remaining two trials had 205 and 252 participants.

One poor quality RCT reported an improvement in hot flash frequency with promensil compared with placebo (reduction of 48.5% vs 0%  $P < 0.001$ ). The meta-analysis reported a significant reduction in hot flush frequency/day of -2.80 (95% CI -4.31 to -1.29) for this study.

None of the trials reported differences in severity scores on the Greene Climacteric Scale or in a symptom diary. One good quality trial reported that the reduction in hot flash frequency was significantly faster with promensil than placebo.

### *Meta-analysis of red clover trials*

The combined weighted mean difference in number of daily hot flashes for red clover isoflavones compared with placebo was -0.44 (95% CI, -1.47 to 0.58) (not significant). The trial quality and type of red clover isoflavone did not influence the results. None of the trials were conducted in women with breast cancer using SERMs. A Forest plot of the meta-analysis was presented in the paper.

### *Summary of meta-analysis of red clover trials*

All comparisons vs placebo

Type of red clover	N of trials	N participants*	Trial quality	No of comparisons in meta-analysis	Mean difference in no of Daily hot flashes vs. placebo	Severity or composite score
Promensil 40mg/d	4	204	Poor-fair	4	-0.40 (95% CI -2.33 to 1.53)	
Promensil 80-82 mg/d	2	199	Fair to good	2	-0.79 (95% CI -2.35 to 0.78)	
Promensil 160mg/d	1	25	Poor	1	-0.30 (95% CI -5.54 to 4.94)	
Fair-good Promensil	4	349	Fair to good	4	0.10 (95% CI -0.60 to 0.79)	

All Promensil	6	428	Poor to good	7	-0.59 (95% CI -1.84 to 0.67)	
Rimostil	1	168	Good	1	0.20 (95% CI -1.26 to 1.66)	
All fair-good	4	517	Fair to good	5	0.11 (95% CI -1.51 to 0.74)	
All combined	6	596	Poor-good	8	-0.44 (95% CI -1.47 to 0.58)	No difference

\*Participant numbers from Forest Plot

Although there was a small overall reduction in hot flash frequency for women taking red clover vs. placebo this was not statistically significant.

*Soy isoflavones*

Soy isoflavones were compared with placebo in 11 trials. Four trials were of women with breast cancer. Three trials (two of fair quality and 1 of poor quality – none of the breast cancer trials), reported a reduction in hot flash frequency with soy isoflavones compared with placebo. The isoflavone composition and doses were genistein (54 mg/day), genistein and daidzein (70 mg/d), and genistein and daidzein (50 mg/d). No differences in hot flash frequency compared with placebo were reported in another three fair quality trials of similar composition.

Severity scores improved when compared with placebo in 3 trials of genistein, diadzein and glycitein (33 mg/day- 1 trial fair quality) or genistein and daidzein (50 mg/day – 2 trials: 1 fair, 1 poor quality). Another 5 trials, including the 4 of women with breast cancer, found no differences in severity scores when compared with placebo.

There were no differences in adverse effects between isoflavone and placebo groups. Gastrointestinal symptoms were the most common in both groups. Endometrial thickness was evaluated in 6 trials and there were no differences between isoflavone and placebo groups over the duration of the trials.

*Soy isoflavone studies of women with breast cancer*

Four trials evaluated soy isoflavones in women with breast cancer (MacGregor et al 2005, Nikander et al 2003, Quella et al 2000, Secreto et al 2004).

Participant numbers ranged from 62 to 262 women.

Duration 8 weeks to 6 months.

Doses ranged from 35 to 150 mg / day.

*Meta analysis of soy isoflavone trials*

A meta-analysis of 6 trials included one RCT of women with breast cancer (Quella et al 2000).

A Forest plot was reported in the paper. The results of the meta-analysis are shown in the following table.

*Summary of meta-analysis of soy isoflavone trials*

All comparisons vs placebo

Dose of isoflavones	N of trials	N participants*	Trial quality	No of comparisons in meta-analysis	Mean difference in no of Daily hot flashes vs. placebo	Severity or composite score
4 to 6 weeks 50-70 mg/d	4	353	Poor-fair	4	-1.48 (95% CI -2.49 to -0.48)	
4 to 6 weeks 150 mg/d*	1	177	Fair	1	0.71 (95% CI -1.30 to 2.72)	
4 to 6 week trials combined	5	530	Poor-fair	5	-1.15 (95% CI -2.33 to 0.03)	Improved in 3/7 trials
12-16 weeks 50-70 mg/d	4	404	Fair	4	-0.97 (95% CI -1.82 to -0.12)	
6 month trials 50-70 mg/d	2	152	Fair	2	-1.22 (95% CI -2.02 to -0.42)	

\*Trial of breast cancer patients, 78% on tamoxifen (Quella 2000)

There was a significant effect of soy isoflavones in reducing hot flash frequency on 50-70 mg/day for 4-6 weeks, 12-16 weeks and 6 months. These trials did not include breast cancer patients. The effect at 4-6 weeks was not significant when the one trial of breast cancer patients using SERM and a higher dose of soy isoflavones was included (Quella 2000).

**Author Conclusions:**

Hot flash frequency was not reduced when all trials of red clover isoflavone extracts were combined, and results for soy isoflavone extracts were contradictory even among the largest and highest quality trials. These results are consistent with other recent systematic reviews.

The authors also reviewed trials of other forms of soy isoflavones, such as flour, powder, and food items, in another study. However, the trials were difficult to compare because of the variability of components and doses. Overall, evidence does not support benefit in relieving hot flashes.

**General comments –**

Some trials use cumulative symptoms scores (e.g. Kupperman Index and Greene Climacteric Scale) to assess hot flashes and other menopausal symptoms. Use of these scores is problematic because some have not been validated, different components are measured which cannot be compared directly, and measures of vasomotor symptoms may not be specific.

The authors report a significant level of heterogeneity in the meta-analyses of soy and red clover isoflavones but this was not commented on in the findings. It appears from the data presented in the meta-analysis that the trial of breast cancer patients (Quella 2000) reduced the effectiveness of soy isoflavones overall in the 4-6 week studies. From the way the results are presented in the paper the authors suggest that there is an inconsistent effect of soy isoflavones, as can be seen from the Forest Plot. However the combination of trials from each individual time period (4-6 weeks, 12-16 weeks and 6 months) all favoured isoflavones when the trial of breast cancer was removed. This suggests there may be a weak effect of soy isoflavones in women not undergoing breast cancer treatment. No overall estimate of effect from all trials in the meta-analysis was reported. Only studies of preparatory extracts of soy and red clover were included.

An update search identified a further systematic review of complementary and alternative therapies for hot flashes in breast cancer survivors (Bordeleau *et al* 2007). Another RCT was identified in the review of 123 breast cancer survivors randomized to a soy beverage (90mg isoflavones/drink) or placebo. A reduction in 24 hour hot flash scores was 30% with soy beverage and 40% with placebo, these were not significantly different (Van Patten *et al* 2002).

## **Guidelines**

Hickey M, Saunders CM, Stuckey BGA. Management of menopausal symptoms in patients with breast cancer: an evidence-based approach. *Lancet Oncology* 2005;6(9):687-95.

Alternatives to HRT for management of symptoms of the menopause. Royal College of Obstetricians and Gynaecologists (2006). Scientific Advisory Committee Opinion Paper 6.

### *Soy isoflavone extracts*

The RCOG and Hickey guidelines acknowledge the inconsistent effects of soy isoflavones on menopausal symptoms from a technology report published by the same group as the systematic review. They also raise concerns about the potential effects on endometrial hyperplasia from a recent RCT (Unfer 2004).

### *Red clover extracts*

The RCOG guideline suggests that red clover has a small effect in reducing the frequency of hot flushes from two small RCTs (N=30) and one larger RCT (N=169). The recent systematic review in the evidence table also includes these studies and the overall combined effect is small but not statistically significant.

## Intervention: Other complementary and alternative therapies

### Systematic review of RCTs

### Black cohosh, DHEA, Vitamin E, Kava, Phospholipid liposomes, Mind, body and behavioural therapies

Nedrow A, Miller J, Walker M, Nygren P, Huffman LH, Nelson HD. Complementary and alternative therapies for the management of menopause-related symptoms - A systematic evidence review. Arch Intern Med 2006;166(14):1453-65.

Design: Systematic review of RCTs (1966-2005)

Level 1++

Country: Multinational

Aim: To assess the effectiveness of complementary and alternative therapies on the management of menopausal symptoms.

#### Inclusion criteria

English-language, randomized controlled trials and meta-analyses comparing a complementary or alternative therapy with placebo or control for the treatment of menopausal symptoms. Trials of women with breast cancer.

**Exclusion criteria** Non-randomized studies, methodologically flawed studies, trials of non-menopausal women or of animals.

#### Population

#### Interventions

Phytoestrogens- these are covered in the previous review by Nelson from the same centre.

Black cohosh

2-dehydroepiandrosterone (DHEA)

Vitamin E

Kava

Phospholipid liposome injections

Mind-Body and Behavioural Therapies

#### Outcomes

Outcomes included hot flash frequency and severity, sleep disturbance, vaginal dryness, vaginal bleeding, urinary frequency or incontinence, quality-of-life changes, depression, anxiety, sexual dysfunction, and cognitive function.

These are commonly measured by the Kupperman Index (self report of hot flashes and 11 other symptoms) and the Greene Climacteric Scale (21 self-reported items).

#### Follow up -

#### Results

Forty eight biological therapies, 9 mind-body therapies, 1 manipulative or body-based therapy, 2 energy therapies, and 10 whole medical systems met the inclusion criteria.

*Black cohosh*

Four trials of black cohosh including 2 of women with breast cancer (Jacobson *et al* 2001, Hernandez Munoz & Pluchino 2003) met the inclusion criteria. Characteristics of the two breast cancer studies are shown in the table below.

*Breast cancer studies*

Study	Duration	Black cohosh dose	Comparison	Hot flash frequency
Jacobson 2001 Fair quality N=85	9 weeks	1 tablet twice daily	Placebo	Improved sweating in BC group P=0.04 No difference in mean no of hot flashes, severity or other symptoms
Hernandez Munoz 2003 Poor quality N=136	9 weeks	20 mg twice daily	Usual care	Improved hot flashes in BC group 47% free of hot flashes in BC group vs. 0% free in usual care P<0.01

The largest and most recent fair quality trial of 304 women randomized to 40mg/day of black cohosh or placebo for 12 weeks reported an improvement in the treatment group for several menopausal symptoms including mood, sleep disorders, sweating and hot flashes (Osmers *et al* 2005). In contrast a smaller fair quality trial with a different botanical formula of black cohosh did not find a reduction in hot flashes (Wuttke *et al* 2003). In the two trials of breast cancer survivors, one fair quality (Jacobson *et al* 2001) found no improvement in the frequency of hot flashes although sweating was significantly improved, whilst one poor quality (Munoz & Pluchino 2003) found a significant reduction in hot flash frequency in the intervention group.

One further RCT of black cohosh in women with breast cancer was identified in our search (Pockaj *et al* 2006) this is described below:

Pockaj BA, Gallagher JG, Loprinzi CL, Stella PJ, Barton DL, Sloan JA, et al. Phase III double-blind, randomized, placebo-controlled crossover trial of black cohosh in the management of hot flashes: NCCTG Trial N01CC1. *Journal of clinical oncology* :Official journal of the American Society of Clinical Oncology 2006;24(18):2836-41.

*Design:* double-blind, randomized, cross-over clinical trial with two 4-week periods, between 2003-2004.

*Intervention:* Black cohosh (1 capsule, Cimicifuga racemosa 20 mg twice

daily) vs. placebo.

A daily hot flash diary was completed during one baseline week and two 4-week crossover treatment periods. Hot flash scores were measured by a point system (1 to 4 for mild to very severe) for each hot flash, the scores were then totalled.

#### *Results*

Patients recruited N=132.

<b>Outcome</b>	<b>Black cohosh</b>	<b>Placebo</b>	<b>P value</b>
Change in hot flash score (week 4 compared to week 1)	Decrease of 20%	Decrease of 27%	0.53
Mean hot flash frequency	Decrease of 17%	Decrease of 26%	0.36
Patient preference of treatment	34%	38%	28% had no preference

Both placebo and black cohosh reduced the hot flash score and frequency when compared to baseline levels. Patient treatment preferences were measured after completion of both treatment periods. Thirty-four percent of patients preferred black cohosh treatment, 38% preferred the placebo, and 28% had no preference of either treatment. No evidence of effectiveness was found for black cohosh.

#### *DHEA*

Two studies were of fair and poor quality, neither included women with breast cancer. The fair quality trial (Barnhart *et al* 1999, N=60, 12 week course) did not show any benefit between DHEA and placebo for a range of menopausal symptoms including sleep, mood, cognition, sexual symptoms, vaginal dryness or quality of life.

#### *Vitamin E*

One fair quality crossover trial of women with breast cancer (Barton *et al* 1998, N=125, 4 weeks/phase) compared 800IU/day of vitamin E with placebo. There were no significant differences between groups in hot flash frequency or severity.

#### *Kava*

One fair quality study of kava (including calcium 1g/day) vs. calcium (1g/day) found an improved anxiety score in the treatment groups (Cagnacci *et al* 2003, N=80, 12 week course). There were no between group differences in Green Climacteric Scale and depression scores. This trial did not involve women with breast cancer.

#### *Phospholipid liposomes*

A fair quality study of intramuscular liposomes vs. placebo injection found an improved Green Climacteric Scale ( $p=0.001$ ), and anxiety score (Hamilton Anxiety Scale,  $p<0.001$ ) in the treatment groups when compared with placebo. This trial did not involve women with breast cancer.

*Mind-Body and Behavioural Therapies*

Only one trial of women with breast cancer was included of the 9 trials identified (Ganz *et al* 2000). This was rated as fair in quality.

Ganz PA, Greendale GA, Petersen L, Zibecchi L, Kahn B, Belin TR. Managing menopausal symptoms in breast cancer survivors: results of a randomized controlled trial. *Journal of the National Cancer Institute* 2000;92(13):1054-64.

*Inclusion criteria:*

- 1) Disease-free, female breast cancer patients, between 8 months and 5 years after diagnosis of stage I or II disease;
- 2) Perimenopausal or postmenopausal (defined by amenorrhea of  $\geq 6$  months);
- 3) Chemotherapy or radiation therapy completed at least 4 months before enrollment. Tamoxifen use not excluded;
- 4) Presence of at least one target symptom (hot flashes, vaginal dryness, or stress urinary incontinence) of moderate to severe intensity;
- 5) Acceptance of behavioural or pharmacological treatment for at least one target symptom.

*Exclusion criteria*

- 1) History of other cancers except non-melanoma skin cancer;
- 2) Serious chronic medical conditions that may influence the assessment of health-related QOL;
- 3) Abnormal Pap smear showing dysplasia or more severe changes;
- 4) Symptoms of a major psychiatric illness (e.g., depression) that were not being treated or not controlled by medication;
- 5) Inability to read and write in English;
- 6) Active alcohol or substance abuse;
- 7) Oestrogen Replacement Therapy within the past 3 months; and
- 8) Major cognitive impairment or inability to provide informed consent.

*Population*

76 postmenopausal breast cancer survivors  
Intervention N=33  
Usual care N=39

*Intervention*

A Comprehensive Menopausal Assessment (CMA) intervention programme. This was delivered by a nurse practitioner and focused on symptom assessment, education, counselling and, as appropriate, specific pharmacologic and behavioural interventions for each of the three target symptoms (hot flashes, vaginal dryness, stress urinary incontinence).

The comparison group received usual care and were free to use medication or alternative therapies to relieve symptoms.

*Outcomes*

Psychosocial symptoms were assessed by a self-report screening instrument, and distressed women were referred for counselling if needed.

Composite menopausal symptom scale

RAND Short Form Health Survey Vitality Scale

Cancer Rehabilitation Evaluation System (CARES) Sexual Functioning Scale

*Follow-up*

The intervention took place over a 4-month period.

Outcomes measured were scores at baseline and at 4-month follow-up.

*Results*

Change scores for the menopausal symptom scale differed significantly between groups (P= 0.0004) with reduced symptoms in the intervention group.

There was no significant difference between groups in the RAND Vitality Scale (P=0.77).

There was a statistically significant improvement in sexual functioning for the intervention group on the CARES scale (p=0.04).

<b>Outcome</b>	<b>CMA change score</b>	<b>Control change score</b>	<b>P value</b>
Menopausal Symptom Score	Mean change score 0.61(95%CI 0.40-0.82)	Mean change score 0.19(95%CI 0.06-0.44)	P=0.0004
Sexual functioning scale	Adjusted mean change score 0.38 (95%CI 0.05-0.71)	Adjusted mean change score 0.015 (95%CI -0.37-0.40)	P=0.04

**Author conclusions:** A clinical assessment and intervention program for menopausal symptom management in breast cancer survivors is feasible and acceptable to patients, leading to reduction in symptoms and improvement in sexual functioning. Measurable improvement in a general QOL measure was not demonstrated.

*Body-based therapies*

One small crossover placebo controlled trial enrolling 15 women with breast cancer evaluated magnetic devices placed over 6 Chinese acupressure points corresponding to hot-flash relief (Carpenter *et al* 2002). The device was only applied for 72 hours. Complete data were available from 11 survivors of breast cancer. Results showed that magnetic therapy and placebo reduced

hot flash frequency and bothersome hot flashes. There was significantly more effect in the placebo group ( $p=0.02$ ). There were no differences between groups in hot flash severity, interference with daily activities, and overall quality of life.

**General comments -**

**Systematic review  
Psycho-educational interventions**

An update search identified another systematic review of psycho-educational interventions to relieve hot flashes. Trials of women with breast cancer were also included.

Tremblay A, Sheeran L, Aranda SK. Psycho-educational interventions to alleviate hot flashes: a systematic review. *Menopause-the Journal of the North American Menopause Society* 2008;15(1):193-202

Design: Systematic review (1980-2006)

Level 1+

Country: Canada

Aim: To assess the evidence of psycho-educational interventions to improve severe hot flashes in women after breast cancer treatment.

**Inclusion criteria**

Any experimental design

Participants had to have vasomotor symptoms

English language articles

**Exclusion criteria**

Case reports and descriptive studies

**Population**

**Interventions**

Psycho-educational interventions defined as any intervention that included education, counselling, cognitive-behavioural therapy, group therapy, psychological or relaxation interventions.

**Outcomes**

Hot flash frequency

**Follow up -**

**Results**

14 articles met the inclusion criteria

The one study of women with breast cancer that evaluated psycho-educational intervention was by Ganz *et al* 2000 which is included in the evidence table.

*Relaxation studies*

Two studies of breast cancer survivors were identified. Both were rated as poor in quality. The findings are reported in the following table.

<b>Study</b>	<b>Design</b>	<b>Intervention</b>	<b>Results</b>
Fenlon 1999 Poor quality	RCT N=24	Deep breathing relaxation vs. control	Hot flash frequency, night sweats and distress showed a trend in improvement. Psychological morbidity improved in relaxation group

			(p=0.005). However 75% of intervention group also used other measures.
Nedstrand 2005 Poor quality	RCT N=38	Applied relaxation vs. electro-acupuncture	Hot flash frequency and menopausal symptoms improved in both groups (p<0.0001 and p<0.001 respectively). Effects were maintained at 3 and 6 months.

All the interventions for breast cancer patients appear to have had some effect. This was significant in relieving menopausal symptoms in the trials by Ganz (2000) and Nedstrand (2005). However sample sizes were very small and the effects in the intervention group in the study by Fenlon (1999) were confounded by other measures taken to relieve symptoms. In the study by Ganz (2000) reported earlier, again other medications were allowed in both the intervention and control groups. Larger randomized studies are required.

**Author conclusions:** Psycho-educational interventions, including relaxation, seem to alleviate hot flashes in menopausal women and breast cancer survivors; however, the methodological quality of published research is either fair or poor. More studies are required, especially in the breast cancer population where only a few studies are available, before psycho-educational interventions are offered as a treatment option.

**General comments -**

**Systematic review  
Black cohosh**

An update search identified another systematic review of black cohosh for treatment of hot flashes in breast cancer patients.

Walji R, Boon H, Guns E, Oneschuk D, Younus J. Black cohosh (*Cimicifuga racemosa* [L.] Nutt.): safety and efficacy for cancer patients. [Review] [60 refs] Support Care Cancer 2007 Aug;15(8):913-21.

Design: Systematic review (1950 - 2007)

Level 1+

Country: Canada

Aim: To critically assess studies of the safety and efficacy of black cohosh for breast cancer patients.

**Inclusion criteria**

Primary in vitro and in vivo or studies, clinical trials of black cohosh in patients with current or a history of breast cancer.

Reviews published from 2002 – March 2007

**Exclusion criteria**

Abstracts, letters, editorials, commentaries, preliminary and duplicate reports

Reviews published before 2002

Non-English language articles

**Population**

**Interventions**

Studies of black cohosh in women with breast cancer.

Jadad scale used for quality assessment of studies (Scale 1 – 5, 1= poor, 5 = good)

**Outcomes**

Efficacy

Safety

**Follow up -**

**Results**

26 articles selected

5 clinical articles included (21 pre-clinical studies not reviewed in this table)

The results of included studies are shown below:

Study	Design	N of patients	Intervention	Duration	Outcome
Jacobson 2001 QA 5	RCT	85	1 tablet twice daily	-	Improved sweating in BC group (p=0.04)
Pockaj 2006 QA 4	RCT cross-over	132	2 x 20mg daily	8 weeks	No differences in hot flashes or QoL

Munoz 2003 QA 2	RCT open- label	136	2 x 20 mg daily	12 months	Improved hot flashes in BC group (p<0.01)
Pockaj 2004 QA 1	Pilot open- label	23	20 mg	4 weeks	Significant reduction of hot flash scores and frequency
Rebbeck 2007	NRS case- control	2473	Interview of supplement intake		Breast cancer protective effect

The results show conflicting findings of the effects of black cohosh in women with breast cancer. However the strongest study indicates that there may be a reduction in excessive sweating with black cohosh, but no changes in other menopausal symptoms. The authors add that there was a large drop-out rate in this trial (20%) and intensity scores for hot flashes were on a 3 point scale, whereas a 5 or 7 point scale may have been more sensitive.

**General comments -**

## Randomized Controlled Trial Acupuncture

An update search identified an RCT of acupuncture for treatment of hot flashes in breast cancer patients.

Deng G, Vickers A, Yeung S, Cassileth B. Randomized, controlled trial of acupuncture for the treatment of hot flashes in breast cancer patients.[see comment]. J Clin Oncol 2007 Dec 10;25(35):5584-90.

Design: RCT (2002-2005)

Level 1+

Country: USA, setting: Single setting

Aim: To determine immediate and long-term effects of true acupuncture vs sham acupuncture on hot flash frequency in women with breast cancer.

### Inclusion criteria

Undergoing treatment

Karnofsky performance score > 60

Average of 3 or more hot flashes/day

### Exclusion criteria

Planned surgery

Chemotherapy, radiotherapy, immunotherapy or initiation or cessation of hormonal therapy during trial or 3 weeks before

Pharmacologic treatment of hot flashes or SSRIs- unless SSRI dose was stable for 4 weeks before the study

Skin infections

Previous acupuncture

**Population** number of patients = 72 randomized, 70 treated

Median age 55 years (48-59)

Tamoxifen use 40%

Aromatase inhibitors 25%

SSRIs 34%

### Interventions

Randomization was stratified by:

Concurrent treatment with any of: oestrogen receptor modulator, gonadotrophin-releasing hormone analogue, aromatase inhibitor

Concurrent use of hot flash medication or SSRI

More than 7 hot flashes/day at baseline

Menopausal status at diagnosis

True acupuncture (n=40) was compared with sham acupuncture (n=30)

Treated twice weekly for 4 weeks, 19 acupuncture points were applied by licensed acupuncturists.

Outcomes were assessed at week 6.

At week 7 true acupuncture was offered to the sham group.

Outcomes assessed in both groups at 6 weeks and 6 months.

### Outcomes

Hot flash frequency at 6 weeks and 6 months from hot flash diaries.

**Follow up Week 6 and 6 months****Results**

Data for hot flashes are shown in the following table:

<b>Time</b>	<b>Acupuncture mean hot flashes/day (SD)</b>	<b>Placebo mean hot flashes/day (SD)</b>	<b>Between group comparison 95%CI</b>	<b>P value</b>
Baseline	N=42 8.7 (3.9)	N=29 10 (6.1)		
Week 4	N=38 5.8 (4.8)	N=27 7.8 (5.9)	-2.7 to 0.9	0.3
Week 6	N=39 6.2 (4.2)	N=28 7.6 (5.7)	-2.4 to 0.7	0.3
6 months	N=33 6.1 (4.9)	N=17 6.8 (5.7)		

There was no difference in hot flush frequency between groups at 6 weeks. During week 1 both groups showed a reduction in hot flash frequency (7.3 acupuncture vs. 7.9 sham) but this rate of decline was not maintained. Treatment effects were maintained at 6 months.

**General comments –**

P values were not provided for patient characteristic data. Fewer participants in the sham group were on tamoxifen (33% sham vs. 48% true). Tamoxifen use may influence intensity of hot flashes. One third of participants were taking SSRIs to reduce hot flashes so any reduction provided by acupuncture may have been minimal in this group leading to an underestimate of the effect size.

## Chapter 9 – Follow-up

### ***9.1 What is the role of breast imaging modalities in the follow-up of patients with invasive breast cancer and in patients with DCIS?***

#### **Short Summary**

##### **Invasive Breast Cancer**

Evidence from three systematic reviews of observational studies does not confirm that routine follow-up mammography directly improves survival in patients treated for breast cancer, even though one included observational study is suggestive of improved 5 year survival for patients in whom ipsilateral recurrence is detected by mammography (McGahan and Noorani 2000; Temple *et al.* 1999; Grunfeld *et al.* 2002; Montgomery *et al.* 2007).

Evidence from one RCT suggests that in the first 18 months of follow-up, further tests prompted by mammography are more frequent in patients treated initially with breast conserving surgery plus radiotherapy compared to patients who received breast conserving surgery alone (Holli *et al.* 1998).

Estimates of the proportion of cases of recurrent breast cancer that are detected first by follow-up mammography come from observational studies, but there is wide variation. Two systematic reviews of observational studies summarise this proportion. For ipsilateral local recurrence, the proportion detected first by follow-up mammography had a range of 8%-50% (Grunfeld *et al.* 2002; McGahan and Noorani 2000) and median values of 26% (McGahan & Noorani 2000) and 27% (Grunfeld *et al.* 2002). For contralateral breast cancer, the proportion detected first by follow-up mammography had a range of 8%-80% (Grunfeld *et al.* 2002; McGahan & Noorani 2000) and median values 36% (McGahan & Noorani 2000) and 45% (Grunfeld *et al.* 2002).

Evidence from a systematic review of observational studies suggests that the sensitivity of mammography in detecting ipsilateral local recurrence has range of 38%-74% and specificity of 39%-60%. Sensitivity and specificity for the detection of contralateral breast cancer was provided for physical examination plus mammography combined, with sensitivity (range): 81%-88% and specificity (range): 96.5%-99.9% (Temple *et al.* 1999).

Evidence on the role of MRI in the follow-up of patients treated for breast cancer comes from observational studies and suggests that the sensitivity and specificity of MRI in detecting locally recurrent breast cancer are potentially high. In seven diagnostic studies of follow-up MRI, sensitivity had a range of 85.7%-100%. Specificity had a range of 82%-100% (Aichinger *et al.* 2002; Bone *et al.* 1995; Buthiau *et al.* 1995; Coulthard *et al.* 1999; Heywangkobrunner *et al.* 1993; Preda *et al.* 2006; Viehweg *et al.* 1998). Follow-up MRI can detect multifocal tumours, multicentric tumours and DCIS (Bone *et al.* 1995) and also incidental breast cancer tumours in the contralateral breast in patients treated for breast cancer but in whom the

contralateral is clinically and mammographically asymptomatic (Lieberman *et al.* 2003). There is some evidence that follow-up MRI has higher diagnostic performance when the interval from radiotherapy to MRI is longer (Heywangkobrunner *et al.* 1993; Viehweg *et al.* 1998).

Evidence on the role of ultrasound in the follow-up of patients treated for breast cancer comes from observational studies and shows the sensitivity of ultrasound in detecting locally recurrent breast cancer had a range of 70.6%-90.9% and specificity had a range of 82%-98.3%.

### DCIS

A very small volume of poor quality evidence was identified on follow-up mammography in patients treated initially for DCIS, in two retrospective studies (Lieberman *et al.* 1997; Weng *et al.* 2000). These two studies suggest that follow-up mammography is able to detect locally recurrent breast cancer in some patients treated initially for DCIS.

### PICO

	Population	Intervention	Comparison	Outcome
<b>Invasive Breast Cancer</b>	Patients with invasive breast cancer	Imaging modalities for the breast including: <ul style="list-style-type: none"> <li>• Mammography</li> <li>• Ultrasound</li> <li>• Magnetic Resonance Imaging (MRI)</li> <li>• Mammoscintigraphy</li> <li>• PET/CT</li> </ul>	Versus any or none	<ul style="list-style-type: none"> <li>• Detection rates of new or recurrent disease</li> <li>• Psychological morbidity</li> <li>• Cost Effectiveness</li> <li>• Diagnostic Accuracy</li> </ul>
<b>DCIS</b>	Patients with DCIS	Imaging Modalities for the breast including: <ul style="list-style-type: none"> <li>• Mammography</li> <li>• Ultrasound</li> <li>• Magnetic Resonance Imaging (MRI)</li> </ul>	Versus any or none	<ul style="list-style-type: none"> <li>• Detection rates of new or recurrent disease</li> <li>• Psychological Morbidity</li> <li>• Cost Effectiveness</li> <li>• Diagnostic Accuracy</li> </ul>

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

### Evidence Summary

#### Invasive Breast Cancer

All of the identified evidence originates from observational studies resulting in poor quality evidence. For follow-up mammography, three systematic reviews of observational studies reflect the nature of the evidence. All of the studies address the role of one or more of mammography, MRI or US in the follow-up of patients treated for primary breast cancer and are aimed at detecting 'new' disease; most commonly local recurrence in the breast, but also contralateral breast cancer. There is a high degree of heterogeneity in the studies in terms of methodology, follow-up regimens, outcome measures and patient populations. There is a high degree of inconsistency with regard to values of sensitivity and specificity; many of these values are derived from small subgroups e.g. in series of patients where recurrent disease is a rare event,

and should be interpreted cautiously. With the exception of one study from South Korea, all remaining studies originate from Western Europe or North America. Follow-up regimens are not consistently reported but are likely to differ in some studies from practice in the UK.

Evidence from three systematic reviews of observational studies does not confirm that routine follow-up mammography directly improves survival in patients treated for breast cancer, even though one included observational study is suggestive of improved 5 year survival for patients in whom ipsilateral recurrence is detected by mammography.

Evidence from one RCT suggests that in the first 18 months of follow-up, further tests prompted by mammography are more frequent in patients treated initially with breast conserving surgery plus RT compared to patients who received breast conserving surgery alone.

Evidence from observational studies suggests that the sensitivity and specificity of MRI in detecting locally recurrent breast cancer are potentially high (Table 1). In 7 diagnostic studies of follow-up MRI, sensitivity had range 85.7%-100% (discounting one outlier value of 0%, based on small numbers). Specificity had range 82%-100%

Evidence on the role of US in the follow-up of patients treated for breast cancer comes from observational studies and is summarised in Table 2. In four observational studies the sensitivity of US in detecting locally recurrent breast cancer had range 70.6%-90.9% and specificity had range 82%-98.3%.

**Table 1: sensitivity and specificity of follow-up MRI in detecting locally recurrent breast cancer**

Study	Size	Sensitivity	Specificity	Notes
(Aichinger <i>et al.</i> 2002)	42	100%	82%	
(Bone <i>et al.</i> 1995)	83	85.7% [95% CI 60.1%- 96.0%]	100% [95% CI 94.7%- 100%].	Initial treatment: mastectomy and implant reconstruction.
(Buthiau <i>et al.</i> 1995)	82	100% [95% CI 93.7%- 100%]	84% [95% CI 65.4%- 93.6]	Existing suspicion of recurrence on conventional imaging.
(Coulthard <i>et al.</i> 1999)	59	0% [95% CI 0%-56.1%]	92.9% [95% CI 83.0%- 97.2%]	Sensitivity value based on very small subgroup.
(Heywangkobrunner <i>et al.</i> 1993)	62	100% [95% CI 74%- 100%]	85% [95% CI 74%- 92%]	Based on MRI plus conventional examination/imaging.
(Preda <i>et al.</i> 2006)	93	sensitivity 94% [95% CI 72%-	90% [95% CI 82%- 95%]	Based on MRI plus conventional examination/imaging.

		99%]		
(Viehweg <i>et al.</i> 1998)	166	100% [95% CI 87.5%-100%]	87.8% [95% CI 82.2%-91.8%]	

**Table 2: sensitivity and specificity of follow-up US in detecting locally recurrent breast cancer**

Study	Size	Sensitivity	Specificity	Notes
(Aichinger <i>et al.</i> 2002)		86%	82%	Colour doppler US plus echo signal amplifier.
(Balu-Maestro <i>et al.</i> 1991)	272	90.9% [95% CI 72.2%-97.5%]	Not available	
(Ciatto <i>et al.</i> 1995)	43	76.7% [95% CI 62.3%-86.9%]	Not available	
(Shin <i>et al.</i> 2005)	1968	70.6% [95% CI 53.8%-83.2%]	98.3% [95% CI 97.6%-98.8%]	Detection of occult breast cancer i.e. recurrence in the breast, adjacent node bearing areas, mastectomy bed and contralateral breast cancer.

### DCIS

There is a very small body of evidence available to address this question consisting of two retrospective case studies thus providing poor quality evidence.

Neither of the included studies were well designed to evaluate the role of follow-up mammography in patients treated for DCIS.

Results from the studies suggest that follow-up mammography is able to detect locally recurrent breast cancer in some patients treated initially for DCIS.

### Further details - Invasive Breast Cancer

#### The role of follow-up mammography

14 studies were selected which provide evidence on the role of surveillance mammography in the follow-up of patients treated for breast cancer (Aichinger *et al.* 2002; Ashkanani *et al.* 2001; Auguste *et al.* 1994; Balu-Maestro *et al.* 1991; Churn & Kelly 2001; Ciatto *et al.* 1995; Fajardo *et al.* 1993; Grunfeld *et al.* 2002; Holli *et al.* 1998; Johnson *et al.* 2000; Kaas *et al.* 2001; McGahan & Noorani 2000; Paszat *et al.* 2007; Robinson *et al.* 2007; Temple *et al.* 1999; Yau *et al.* 2007).

One RCT investigated the role of follow-up mammography in patients with low-risk breast cancer randomised to either breast conserving surgery plus RT or breast conserving surgery alone. Falsely positive mammography findings were twice as frequent in patients who received RT compared to patients who received no RT ( $p=0.04$ ), with positive predictive values 15% and 33.3%, respectively. In the first 18 months of follow-up, further tests prompted by mammography were more frequent in patients who received RT compared to patients who received no RT with OR = 2. Beyond 18 months of follow-up the rate of further tests prompted by mammography was equal between randomised groups with OR = 1 (Holli *et al.* 1998).

A systematic review of observational studies examined the ability of physical examination and mammography to detect ipsilateral local recurrence and contralateral breast cancer (Temple *et al.* 1999). In detecting ipsilateral local recurrence (8 studies) the sensitivity of mammography had mean 59.3%, median 60% and range 38%-74%. The specificity of mammography had mean 54.5%, median 59.5% and range 39%-60%. Physical examination had mean sensitivity 63.5%, median 68% and range 29%-75% and mean specificity 23.5, median 23.5% and range 17%-30%. Data for the detection of contralateral breast cancer was provided for physical examination plus mammography combined (based upon 2 screening programme studies) and had sensitivity (range): 81%-88% and specificity (range): 96.5%-99.9%. Mammography detected more locally recurrent ipsilateral breast tumours at the noninvasive stage than did physical examination, but this was not found to influence 5 year survival. Two included studies found that the incidence of contralateral breast cancer increased after the introduction of follow-up mammography. A third study found that the incidence of contralateral breast cancer increased when mammography was added to physical examination in follow-up. None of these three studies analysed survival (Temple *et al.* 1999).

A second systematic review was conducted of observational studies of follow-up mammography in patients treated with breast conserving surgery and RT (McGahan & Noorani 2000). The review found that routine mammography was not associated with a reduction in time to detection of recurrent breast cancer, compared to clinical examination. For ipsilateral recurrent breast cancer (local or loco-regional recurrence) the detection rate of mammography had mean 28.3%, median 26% and range 12%-50%. For contralateral breast cancer the detection rate of mammography had mean 43.6%, median 36% and range 18%-80%. No evidence was found to suggest that routine mammography directly improved overall survival. However, the review suggested that local recurrence detected by mammography may be more frequently associated with smaller tumour size, lower stage and older patient age (McGahan & Noorani 2000).

A further systematic review of observational studies was conducted to examine the effect of routine surveillance mammography in detecting ipsilateral recurrence (IR) or contralateral breast cancer in patients treated predominantly with breast conserving surgery and RT (Grunfeld *et al.* 2002). The proportion of patients in whom IR was detected by mammography alone had mean 26.5%, median 27% and range 8%-50%, based on 10 studies. In

the remaining cases, IR was detected by either physical examination or a combination of physical examination and mammography. The proportion of patients in whom CBC was detected by mammography alone had mean 45.5%, median 45% and range 8%-80%, based on 9 studies. There was no evidence for any difference in the median interval to detection of IR by mammography alone compared to other methods. Two studies reported that mammography detected cases of CBC at an earlier stage than palpation alone. Two studies found no effect of mode of detection of IR and either overall survival or disease free survival. One study demonstrated improved 5 year survival in patients in whom IR was detected by mammography. Only one study examined the relationship between the mode of detection of CBC and survival and found no effect. (Grunfeld *et al.* 2002)

A systematic review by Montgomery *et al.* (2007) was conducted to establish the proportion of potentially treatable locoregional relapses and new contralateral breast cancers detected by clinical examination, mammography and patient self-examination. All studies with information on proportion of relapses detected by clinical examination, mammography and self-examination were included. A total of 30-40% of potentially treatable relapses are detected by patient self-examination. In studies published before 2000, 15% of such relapse is mammographically detected with 46% detected by routine clinical examination. In those published after 2000, 40% are mammographically detected with 15% detected on routine clinical examination. Patients with ipsilateral breast relapse detected clinically appear to do less well than those with relapse detected by self-examination or mammography. As experience with mammography has increased, routine clinical surveillance detected fewer potentially treatable relapses in more modern cohorts. There was no evidence to suggest that clinical examination provided a survival advantage compared with other methods of detection.

A relatively large observational study conducted a nested case control study to estimate the association between receipt of surveillance mammogram and breast cancer mortality in stage I and II breast cancer patients who were at least 65 years old. The study reported that with each additional surveillance mammogram there was an associated 0.69-fold decrease in the odds of breast cancer mortality. The associations evaluated showed that a protective association was strongest among women with stage I disease, those who received mastectomy, and those in the oldest age group (Lash *et al.* 2007)

A small prospective case series study assessed the performance of mammography in detecting locally recurrent breast cancer in patients treated initially by breast conserving surgery (n=38) or mastectomy (n=4) and found that mammography had sensitivity 45% and specificity 77% (Aichinger *et al.* 2002).

A retrospective case series study investigated the rate of detection of local recurrence by annual bilateral mammography in 695 women with breast cancer treated by breast conserving surgery (Ashkanani *et al.* 2001). Local recurrence was confirmed in 21/695 = 3% of patients at a mean follow-up period of 3.5 years. Clinical examination was the first method of detection of

local recurrence in 11/21 = 52.4% of patients with confirmed local recurrence. Surveillance mammography was the first method of detection of local recurrence in 10/21 = 47.6% of patients with confirmed local recurrence, although mammography was able to predict local recurrence in 13 patients i.e. 13/20 = 65% of patients with local recurrence who received mammography. In 52 patients mammogram results were falsely positive; at a rate of 52/2181 = 2.4% of all mammographies (Ashkanani *et al.* 2001).

A retrospective case series study investigated the performance of mammography in detecting recurrent breast cancer in patients treated with breast conserving surgery and radiotherapy and found that mammography had sensitivity 64% and specificity 67% (Auguste *et al.* 1994).

A retrospective case series study examined the sensitivity of follow-up mammography in detecting local recurrence in patients treated for breast cancer (Balu-Maestro *et al.* 1991). Mammography performed every 6 months in the first 3 years from treatment and annually thereafter had sensitivity 95.5% [95% CI 78.2%-99.2%] based on 22 recurrences in a subgroup of 171 patients with complete data (Balu-Maestro *et al.* 1991).

A retrospective case series examined the value of follow-up of 505 patients who underwent breast conserving surgery for breast cancer (Churn & Kelly 2001). There were 31 cases of local recurrence. There was no set protocol for follow-up mammograms, but in 25 patients in whom local recurrence was the only detected recurrence, the method of detection was as follows: mammography: 7 (28%), routine clinic appointment: 8 (32%), interim referral: 9 (36%) and unknown: 1 (4%) (Churn & Kelly 2001).

A retrospective case series study examined follow-up mammography in 121 patients with proven locally recurrent breast cancer following initial treatment with breast conserving surgery (Ciatto *et al.* 1995). A protocol of annual mammography for the first five follow-up years and biennial mammography thereafter had sensitivity of 63.6% [95% CI 54.8%-71.7%] in detecting local recurrence (Ciatto *et al.* 1995).

A retrospective case series study assessed the efficacy of routine mammography of the postoperative site in 827 patients treated with mastectomy for breast cancer, including 32 patients who underwent bilateral mastectomy (Fajardo *et al.* 1993). In 859 breasts studied 39 tumours recurred locally (4.5%) at a mean of 3.5 years from diagnosis. The Method of first detection of ipsilateral local recurrence was: clinical examination: 35/39 = 89.7%, scintigraphy: 4/39 = 10.3%, mammography: 0/39 = 0%. In 20 patients with suspicious findings on clinical examination which prompted mammography, mammography detected locally recurrent cancer in 2 patients (10%) (Fajardo *et al.* 1993).

A retrospective case series examined the efficacy of annual clinical examination and biennial mammography to detect metachronous tumours occurring in the contralateral breast in 205 patients treated for breast cancer with mastectomy (Johnson *et al.* 2000). 17 metachronous, contralateral

tumours were detected at a median of 10 years from the initial surgery. The method of detection was as follows: patient: 8/17 = 47%, clinical examination: 4/17 = 24%, routine follow-up mammography: 5/17 = 29% (Johnson *et al.* 2000).

A retrospective case series investigated the outcome of 275 patients with confirmed contralateral, metachronous breast cancer, comparing two when frequencies of follow-up mammography: annual (defined retrospectively by mean interval between mammograms of 12 months) versus biennial (defined retrospectively by mean interval between mammograms of  $\geq 15$  months) (Kaas *et al.* 2001). There was no significant difference in 5-year disease specific survival after detection of contralateral breast cancer between the annual mammography group (75%) and the biennial mammography group (75%,  $p=1$ ). Disease specific survival at 5 years was statistically significantly higher (85%) for patients in whom contralateral breast cancer was mammography detected, compared to patients in whom it was clinically detected (69%,  $p=0.015$ ). When this analysis was stratified by pathological stage of the initial breast cancer tumour, the difference remained statistically significant ( $p=0.015$ ). The proportion of contralateral breast cancers detected by mammography was 109/275 = 39.6% in all patients, 50/141 = 35.5% in the annual mammography group and 26.9% in the biennial mammography group ( $p=0.62$ ) (Kaas *et al.* 2001).

A large, retrospective cancer registry analysis of 12279 women treated for primary breast cancer by breast conserving surgery with or without RT or mastectomy examined the utility of annual follow-up mammography by its relationship with subsequent breast surgery (Paszat *et al.* 2007). Breast surgery occurring within 4 months of a follow-up mammogram was assumed to be prompted by follow-up mammography. Breast surgery occurring 4 months or more after a follow-up mammogram was assumed to be prompted by clinical examination and/or symptoms. Two-thirds of breast operations occurred four months or more after the previous follow-up mammography, suggesting that follow-up mammography detected one third of recurrences/contralateral tumours in the breast (Paszat *et al.* 2007).

A retrospective case series investigated how well mammography performed in young patients to detect new contralateral primary breast cancer. Characteristics of the tumor at baseline and the contralateral tumor were recorded as well as the method of detection of the contralateral breast cancer. A subset of patients was identified based on the age at which they were diagnosed with their initial primary cancer: < 40 years (group A) and 55-59 years (group B). Older patients were significantly more likely to have their second primary tumor detected by routine follow-up mammography compared with the younger cohort. Older patients were also more likely to have estrogen receptor-positive, lower grade second primary tumors, and there was a trend toward smaller tumors. Tumors detected by mammography were more likely to be lower grade, estrogen receptor positive, and smaller. Older patients were more likely to have a contralateral breast cancer detected by conventional mammography, whereas younger patients tended to have

cancer detected by physical examinations or by self-diagnosis. (Robinson *et al.* 2007)

Yau *et al.* (2008) retrospectively reviewed effectiveness on 511 invasive and non-invasive breast cancers treated with breast conservation therapy (BCT). The median follow-up was 5.9 years. The 5-year actuarial ipsilateral breast tumour recurrence (IBTR) rate was 4.5% and contralateral breast cancer (CBC) rate was 2.0% (which represented eight times increase in risk). IBTR of 43% and 62% CBC were first detected by surveillance mammography. The IBTR detection rates per 1000 mammograms were 5.2 for patients (n=349) with one or more IBTR risk factors (age  $\leq$  45, positive/close margins or histological grade 3) and 0.6 for patients (n=162) without. No survival difference was observed between different modes of IBTR detection (p=0.342).

### **The role of follow-up MRI**

Eight of the selected studies of follow-up imaging in patients treated for breast cancer address follow-up MRI (Aichinger *et al.* 2002; Bone *et al.* 1995; Buthiau *et al.* 1995; Coulthard *et al.* 1999; Heywangkobrunner *et al.* 1993; Liberman *et al.* 2003; Preda *et al.* 2006; Viehweg *et al.* 1998).

A small prospective case series study assessed the performance of follow-up MRI in detecting locally recurrent breast cancer in patients treated initially by breast conserving surgery (n=38) or mastectomy (n=4) and found that MRI had sensitivity 100% and specificity 82% (Aichinger *et al.* 2002).

A prospective case series study examined the role of MRI in the follow-up of 83 patients who underwent mastectomy for breast cancer followed by reconstruction with prosthetic implants (Bone *et al.* 1995). MRI was performed on both breasts and the interpreting clinicians had also information from mammography. In detecting ipsilateral recurrent breast cancer, MRI had sensitivity 85.7% [95% CI 60.1%-96.0%] and specificity 100% [95% CI 94.7%-100%]. MRI detected 1 of 5 ipsilateral multifocal tumours and 5 of 5 ipsilateral multicentric tumours. 6 of 14 histologically proven ipsilateral recurrences were DCIS. For contralateral breast cancer, MRI correctly identified as malignant 1 of 2 contralateral invasive tumours, 1 of 1 contralateral DCIS tumour. MRI was falsely positive in 1 of 2 benign lesions (Bone *et al.* 1995).

A prospective case series study examined the effectiveness of contrast-enhanced MRI of the breast to detect local recurrence in patients treated for breast cancer with either breast conserving surgery (n=61) or mastectomy plus implant reconstruction (n=21) (Buthiau *et al.* 1995). All patients underwent contrast-enhanced MRI and diagnostic biopsy due to suspicion of local recurrence on conventional imaging. The histologically proven rate of local recurrence was 69.5%. In detecting local recurrence and based on all 82 patients, contrast-enhanced MRI had sensitivity 100% [95% CI 93.7%-100%] and specificity 84% [95% CI 65.4%-93.6%] (Buthiau *et al.* 1995).

A small, retrospective case series examined the performance of contrast-enhanced follow-up MRI in 63 women treated for breast cancer, of whom 26 had suspicion of recurrent disease based upon clinical examination or mammography (Coulthard *et al.* 1999). MRI was performed once only, of both breasts. There were 4 falsely positive results on MRI in either the ipsilateral or contralateral breast, demonstrated as scarring or benign lesion by biopsy. In detecting ipsilateral local recurrence, follow-up MRI had sensitivity 0% [95% CI 0%-56.1%] and specificity 92.9% [95% CI 83.0%-97.2%] (Coulthard *et al.* 1999). The value for sensitivity is based upon a very small subgroup, as evidenced by the wide confidence interval.

A prospective case series study examined the performance of follow-up MRI in detecting recurrent breast cancer in 62 patients treated by breast conserving surgery and RT (Heywangkobrunner *et al.* 1993). All patients underwent clinical examination, mammography and MRI. Some patients underwent US in addition. Using the information provided by all examinations including MRI, sensitivity for the detection of local recurrence was 100% [95% CI 74%-100%] and specificity 85% [95% CI 74%-92%]. Specificity of MRI was higher in the subgroup of studies performed >18 months after RT (100%) than in studies performed 10-18 months after RT (76%) and those performed 0-9 months after RT (73%). Sensitivity was 100% in all three subgroups. 4 of 11 recurrences and 10 of 18 single recurrent foci were detected by MRI alone, based on focal enhancement (Heywangkobrunner *et al.* 1993).

A retrospective case series study examined the rate of detection of contralateral breast cancer by follow-up MRI in 223 patients treated for unilateral breast cancer, in whom the contralateral breast was clinically and mammographically asymptomatic (Lieberman *et al.* 2003). Biopsy of the contralateral breast was recommended due to suspicion of malignancy in 72/223 = 32% of patients, and was performed in 61 patients. In 12/61 = 20% of patients who underwent contralateral breast biopsy, contralateral cancer was histologically confirmed, representing a PPV for MRI of 12/61 = 20%. Of the 12 patients with contralateral breast cancer, 6 had DCIS and 6 had infiltrating carcinoma. In 11 patients (92%) the contralateral cancer was diagnosed within 3 months of the index cancer (Lieberman *et al.* 2003).

A retrospective case series study investigated the performance of MRI in detecting local recurrence of breast cancer in 93 patients treated initially with breast conserving surgery and in whom local recurrence was suspected based upon mammography and/or US imaging (Preda *et al.* 2006). The interpreting clinician utilised information from MRI plus previous mammography/US. For lesions at the site of the surgical scar, MRI had sensitivity 90% [95% CI 60%-98%] and specificity 92% [95% CI 84%-96%]. In addition in 7 patients 13 incidental lesions that were not in contact with the surgical scar were identified by MRI. These lesions were true positive (6), true negative (5), false positive (2) and false negative (0). For all lesions, including those that are incidental and not in contact with the surgical scar, MRI had sensitivity 94% [95% CI 72%-99%] and specificity 90% [95% CI 82%-95%] (Preda *et al.* 2006).

A retrospective case series evaluated the role of follow-up MRI in detecting local recurrence in patients who were treated initially with breast conserving surgery plus RT (Viehweg *et al.* 1998). 207 contrast-enhanced MRI procedures were performed in 166 patients. In 40 MRI procedures performed within 12 months following RT, the additional use of contrast-enhanced MRI changed the overall diagnosis in 6 of 40 procedures (15%) and MRI had sensitivity 100% [95% CI 20.7%-100%] and specificity 74.4% [95% CI 59.0%-85.4%]. These results were based on small numbers as evidenced by the wide confidence intervals. In 167 MRI procedures performed more than 12 months following RT, the additional use of MRI changed the overall diagnosis in 49 of 167 procedures performed (29.3%) and MRI had sensitivity 100% [95% CI 87.1%-100%] and specificity 91.5% [95% CI 85.7%-95.1%]. In all 207 procedures, MRI had sensitivity 100% [95% CI 87.5%-100%] and specificity 87.8% [95% CI 82.2%-91.8%] (Viehweg *et al.* 1998).

### **The role of follow-up US**

Four of the selected studies of follow-up imaging in patients treated for breast cancer address follow-up US; all of which are observational studies (Aichinger *et al.* 2002; Balu-Maestro *et al.* 1991; Ciatto *et al.* 1995; Shin *et al.* 2005).

A small prospective case series study assessed the performance of colour doppler US, with and without echo signal amplifier (ESA), in detecting locally recurrent breast cancer in patients treated initially by breast conserving surgery (n=38) or mastectomy (n=4) (Aichinger *et al.* 2002). Colour doppler US without ESA had sensitivity 64% and specificity 86%. Colour doppler US plus ESA had sensitivity 86% and specificity 82% (Aichinger *et al.* 2002).

A retrospective case series examined the performance of follow-up of 272 patients treated for breast cancer with breast conserving surgery and RT (Balu-Maestro *et al.* 1991). Patients received bilateral US of breast, axilla and neighbouring node bearing tissues every 6 months in the first 3 years from treatment and annually thereafter. The sensitivity of US in detecting local recurrence was 90.9% [95% CI 72.2%-97.5%] (Balu-Maestro *et al.* 1991)

A retrospective case series study examined follow-up US in 43 patients with proven locally recurrent breast cancer following initial treatment with breast conserving surgery (Ciatto *et al.* 1995). In detecting local recurrence, US had sensitivity 76.7% [95% CI 62.3%-86.9%] (Ciatto *et al.* 1995).

A large, retrospective case series study investigated the effectiveness of breast US in the follow-up of 1968 patients treated for breast cancer with either modified radical mastectomy or breast conserving surgery plus RT (Shin *et al.* 2005). Bilateral US of the breast, chest wall, axilla, parasternal and supraclavicular regions was performed at intervals of 6 months or more. Sensitivity of US with regard to occult tumour (recurrence in the breast, adjacent node bearing areas, mastectomy bed and contralateral breast cancer) was 70.6% [95% CI 53.8%-83.2%] and specificity was 98.3% [95% CI 97.6%-98.8%](Shin *et al.* 2005).

### **Further Details - DCIS**

A small, retrospective case series study examined the mode of detection of locally recurrent breast cancer in 20 patients treated initially for DCIS with breast conserving surgery and, in some cases, RT (Lieberman *et al.* 1997). The 20 patients were selected because they experienced local recurrence of breast cancer that was histologically proven and because mammograms were available for the time of detection of the local recurrence. The protocol for follow-up mammography was not reported. The method of detection of the local recurrence was mammography in 17 patients (85%), mammography and physical examination in 2 patients (10%) and physical examination alone in 1 patient (5%). In 13 patients the recurrent lesions were pure DCIS. Of these patients 12 (92%) were detected solely by mammography (Lieberman *et al.* 1997).

A retrospective case series studied 88 cases of pure DCIS in 85 patients who received follow-up mammography with biannual and annual frequency (Weng *et al.* 2000). Patients were treated initially for DCIS by mastectomy or breast conserving surgery plus RT or breast conserving surgery alone. Local recurrence was confirmed by histology in 12 of 88 cases (13.6%) at a median follow-up period of 99 months. The method of detection of local recurrence included mammography in 9 cases (75%). In two cases (16.7%) the local recurrence presented clinically as a palpable mass or lymphadenopathy and in one case (8.3%) local recurrence was detected incidentally at the time of cosmetic surgery (Weng *et al.* 2000).

## Evidence tables – Invasive Breast Cancer

### Randomized controlled trial

Holli, Saaristo, Isola, Hyöty & Hakama . Effect of radiotherapy on the interpretation of routine follow-up mammography after conservative breast surgery: a randomized study. British journal of cancer 78[4]. 1998.

#### Design

Design: Randomized controlled trial (diagnosis, screening), evidence level: 1 +

Country: Finland, setting: Secondary care

#### Inclusion criteria

Patients with small, invasive breast cancer tumours who were considered to be at low risk, defined as follows:

Age >40 years;

Tumour size  $\leq 2$ cm with no extensive intraductal component;

Node negative;

Histological grade I-II;

c-erbB negative;

DNA diploid with S phase fraction  $\leq 8\%$

$\geq 1$ cm tumour free margin from surgery.

#### Exclusion criteria

Defined by inclusion criteria.

#### Population

number of patients = 144, mean age = 56 years.

#### Interventions

Aim: to determine whether follow-up mammography in patients who underwent breast conserving surgery is more difficult to interpret following RT compared to following breast conserving surgery alone.

RT group (n=78): received, after breast conserving surgery and axillary staging, 50 Gy in 2 Gy fractions.

No RT group (n=66): received breast conserving surgery and axillary staging but no further treatment.

All patients underwent follow-up mammography preoperatively and at 18 month intervals during follow-up.

#### Outcomes

Occurrence of positive findings on follow-up mammography;

Further testing prompted by mammography.

**Follow up**

Mean 2.9 years; 411 cumulative follow-up years.

**Results**

Occurrence of positive findings on mammography:

Mammographic findings were positive in 20/78 patients in the RT group compared to 9/66 patients in the 'no RT' group ( $p=0.1$ ). Falsely positive mammography findings were twice as frequent in the RT group (17) compared to the 'no RT' group (6),  $p=0.04$ .

The positive predictive values were as follows:

RT group:  $3/20 = 15\%$

'No RT' group:  $3/9 = 33.3\%$

Further testing:

In the first 18 months of follow-up, further tests prompted by mammography were more frequent in the RT group compared to the 'no RT' group: OR 2.

Beyond 18 months of follow-up the rate of further tests prompted by mammography was equal between randomised groups: OR 1.

**General comments**

Rate of false negative mammography findings not reported; study data is of limited use with regard to performance of mammography.

Results for further testing are based on the number of tests and not the number of patients. The odds ratios appear to relate to the odds of a test being prompted by mammography (as opposed to performing the test independently of mammography).

## Systematic review of diagnostic studies

McGahan & Noorani . Surveillance mammography after treatment for primary breast cancer. 2000.

### Design

Design: Systematic review of diagnostic studies (diagnosis, screening),  
evidence level: 2+  
Country: Canada, setting: Secondary care

### Inclusion criteria

Patient population: patients treated with breast conserving therapy (local excision and RT) for breast cancer; mean age at diagnosis, 41-59 years.

Studies published between 1994 and 1999 were considered which:

- i) Address surveillance mammography and its impact on disease outcomes;
- ii) address other surveillance strategies for breast tumour recurrence, or;
- iii) describe follow-up methods after treatment for breast cancer.

For inclusion studies had to provide data to populate a pre-defined data collection proforma (e.g. including rate of recurrence, time to recurrence, protocol for mammography surveillance and rate of detection of recurrence by mammography). Studies also had to report on 100 subjects or more.

9 studies met all of the inclusion criteria. Studies were non-randomised, case-series studies.

### Exclusion criteria

Women with a primary diagnosis of DCIS.

### Population

number of patients = 7642.

### Interventions

Aim: to review evidence on routine surveillance mammography after treatment for breast cancer.

In the primary studies, patients received biennial, annual or biannual mammography during their follow-up periods.

### Outcomes

Detection rate of routine mammography for ipsilateral breast cancer and contralateral breast cancer.

### Follow up

Not reported.

### Results

Time to recurrence:

The time to breast cancer recurrence ranged from 2.2 to 5.9 years. Routine

mammography was not associated with a reduction in time to detection.

Detection rate by mammography:

Overall, the detection rate of recurrent breast cancer by routine mammography had mean 34.7%, median 32% and range 15%-80% (9 studies).

For ipsilateral breast cancer alone (local or loco-regional recurrence) the detection rate of mammography had mean 28.3%, median 26% and range 12%-50%.

For contralateral breast cancer alone the detection rate of mammography had mean 43.6%, median 36% range 18%-80%.

Authors' conclusions:

No evidence was found to suggest that overall survival increased due to the earlier detection of locally recurrent disease. However, local recurrence detected by mammography may be more frequently associated with smaller tumour size, lower stage and older patient age. Contralateral breast cancer may be more frequently detected by mammography than are ipsilateral tumours.

**General comments**

Literature search rigorous: MEDLINE, HealthSTAR, Cancerlit, EMBASE, Pascal, the Cochrane Library and PDQ were searched with no language restrictions.

DARE review utilised in appraising this review (available at <http://www.crd.york.ac.uk/CRDWeb/ShowRecord.asp?View=Full&ID=12000008559>).

Ipsilateral recurrence defined as follows:

Local recurrence: recurrence confined to the conserved breast only

Loco-regional recurrence: recurrence in the breast or axilla

Grunfeld, Noorani, McGahan, Paszat, Coyle, van, Joyce & Sawka .  
Surveillance mammography after treatment of primary breast cancer: a  
systematic review (DARE review available). Breast 11[3]. 2002.

### **Design**

Design: Systematic review of diagnostic studies (diagnosis, screening),  
evidence level: 2-  
Country: Canada, setting: Secondary care

### **Inclusion criteria**

Published between 1980-2002

>=100 subjects

Reporting study period, rate of recurrence, time to recurrence and rate of  
detection by mammography.

Population represented by included studies: patients treated for primary,  
invasive breast cancer. Stage of disease at initial diagnosis was variable. The  
vast majority of patients received breast conserving surgery and commonly,  
RT. Some patients received chemotherapy or hormone therapy.

### **Exclusion criteria**

DCIS.

No restrictions were applied in terms of language, primary treatment, protocol  
for mammography surveillance.

### **Population**

-

### **Interventions**

Aim: to systematically review the literature on the effect of routine surveillance  
mammography in detecting ipsilateral recurrence (IR) or contralateral breast  
cancer (CBC).

### **Outcomes**

Rate of detection of IR and CBC by mammography alone.

### **Follow up**

Not reported.

### **Results**

15 studies met the inclusion criteria. The included studies were all  
observational studies.

Detection of IR by mammography:

The proportion of patients in whom IR was detected by mammography alone  
had mean 26.5%, median 27% and range 8%-50%, based on 10 studies. In

the remaining cases, IR was detected by either physical examination or a combination of physical examination and mammography.

Three studies reported no difference in the median interval to detection of IR by mammography alone compared to other methods (start point of interval not reported; presumably diagnosis of cancer).

Effect of mode of detection on survival:

Two studies found no effect of mode of detection of IR and either overall survival or disease free survival. One study demonstrated improved 5 year survival in patients in whom IR was detected by mammography.

Detection of CBC by mammography:

The proportion of patients in whom CBC was detected by mammography alone had mean 45.5%, median 45% and range 8%-80%, based on 9 studies.

Two studies reported that mammography detected cases of CBC at an earlier stage than palpation alone.

Effect of mode of detection on survival:

Only one study examined the relationship between the mode of detection of CBC and survival and found no effect.

### **General comments**

Rigorous literature search performed. Search strategy reported.

The included studies were highly heterogeneous in their methodology, mammography regimens and patient populations.

Five studies did not report their mammography regimen. In the remainder of the studies, mammography was performed bi-annually, annually or semi-annually.

The effect in favour of mammography in terms of survival demonstrated by one study is subject to lead time bias and length bias.

Temple, Wang & Mcleod . Preventive health care, 1999 update: 3. Follow-up after breast cancer. Canadian Task Force on Preventive Health Care. CMAJ Canadian Medical Association Journal 161[8]. 1999.

### **Design**

Design: Systematic review of combined study designs (diagnosis, screening), evidence level: 2-  
Country: Canada, setting: Secondary care

### **Inclusion criteria**

Studies of women with invasive ductal carcinoma of the breast of stage I-III and also:  
>= 5 years of follow-up data;  
Description of adjuvant therapy, if received.

### **Exclusion criteria**

Evidence of distant disease at the time of diagnosis.

### **Population**

-

### **Interventions**

Aim: to investigate the role of follow-up in improving survival and quality of life in patients with early breast cancer.

Interventions reviewed include:

Blood tests and imaging to detect distant disease (not cited here);  
Physical examination with and without mammography.

### **Outcomes**

Detection in follow up of ipsilateral disease and contralateral disease;  
Survival.

### **Follow up**

Minimum of 5 years specified as a study inclusion criterion.

### **Results**

Detection of ipsilateral local recurrence by mammography and physical examination (based upon 8 non-randomised studies):

Sensitivity (mean; median; range):

Mammography: 59.3%; 60%; 38%-74%

Physical examination: 63.5%; 68%; 29%-75%

Specificity (mean; median; range):

Mammography: 54.5%; 59.5%; 39%-60%

Physical examination: 23.5%; 23.5%; 17%-30%.

Detection of contralateral breast cancer by physical examination plus mammography (based upon 2 screening programme studies):

Sensitivity (range): 81%-88%

Specificity (range): 96.5%-99.9%.

Stage of ipsilateral recurrence by method of detection (based on two retrospective studies):

Mammography detected more locally recurrent ipsilateral breast tumours at the noninvasive stage than did physical examination, but this was not found to influence 5 year survival.

Detection of contralateral breast cancer (based on 3 retrospective studies):

Two studies found that the incidence of contralateral breast cancer increased after the introduction of follow-up mammography. A third study found that the incidence of contralateral breast cancer increased when mammography was added to physical examination in follow-up. None of these three studies analysed survival.

#### **General comments**

DARE review (Database of Abstracts of Reviews of Effects; Centre for Reviews & Dissemination, University of York) utilised when appraising this systematic review:

<http://www.crd.york.ac.uk/CRDWeb/ShowRecord.asp?ID=11999009768>

No inclusion criteria are stated based on study design.

Literature search: MEDLINE database; English language.

Quality of included studies: assessed using a hierarchical scale of I (RCT) - III (expert opinion).

Review is weak in terms of mixed study design, lack of reporting of assessment of validity and data extraction.

Authors report that sensitivity and specificity data for mammography and physical examination are based on small, retrospective studies of highly selected patient groups; apparently patients in whom a biopsy was performed as reference standard. It is probable that reference standard was performed only in cases with suspicious mammography/physical examination result, leading to partial verification bias.

Comparisons of mammography and physical examination

## Prospective case series

Aichinger, Schulz-Wendtland, Kramer, Lell & Bautz . [Scar or recurrence--comparison of MRI and color-coded ultrasound with echo signal amplifiers]. [German]. Rofo: Fortschritte auf dem Gebiete der Rontgenstrahlen und der Nuklearmedizin 174[11]. 2002.

### Design

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Germany, setting: Secondary care

### Inclusion criteria

42 patients who underwent imaging between September 1998 and January 2000 for suspected locally recurrent breast cancer.

38 patients underwent breast conserving surgery and 4 patients underwent mastectomy.

### Exclusion criteria

Not known.

### Population

Age range 36 to 81 years, median age = 59 years.

### Interventions

Aim: to compare the effectiveness of MRI and colour doppler US (with and without echo signal amplifier, ESA) to differentiate locally recurrent breast cancer from scar tissue after surgical treatment.

All patients underwent clinical examination, US, MRI and mammography (n=38).

### Outcomes

Diagnostic performance of colour doppler US, mammography and MRI in detecting locally recurrent breast cancer.

### Follow up

Not known

### Results

Diagnostic performance of colour doppler US, mammography and MRI in detecting locally recurrent breast cancer was as follows:

Mammography:  
Sensitivity = 45%  
Specificity = 77%

Colour doppler US (without ESA):

Sensitivity = 64%  
Specificity = 86%

Colour doppler US plus ESA:

Sensitivity = 86%  
Specificity = 82%

MRI:

Sensitivity = 100%  
Specificity = 82%

**General comments**

Criteria for positive result on colour doppler US were tumour vascularisation and flow pattern.

Reference standard was either histological findings or the results of follow-up for at least 12 months.

Bone, Aspelin, Isberg, Perbeck & Veress . Contrast-enhanced MR imaging of the breast in patients with breast implants after cancer surgery. Acta Radiol. 36[2]. 1995.

### **Design**

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Sweden, setting: Secondary care

### **Inclusion criteria**

83 patients who underwent mastectomy for breast cancer followed by reconstruction with saline or silicone-filled implants; examined with MRI between September 1992 and September 1993.

Median interval between cancer surgery and MRI: 18 months (range 4-127 months).

No patients received RT.

### **Exclusion criteria**

None reported.

### **Population**

, age range 33 to 75 years, median age = 50 years.

### **Interventions**

Aim: to assess the value of contrast-enhanced MRI in detecting locally recurrent breast cancer in patients who underwent mastectomy and breast reconstruction.

All patients underwent contrast-enhanced MRI of both breasts.

### **Outcomes**

Diagnostic performance of MRI with regard to:

Ipsilateral local recurrence;

Multifocal tumours (defined as several foci in the same quadrant);

Multicentric tumours (defined as recurrence in different quadrants of the same breast);

Contralateral breast cancer.

### **Follow up**

Median 10 months, range 5-18 months

### **Results**

Staging performance of MRI in detecting ipsilateral recurrent cancer:

Sensitivity = 12/14 = 85.7% [95% CI 60.1%-96.0%]

Specificity = 69/69 = 100% [95% CI 94.7%-100%]

PPV = 12/12 = 100% [95% CI 75.8%-100%]

NPV = 69/71 = 97.2% [95% CI 90.3%-99.2%].

6/14 histologically proven recurrences were DCIS.

Multifocal tumours:

MRI detected 1/5 multifocal tumours.

Multicentric tumours:

MRI detected 5/5 multicentric tumours.

Contralateral breast cancer:

MRI detected as malignant the following contralateral breast lesions:

1/2 invasive tumours;

1/1 DCIS tumour;

1/2 benign lesions (i.e. a false positive case).

### **General comments**

Reference standard was histopathological examination of excised lesions, suspected to be locally recurrent tumour, or clinical follow-up of patients with negative MRI results (median 10 months, range 5-18 months). Biopsy was in some cases prompted by mammography.

Diagnosing clinician also had information from mammography available.

Diagnostic outcome measures are based on small subgroups.

Buthiau, Rixe, Nizri, Piette & Khayat . [Breast cancer: role of MRI in follow-up of cases treated]. [French]. Bull.Acad Natl Med 179[3]. 1995.

### **Design**

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: France, setting: Secondary care

### **Inclusion criteria**

82 patients treated for breast cancer with either breast conserving surgery or mastectomy plus implant reconstruction between October 1993 and December 1994.

### **Exclusion criteria**

Not known.

### **Population**

number of patients = 82, age range 26 to 74 years.

### **Interventions**

Aim: to report on the effectiveness of contrast-enhanced MRI of the breast to detect local recurrence in patients treated for breast cancer with either breast conserving surgery (n=61) or mastectomy plus implant reconstruction (n=21).

All patients underwent contrast-enhanced MRI and diagnostic biopsy.

### **Outcomes**

Diagnostic performance of contrast-enhanced MRI.

### **Follow up**

Not known.

### **Results**

Rate of local recurrence =  $57/82 = 69.5\%$ .

Performance of contrast-enhanced MRI (all 82 patients):

Sensitivity =  $57/57 = 100\%$  [95% CI 93.7%-100%]

Specificity =  $21/25 = 84\%$  [95% CI 65.4%-93.6%]

PPV =  $57/61 = 93.4\%$  [95% CI 84.3%-97.4%]

NPV =  $21/21 = 100\%$  [95% CI 84.5%-100%].

### **General comments**

Reference standard was histological diagnosis from biopsy, performed in all cases.

High rate of local recurrence is likely to arise since patients had suspicion of recurrence on conventional imaging.

Heywangkobrunner, Schlegel, Beck, Wendt, Kellner, Lommatzsch, Untch & Nathrath . Contrast-Enhanced Mri of the Breast After Limited Surgery and Radiation-Therapy. J Comput.Assist.Tomogr. 17[6]. 1993.

### **Design**

Design: Prospective case series (diagnosis, screening), evidence level: 3  
Country: Germany, setting:

### **Inclusion criteria**

62 patients treated by breast conserving surgery and RT and who received either 24 months of clinical and mammographic follow-up (n=60) or histopathologic results (n=17).

A total of 77 MRI studies were performed.

### **Exclusion criteria**

None reported.

### **Population**

number of patients = 62.

### **Interventions**

Aim: to examine the performance of MRI in detecting recurrent breast cancer in patients treated by breast conserving surgery and RT, and to record the changes on MRI at different times since treatment.

All patients underwent mammography and MRI. Some patients underwent US in addition.

### **Outcomes**

Sensitivity and specificity of MRI in detecting recurrent breast cancer.

### **Follow up**

Range 2-5 years

### **Results**

Post MRI:

Sensitivity = 11/11 = 100% [95% CI 74%-100%]

Specificity = 56/66 = 85% [95% CI 74%-92%]

Pre-MRI (conventional imaging):

Sensitivity = 7/11 = 64% [95% CI 35%-85%]

Specificity = 51/66 = 77% [95% CI 66%-86%].

Specificity of MRI was higher in the subgroup of studies performed >18 months after RT (100%) than in studies performed 10-18 months after RT (76%) and those performed 0-9 months after RT (73%). Sensitivity was 100% in all three subgroups.

4 of 11 recurrences and 10 of 18 single recurrent foci were detected by MRI alone, based on focal enhancement.

**General comments**

95% CIs provided by spreadsheet available at Cardiff University; Newcombe, (2006):

[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/index.htm](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/index.htm)

Sensitivity and specificity values reported for subgroups based on time since RT depend on small numbers of MRI studies.

Pre-MRI data refer to diagnoses based on clinical examination, mammography and US.

Post-MRI data incorporate use of MRI and also information from clinical examination, mammography and US. This may over-estimate the performance of MRI as a single modality but reflects likely setting.

## Retrospective case series

Ashkanani, Sarkar, Needham, Coldwells, Ah-See, Gilbert, Hutcheon, Eremin & Heys . What is achieved by mammographic surveillance after breast conservation treatment for breast cancer? Am J Surg 182[3]. 2001.

### Design

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

### Inclusion criteria

695 women with breast cancer treated by breast conserving surgery between 1990-1995 identified from a total series of 2300 patients.

### Exclusion criteria

Patients who underwent mastectomy.

### Population

number of patients = 695, age range 33 to 76 years, mean age = 59 years.

### Interventions

Aim: to investigate the rate of detection of local recurrence by mammography and clinical examination.

All patients were followed up by clinical examination as follows:  
3-4 monthly in the first two years;  
6 monthly for the next 3 years;  
annually thereafter.

All patients received annual bilateral mammography.

### Outcomes

Rate of local recurrence;  
Means of detection of local recurrence

### Follow up

Mean 3.5 years (range 2-7)

A total of 2181 mammograms were performed (i.e. a mean of 3.1 per patient).

### Results

Local recurrence was confirmed in 21/695 = 3% of patients at a mean follow-up period of 3.5 years. Of these 21 patients, 1 patient received no mammography at all.

Clinical examination was the first method of detection of local recurrence in 11/21 = 52.4% of patients with confirmed local recurrence. Surveillance mammography was the first method of detection of local recurrence in 10/21 =

47.6% of patients with confirmed local recurrence, although mammography was able to predict local recurrence in 13 patients i.e.  $13/20 = 65\%$  of patients with local recurrence who received mammography. In 52 patients mammogram results were falsely positive; at a rate of  $52/2181 = 2.4\%$  of all mammographies.

**General comments**

Reference standard for local recurrence was fine needle aspiration cytology or biopsy. Reference standard was only performed in cases with suspicious results by either mammography or clinical examination (so there is a likelihood of partial verification bias). Furthermore these measures reflect repeated testing by mammography during each patient's follow-up period.

Auguste, Gerold, Rothenberg, Litvak & Gentin . Detection of Recurrent Carcinoma in the Irradiated Breast. Complications in Surgery 13[4]. 1994.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

### **Inclusion criteria**

103 consecutive female patients treated with lumpectomy and breast RT for stage I-II breast cancer at a single centre during a 5-year period.

### **Exclusion criteria**

None reported.

### **Population**

number of patients = 103, mean age = 57 years.

### **Interventions**

Aim: to evaluate the performance of mammography in detecting recurrent breast cancer in patients treated with breast conserving surgery and radiotherapy.

### **Outcomes**

Sensitivity and specificity of mammography in detecting recurrent breast cancer.

### **Follow up**

Minimum 6 months (range 6 months to 5 years).

Interval from initial treatment and histological confirmation of recurrence had mean 24.7 months (range 10-42 months).

### **Results**

Mammography:  
Sensitivity = 64%  
Specificity = 67%

Clinical examination:  
Sensitivity = 83%  
Specificity = 17%

### **General comments**

Frequency and timing of follow-up mammography not stated, but in discussion section, authors recommend commencement at 6 months after therapy and thereafter annually.

Reference standard was histological findings of biopsy, which was performed only in suspicious cases, either on mammography or clinical examination.

Balu-Maestro, Bruneton, Geoffray, Chauvel, Rogopoulos & Bittman .  
Ultrasonographic posttreatment follow-up of breast cancer patients. J  
Ultrasound Med 10[1]. 1991.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: France, setting: Secondary care

### **Inclusion criteria**

272 patients treated by breast conserving surgery and RT.

### **Exclusion criteria**

101 patients with incomplete data (from sensitivity values).

### **Population**

number of patients = 171.

### **Interventions**

Aim: to report on the effectiveness of US for the follow-up of patients with treated breast cancer.

Patients received bilateral US of breast, axilla and neighbouring node bearing tissues every 6 months in the first 3 years from treatment and annually thereafter.

Patients also received clinical examination plus mammography at the same frequency as US, and in addition, annual mammography of the contralateral breast.

### **Outcomes**

Sensitivity of US and Mammography.

### **Follow up**

Range: 1 month to 12 years. No median reported.

### **Results**

Recurrence rates:

in 272 patients there were 27 locally recurrent tumours, 8 cases of contralateral breast cancer and 2 cases of residual tumour.

Sensitivity of US and mammography with regard to local recurrence was as follows:

US: 20/22 = 90.9% [95% CI 72.2%-97.5%]

Mammography: 21/22 = 95.5% [95% CI 78.2%-99.2%]

### **General comments**

Sensitivity values reported are based on 22 recurrences in a subgroup of 171 patients with complete data.

There is no way of checking any values in this paper, or of deriving further values; specificity is not reported.

No consistent reference standard is described, but is based upon comparison of clinical follow-up, sonographic, mammographic and histological data; hence high likelihood of disease progression bias/differential verification bias.

95% CIs provided by spreadsheet available at Cardiff University; Newcombe, (2006):

[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/index.htm](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/index.htm)

Churn & Kelly . Outpatient follow-up after treatment for early breast cancer: updated results after 5 years. Clin Oncol (R Coll.Radiol.) 13[3]. 2001.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

### **Inclusion criteria**

612 patients referred to a single centre in 1993 for treatment for breast cancer of stage pT1-3, N0-1 or NxM0.

30.9% of patients were of <50 years of age.

Results cited here are for 505 patients who underwent breast conserving surgery; study did not audit contralateral breast cancer in patients treated by mastectomy.

### **Exclusion criteria**

None reported.

No data are cited here for patients who underwent mastectomy.

### **Population**

number of patients = 505.

### **Interventions**

Aim: to investigate the value of frequent outpatient follow-up of patients treated for breast cancer.

An audit was performed of the follow-up of a series of patients with breast cancer. The follow-up schedule was:

3-4 monthly intervals for the first 2-3 years;

6 monthly up to five years;

annually thereafter.

There was no set protocol for follow-up mammograms during the study period.

### **Outcomes**

Rate of local recurrence (in the ipsilateral breast, chest wall or axilla)

Means of detection of local recurrence.

### **Follow up**

Median 74 months (range 4-89 months)

### **Results**

Local recurrence-free survival at 5 years was 94.5% (local relapse rate 5.5%).

There were 31 cases of local recurrence in 5 years:

25 as first relapse;

4 concurrent with distant metastases;

2 after presentation of systemic disease.

In 25 patients in whom local recurrence was the only detected recurrence, the method of detection was as follows:

Mammography: 7 (28%)

Routine clinic appointment: 8 (32%)

Interim referral: 9 (36%)

Unknown: 1 (4%)

### **General comments**

A study disadvantage is that the exact frequency of mammograms is not known (nor in how many patients mammography was performed), but the authors report that mammography was performed usually less frequently than annually.

Ciatto, Ambrogetti & Muraca . [Combined diagnosis of breast cancer recurrences after conservative treatment. Critical review of 143 consecutive cases]. [Italian]. Radiol.Med (Torino) 90[4]. 1995.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Italy, setting: Secondary care

### **Inclusion criteria**

143 patients with breast cancer treated consecutively with breast conserving surgery between 1984-1994, all of whom had intramammary recurrence.

### **Exclusion criteria**

Patients with no local recurrence.

### **Population**

number of patients = 143, age range 32 to 87 years, mean age = 55 years.

### **Interventions**

All patients received regular clinical examination and mammography as follows:

Clinical examination: 4 monthly for the first two years, 6 monthly up until the 5th year and annually thereafter;

Mammography: annually for the first five years and biennially thereafter.

### **Outcomes**

Means of detection of local recurrence; sensitivity.

### **Follow up**

Mean 3.7 years (reported as disease-free interval)

### **Results**

Of the total of 143 patients, 121 patients underwent mammography and 43 patients underwent US. Adherence to the follow-up protocol was 90%.

Sensitivity of imaging was as follows:

Mammography: 77/121 = 63.6% [95% CI 54.8%-71.7%]

US: 33/43 = 76.7% [95% CI 62.3%-86.9%]

### **General comments**

Study provides no data for patients without local recurrence, hence specificity cannot be calculated.

The sensitivity values reflect repeated imaging procedures, given the mean follow-up period of 3.7 years and adherence rate of 90%.

The protocol for US is not known.

Coulthard, Beveridge & Potterton . MRI in routine breast cancer follow-up: correlation with clinical outcome. Clin Radiol. 54[7]. 1999.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

### **Inclusion criteria**

63 women with breast cancer attending a follow-up clinic between October 1993 and September 1994.

59 patients had complete clinical follow up and are reported in the analysis.

### **Exclusion criteria**

4 patients with incomplete follow-up.

### **Population**

number of patients = 59, age range 30 to 74 years, median age = 54 years.

### **Interventions**

Aim: to evaluate the effectiveness of contrast-enhanced MRI in the follow-up of patients treated for breast cancer.

All patients underwent contrast-enhanced MRI of both breasts.

Patients were considered in two groups:

Patients referred for MRI due to equivocal results of follow-up (possibly suggestive of malignancy) by clinical examination or mammography (equivocal group; n=26);

Patients referred for MRI with no particular suspicion of recurrent disease, and changes on mammography or clinical examination suggestive of scarring etc. (control group; n=33).

### **Outcomes**

Diagnostic performance of MRI.

### **Follow up**

MRI was performed at a median of 55 months since surgery (range 15-144 months).

Median follow-up after MRI: 36 months (range 10-47 months).

### **Results**

In the 'equivocal' group, 2/26 patients experienced distant metastasis that was

detected in follow-up.

There were 4 falsely positive results on MRI in either the ipsilateral or contralateral breast, demonstrated as scarring or benign lesion by biopsy.

In the 'control' group, 1/33 patients experienced distant (pleural) metastasis that was detected by MRI and 3/33 patients experienced ipsilateral breast recurrence that was detected in follow-up.

Therefore with regard to ipsilateral local recurrence only, the diagnostic performance of MRI was as follows:

Sensitivity =  $0/3 = 0\%$  [95% CI 0%-56.1%]

Specificity =  $52/56 = 92.9\%$  [95% CI 83.0%-97.2%]

PPV =  $0/4 = 0\%$  [95% CI 0%-50%]

NPV =  $52/55 = 94.6\%$  [95% CI 85.2%-98.1%].

### **General comments**

Criteria for apparent malignancy on MRI are vague, but appear to be abnormal enhancement.

Reference standard was either histological findings when provided by MRI prompted biopsy, or clinical outcome demonstrated by follow-up annual clinical examination and mammography).

MRI was performed once only, at a median of 55 months since surgery (range 15-144 months). Clinical follow up after MRI was reported at a median of 36 months (range 10-47 months) since MRI, after exposure to possible several further mammographies; and therefore introduces disease progression bias.

Diagnostic outcomes for MRI are based upon small subgroups.

95% CIs provided by spreadsheet available at Cardiff University; Newcombe, (2006):

[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/index.htm](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/index.htm)

Fajardo, Roberts & Hunt . Mammographic surveillance of breast cancer patients: should the mastectomy site be imaged? AJR American Journal of Roentgenology. 161[5]. 1993.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

### **Inclusion criteria**

827 patients treated with mastectomy for breast cancer between 1985 and 1992.

795 patients had unilateral mastectomy and 32 patients had bilateral mastectomy.

80 patients underwent breast reconstruction.

### **Exclusion criteria**

Men (4);

Patients who moved away prior to 1986 (6);

Cases of partial mastectomy (8);

Cases of mastectomy for benign breast disease (20)

Cases of prophylactic mastectomy to the contralateral breast (13).

### **Population**

number of patients = 827, age range 31 to 94 years, mean age = 67 years.

### **Interventions**

Aim: to evaluate the efficacy of routine mammography of the postoperative site in patients treated with mastectomy for breast cancer.

Patients underwent clinical and mammographic surveillance after their breast cancer treatment (frequency not reported).

### **Outcomes**

Method of detection of ipsilateral local recurrence ( with local recurrence defined as that occurring in the ipsilateral chest wall, soft tissues, skin flap or surgical scar).

### **Follow up**

Mean 8 years (range 2-46 years).

### **Results**

Rate of ipsilateral local recurrence after mastectomy:

Of 859 breasts in the study group 39 tumours recurred locally (4.5%) at a mean of 3.5 years from diagnosis (range 2-10 years).

Method of first detection of ipsilateral local recurrence:

Clinical examination:  $35/39 = 89.7\%$

Scintigraphy:  $4/39 = 10.3\%$

Mammography: 0/39 = 0%

In 20 patients with suspicious findings on clinical examination which prompted mammography, mammography detected locally recurrent cancer in 2 patients (10%).

**General comments**

Study does not report the frequency of either mammography or clinical examination, beyond that all patients with local recurrence had received both in the 3 months preceding histological proof of local recurrence.

Study does not report which (if any) of 19 cases of locally recurrent tumours first detected by clinical examination (in addition to the 20 reported) were ALSO visible on mammography.

Johnson, Banerjee & Webster . Mastectomy follow-up by biennial mammograms: is it worthwhile? Breast 9[2]. 2000.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United Kingdom, setting: Secondary care

### **Inclusion criteria**

216 patients treated with mastectomy between 1978-1985.

205 patients were analysed after exclusions.

Patient age not reported.

### **Exclusion criteria**

Patients who underwent previous mastectomy (5);  
Patients who underwent bilateral mastectomy (6).

### **Population**

number of patients = 205.

### **Interventions**

Aim: to assess the efficacy of annual clinical examination and biennial mammography to detect metachronous tumours occurring in the contralateral breast in patients treated for breast cancer with mastectomy.

### **Outcomes**

Rate of metachronous (contralateral) tumours;

Method of detection.

Cost of detecting one case of metachronous, contralateral tumour.

### **Follow up**

Minimum of 12 years.

### **Results**

Rate of metachronous, contralateral tumours:  
 $17/205 = 8.3\%$

Method of detection:

Patient:  $8/17 = 47\%$

Clinical examination:  $4/17 = 24\%$

Routine follow-up mammography:  $5/17 = 29\%$

There was no difference in stage of metachronous tumour by method of detection.

Of 8 patient-detected metachronous tumours, 7 were detected in the second year after the last mammogram.

Median time to detection of metachronous tumour from first operation: 10 years (range 2-16 years).

The cost of detecting one case of metachronous, contralateral tumour = £6500.

**General comments**

Cost estimate was based upon consideration of the cost of out-patient appointments plus mammography.

Kaas, Hart, Besnard, Peterse & Rutgers . Impact of mammographic interval on stage and survival after the diagnosis of contralateral breast cancer. Br J Surg 88[1]. 2001.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Netherlands, the, setting: Secondary care

### **Inclusion criteria**

275 patients with contralateral (metachronous) breast cancer presenting between 1976 AND 1990; 'metachronous' defined as at least 1 year after the first tumour.

Mean age was 52 years at diagnosis of first (ipsilateral) breast cancer and 58 years at diagnosis of contralateral breast cancer.

### **Exclusion criteria**

Patients with unilateral breast cancer;  
Patients with LCIS;  
Patients in whom contralateral cancer was synchronous with distant metastatic disease;  
Patients treated for local recurrence within the preceding two years of detection of contralateral breast cancer.

258 patients were thus excluded from an original series of 581 patients.

48 further patients were excluded due to incomplete data.

### **Population**

number of patients = 275, age range 27 to 95 years.

### **Interventions**

Aim: to investigate the outcome of patients with contralateral breast cancer at different frequencies of follow-up mammography.

Clinical examination was performed as follows:

3 monthly for the first two years;  
6 monthly for the subsequent 3 years;  
Annually thereafter.

Frequency of mammography was variable, and two patient groups were defined using a watershed of a mean of 15 months between mammograms for each individual patient:

Group 1 (n=141): 'Annual mammograms': Women with a mean interval between mammograms of 12 months; mean total of 5.7 mammograms per patient.

Group 2 (n=134): 'Biennial mammograms': Women with a mean interval between mammograms of  $\geq 15$  months.; mean total of 3.4 mammograms per patient.

### **Outcomes**

Method of first detection of contralateral breast cancer; mammography or clinical examination.

Disease specific survival.

### **Follow up**

Median length not reported; 5 year survival reported.

### **Results**

Survival; annual versus biennial mammography:

There was no significant difference in 5-year disease specific survival after contralateral breast cancer between group 1 (75%) and group 2 (75%,  $p=1$ ).

Disease specific survival at 5 years: Mammography detected versus clinically detected contralateral breast cancer:

Mammography: 85%

Clinical examination: 69% ( $p=0.015$ )

When this analysis was stratified by pathological stage of the ipsilateral breast cancer (Cox proportional hazard model), the difference remained statistically significant ( $p=0.015$ ).

In this series of patients (aged 27-95 years) with detected contralateral breast cancer who had available the programme of mammography, clinical examination and self examination, the tumour stage at diagnosis was comparable to that of first breast cancer tumours detected in the Dutch population (aged 50-69 years) by mammography screening programme alone (by looking at the data; no formal analysis).

Proportion of contralateral breast cancers detected by mammography:

All patients:  $109/275 = 39.6\%$

Group 1:  $50/141 = 35.5\%$

Group 2:  $36/134 = 26.9\%$  (no significant difference between the two groups,  $p=0.62$ ).

Detection of contralateral breast cancer by mammography and age (in 185 patients with adequate data available):

Ipsilateral breast cancer: Adjusting for the mammographic results for contralateral breast cancer, patients in whom ipsilateral breast cancer was negative on mammography were a mean of 2 years younger than those with positive result on mammography (ANOVA,  $p=0.0001$ ).

Contralateral breast cancer: Adjusting for the mammographic results for

ipsilateral breast cancer, patients in whom contralateral breast cancer was negative on mammography were a mean of 4 years younger than those with positive result on mammography (ANOVA,  $p=0.03$ ).

The interaction term for these two variables was not statistically significant (ANOVA,  $p=0.84$ ).

**General comments**

Patients in group 1 were statistically significantly younger at the time of diagnosis of ipsilateral breast cancer (mean 51 years and 54 years respectively) and contralateral breast cancer (mean 56 years and 61 years respectively) than patients in group 2 ( $p=0.006$ ).

Lieberman, Morris, Kim, Kaplan, Abramson, Menell, Van Zee & Dershaw . MR Imaging findings in the contralateral breast of women with recently diagnosed breast cancer. Am J Roentgenol. 180[2]. 2003.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

### **Inclusion criteria**

223 patients identified from a series of 1336 breast MRI procedures performed in the years 2000-2001.

Included patients met the following criteria:

Unilateral breast cancer diagnosed in the preceding 6 months of MRI;

Contralateral breast was asymptomatic;

Mammogram undertaken in the preceding 6 months to the MRI showed no evidence of cancer.

36 (16%) patients had pure DCIS as their index cancer.

### **Exclusion criteria**

Defined by inclusion criteria.

### **Population**

number of patients = 223, age range 28 to 79 years, median age = 48 years.

### **Interventions**

Aim: to determine the frequency and positive predictive value of biopsy performed on the basis of MRI in the contralateral breast in women with recently diagnosed breast cancer.

All patients underwent MRI of the contralateral breast. Biopsy was performed in cases classified as suspicious or highly suggestive of malignancy on MRI.

### **Outcomes**

Number of biopsies provoked by MRI;

Positive predictive value of MRI.

### **Follow up**

The median interval between diagnosis of the index cancer and MRI was 27 days (range 0-167 days).

### **Results**

Number of biopsies provoked:

Biopsy of the contralateral breast was recommended due to suspicion of malignancy in 72/223 = 32% of patients, and was performed in 61 patients.

Positive predictive value of MRI:

12/61 = 20% of patients who underwent contralateral breast biopsy were found to have cancer; this represented 12/223 = 5% of patients who underwent MRI. Therefore:  
PPV of MRI: 12/61 = 20%.

Of the 12 patients with contralateral breast cancer, 6 had DCIS and 6 had infiltrating carcinoma.

Stage of contralateral breast cancer was known in 11 patients; stage 0 in 6 patients and stage I in 5 patients.

The interval between diagnosis of index cancer and the contralateral cancer was 38 days (range 12-253 days). In 11 patients (92%) the contralateral cancer was diagnosed within 3 months of the index cancer.

### **General comments**

This study represents detection of contralateral breast cancer close to the time of diagnosis of the index cancer (c.f. 'synchronous?'); 92% of diagnoses were within 3 months. Therefore study may be better considered as one of staging than of true follow-up.

Reference standard to evaluate MRI was biopsy, guided either by US or MRI.

Biopsy was not performed although indicated by MRI in 11 patients due to presence of stage IV disease, patients lost to follow up, patients refusing biopsy, and loss of the lesion on attempting MRI guided biopsy.

Authors offer reasons for low PPV of MRI in this setting:

MRI technique;

Learning curve;

Low threshold for requesting a biopsy based on MRI findings.

Paszat, Grunfeld, van, Coyle, Sawka, Yun, McGahan & Noorani . A Population-based Cohort Study of Surveillance Mammography After Treatment of Primary Breast Cancer. 2007.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Canada, setting: Secondary care

### **Inclusion criteria**

12279 women treated for primary breast cancer between July 1 1991 and December 31 1993, as follows:

Lumpectomy: 19.6%

Lumpectomy plus RT: 41.7%

Mastectomy: 38.7%

### **Exclusion criteria**

Women who received neither mastectomy nor lumpectomy to treat their primary breast cancer (15% of all registered cases).

### **Population**

number of patients = 12279, mean age = 61 years.

### **Interventions**

Aims:

1. To describe the rates of use of annual surveillance mammography following the treatment of primary breast cancer in Ontario.
2. To describe the rates of use of subsequent breast surgery following annual surveillance mammography.

Ontario cancer registry data for all patients treated within the study period were linked to data from the following sources:

1. Ontario Cancer Registry
2. Canadian Institute for Health Information
3. Radiation Oncology Research Unit at Queen's University at Kingston
4. Ontario Health Insurance Plan
5. 1991 Canadian Census

### **Outcomes**

Data were collected up to December 31, 1998 for:

1. Surveillance mammography
2. Subsequent diagnostic procedures on the breast
3. Subsequent breast surgery
4. Death from any cause.

Outcomes are commonly reported by primary treatment group:  
Lumpectomy versus Lumpectomy plus RT versus Mastectomy.

**Follow up**

60 months from diagnosis of breast cancer.

**Results**

Overall survival:

Overall survival at 60 months following diagnosis of breast cancer: 82.7%.

Interval between surveillance mammographies:

Median: 14.7 months, mean 16.4 months.

Use of surveillance mammography:

Women diagnosed at age 70 or older, and women treated by lumpectomy without radiation therapy (RT) were less likely to use surveillance mammography compared to other women treated for breast cancer ( $p < 0.001$ ).

Relationship between surveillance mammography and further surgical procedures:

Two-thirds of subsequent breast surgery performed for women previously treated for breast cancer occurred more than four months following surveillance mammography (suggesting that surveillance mammography does not detect all recurrences in the breast, or all new primary contralateral breast cancers).

**General comments**

Study does not analyse survival according to uptake of surveillance mammography.

In the group treated initially by mastectomy, authors assume that mastectomy/lumpectomy represent the treatment of contralateral primary breast cancer. However, among women initially treated by lumpectomy, ipsilateral lumpectomies can not be distinguished from contralateral lumpectomies and mastectomies. Therefore, no estimate may be made of the proportion of women having ipsilateral breast recurrences or contralateral primary breast cancers following initial lumpectomy.

Surgical procedures occurring within 4 months of a surveillance mammogram were assumed to be prompted by surveillance mammography. Surgical procedures occurring 4 months or more after a surveillance mammogram were assumed to be prompted by clinical examination and/or symptoms, rather than by surveillance mammography.

Preda, Villa, Rizzo, Bazzi, Origgi, Cassano & Bellomi . Magnetic resonance mammography in the evaluation of recurrence at the prior lumpectomy site after conservative surgery and radiotherapy. Breast Cancer Research 8[5]. 2006.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Italy, setting: Secondary care

### **Inclusion criteria**

93 female patients who underwent MRI to investigate suspected local recurrence of breast cancer between April 1999 and July 2003. All patients previously underwent breast conserving surgery and a minimum of 6 months had elapsed since any radiotherapy treatment.

### **Exclusion criteria**

-

### **Population**

number of patients = 93, age range 40 to 72 years, mean age = 53 years.

### **Interventions**

Aim: to investigate the role of MRI in imaging suspected local recurrence of breast cancer.

All 93 patients with suspected local recurrence of breast cancer underwent contrast enhanced MRI of the breast

### **Outcomes**

Sensitivity, specificity, PPV, NPV of MRI with regard to:  
Detection of recurrent cancer in the surgical scar;  
Detection of all lesions, including those that are incidental and not in contact with the surgical scar.

### **Follow up**

36 months (range 12-48 months).

### **Results**

Performance of MRI (lesions at the surgical scar site):

Sensitivity =  $9/10 = 90\%$  [95% CI 60%-98%]

Specificity =  $76/83 = 92\%$  [95% CI 84%-96%]

PPV =  $9/16 = 56\%$  [95% CI 33%-77%]

NPV =  $76/77 = 99\%$  [95% CI 93%-100%]

13 incidental lesions not in contact with the surgical scar were identified by MRI, in 7 patients. These lesions were true positive (6), true negative (5), false positive (2) and false negative (0).

Performance of MRI: all lesions, including those that are incidental and not in contact with the surgical scar:

Sensitivity = 15/16 = 94% [95% CI 72%-99%]

Specificity = 81/90 = 90% [95% CI 82%-95%]

PPV = 15/24 = 63% [95% CI 43%-79%]

NPV = 81/82 = 99% [95% CI 93%-100%]

### **General comments**

In all patients the grounds for suspicion of local recurrence was the result of either mammography and/or US imaging, therefore we could expect a high prevalence of recurrent disease.

MRI results were interpreted by a radiologist who was aware of the mammographic and US findings.

MRI findings were classified as malignant or benign based on combined morphologic and time-signal intensity criteria: a multifactorial score was derived, with a score of 0-3 classed as benign and 4-8 as malignant. This score was mapped to the American College of Radiology classification:

BI-RADS I: negative; score 0-1

BI-RADS II: benign; score 2

BI-RADS III: probably benign; score 3

BI-RADS IV: suspicious; score 4-5

BI-RADS V: malignancy highly likely; score 6-8

Reference standard: histological findings where biopsy was performed (29 patients) ; clinical course of disease over 36 months' follow-up (using mammography and/or US; 64 patients) if no biopsy was performed. Use of two reference standards is unavoidable in this setting but may introduce differential verification bias, and in the case of follow-up, disease progression bias.

Shin, Han, Choe, Nam, Park & Im . Ultrasonographic detection of occult cancer in patients after surgical therapy for breast cancer. J Ultrasound Med 24[5]. 2005.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Korea (South), setting: Secondary care

### **Inclusion criteria**

1968 women who underwent breast US during follow-up after treatment for breast cancer. Treatment for breast cancer was either modified radical mastectomy or breast conserving surgery plus RT. Chemotherapy was given for all invasive ductal carcinomas >1cm in size.

### **Exclusion criteria**

Some data missing for four patients who received their primary treatment at outside institutions.

### **Population**

number of patients = 1968, age range 32 to 67 years, mean age = 49 years.

### **Interventions**

Aim: to investigate the effectiveness of breast US in the follow-up of patients treated for breast cancer.

Patients received clinical examination every 3 months for the first 2-3 years following diagnosis, with bilateral US of the breast, chest wall, axilla, parasternal and supraclavicular regions performed at intervals of 6 months or more.

### **Outcomes**

Local recurrence

Contralateral, metachronous (defined as detected >6 months after initial diagnosis with no evidence of distant metastasis) breast tumours.

### **Follow up**

Not reported directly; mean post-operative duration to recurrence was 3 years (range 8-108 months).

### **Results**

Diagnostic performance of US with regard to occult tumour (recurrence in the breast, adjacent node bearing areas, mastectomy bed and contralateral breast cancer) was as follows:

Sensitivity =  $24/34 = 70.6\%$  [95% CI 53.8%-83.2%]

Specificity =  $1901/1934 = 98.3\%$  [95% CI 97.6%-98.8%]

PPV = 24/57 = 42.1% [95% CI 30.2%-55.0%]  
NPV = 1901/1911 = 99.5% [95% CI 99.0%-99.7%]

**General comments**

Criteria for malignant tumour on US were based on the American College of Radiology Breast Imaging Reporting and Data System assessment categories 4 (suspicious abnormality) and 5 (suggestive of malignancy).

Reference standard was FNAC or core biopsy, performed under US guidance, but only where initial US result scored 4 or 5 as above. In all other cases reference standard was the documented course of disease observed in follow-up and utilising information from subsequent imaging (mammography, CT, PET) and clinical examination.

A total of 3329 US procedures were performed, therefore some patients received only ipsilateral US.

95% CIs provided by spreadsheet available at Cardiff University; Newcombe, (2006):  
[http://www.cardiff.ac.uk/medicine/epidemiology\\_statistics/research/statistics/newcombe/proportions/index.htm](http://www.cardiff.ac.uk/medicine/epidemiology_statistics/research/statistics/newcombe/proportions/index.htm)

Viehweg, Heinig, Lampe, Buchmann & Heywang-Kobrunner . Retrospective analysis for evaluation of the value of contrast-enhanced MRI in patients treated with breast conservative therapy. MAGMA. 7[3]. 1998.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: Germany, setting: Secondary care

### **Inclusion criteria**

207 contrast-enhanced MRI procedures performed in 166 patients treated for breast cancer in the years 1988-1995. All patients had previously undergone breast conserving surgery and RT.

80 MRI procedures followed mammogram results that were indeterminate or suspicious for local recurrence.

127 MRI procedures were performed because breast tissue was difficult to evaluate due to high density, scarring or fibrosis.

### **Exclusion criteria**

3 patients who were either lost to follow-up or died of distant metastases;  
2 patients who died of other causes than cancer.

### **Population**

number of patients = 166, age range 30 to 77 years, mean age = 55 years.

### **Interventions**

Aim: to evaluate the role of MRI in detecting local recurrence in patients who underwent breast conserving surgery plus RT.

Patients underwent contrast-enhanced MRI.

### **Outcomes**

Diagnostic performance of MRI, utilising all previous imaging information and presented as follows:

For patients in whom MRI was performed  $\leq 12$  months from RT;

For patients in whom MRI was performed  $> 12$  months from RT.

### **Follow up**

Minimum 2 years.

### **Results**

MRI procedures performed up to 12 months since RT (40 procedures):

The additional use of contrast-enhanced MRI changed the overall diagnosis in 6 of 40 procedures performed (15%).

Sensitivity =  $1/1 = 100\%$  [95% CI 20.7%-100%]

Specificity =  $29/39 = 74.4\%$  [95% CI 59.0%-85.4%]

PPV = 1/11 = 9.1% [95% CI 1.6%-37.7%]  
NPV = 29/29 = 100% [95% CI 88.3%-100%]

MRI procedures performed >12 months since RT (167 procedures):

The additional use of contrast-enhanced MRI changed the overall diagnosis in 49 of 167 procedures performed (29.3%).

Sensitivity = 26/26 = 100% [95% CI 87.1%-100%]  
Specificity = 129/141 = 91.5% [95% CI 85.7%-95.1%]  
PPV = 26/38 = 68.4% [95% CI 52.5%-80.9%]  
NPV = 129/129 = 100% [95% CI 97.1%-100%]

Values for all 207 procedures:

Sensitivity = 27/27 = 100% [95% CI 87.5%-100%]  
Specificity = 158/180 = 87.8% [95% CI 82.2%-91.8%]  
PPV = 27/49 = 55.1% [95% CI 41.3%-68.2%]  
NPV = 158/158 = 100% [95% CI 97.6%-100%]

### **General comments**

The interval from primary treatment to MRI varied from 1 month to >99 months.

29 patients were examined on two or more occasions.

Criteria for malignancy on contrast-enhanced MRI were based upon lesion distribution, shape and internal structure, using pre and post-contrast images and with access to previous conventional imaging studies; all cases where MRI provoked a confirmatory biopsy were classed as positive.

The outcome values for the 40 procedures within 12 months of radiotherapy are hampered by small numbers.

Reference standard was biopsy where prompted by findings of MRI, or else a minimum of two years' follow up. This may lead to disease progression bias (unlikely to be important in this study due to zero false negative results on MRI) and differential verification bias.

## **Evidence Tables – DCIS**

### **Retrospective case series**

Liberman, Van Zee, Dershaw, Morris, Abramson & Samli . Mammographic features of local recurrence in women who have undergone breast-conserving therapy for ductal carcinoma in situ. AJR American Journal of Roentgenology. 168[2]. 1997.

### **Design**

Design: Retrospective case series (diagnosis, screening), evidence level: 3  
Country: United States, setting: Secondary care

### **Inclusion criteria**

20 patients treated for DCIS with breast conserving surgery between 1972 and 1990 at a single centre who:

- a) experienced histologically proven local recurrence;
- b) had mammograms available for the time of detection of the local recurrence.

Selected patients were identified from a larger series of 172 patients treated during this period.

### **Exclusion criteria**

See inclusion criteria.

### **Population**

Number of patients = 20, age range 20 to 89 years, median age = 60 years.

### **Interventions**

Patients underwent breast conserving surgery to treat initial DCIS; 40% underwent RT in addition.

Authors performed retrospective review of mammographies taken at the time of breast cancer recurrence, clinical charts and histopathologic findings.

### **Outcomes**

Method of detection of recurrent breast cancer.

### **Follow up**

Median 75 months (range 3-210 months).

### **Results**

In 20 women with locally recurrent breast cancer after DCIS, the method of detection of the local recurrence was as follows:

Mammography: 17 (85%)

Mammography and physical examination: 2 (10%)

Physical examination: 1 (5%).

In 13/20 women, recurrent lesions were pure DCIS. Of these 12/13 = 92% were detected solely by mammography.

### **General comments**

The 20 patients are highly selected. In all cases recurrent breast cancer was histologically proven. The protocol for follow-up mammography was not reported. Re: reported results, retrospective selection of patients with mammograms available is not as good a study design as prospective follow-up mammography plus clinical examination. For example this study design cannot demonstrate false positive rate of mammography.

Weng, Juillard, Parker, Chang & Gornbein . Outcomes and factors impacting local recurrence of ductal carcinoma in situ.[see comment]. Cancer 88[7]. 2000.

### **Design**

Design: Retrospective case series (therapy), evidence level: 3  
Country: United States, setting: Secondary care

### **Inclusion criteria**

88 cases of pure DCIS in 85 patients, identified retrospectively as a consecutive case series.

### **Exclusion criteria**

Not reported.

### **Population**

Number of patients = 85, age range 28 to 81 years, median age = 55 years.

### **Interventions**

Aims:

1. To examine survival and recurrence rates in patients treated for DCIS by mastectomy versus breast conserving surgery plus RT versus breast conserving surgery alone.
2. To analyse risk factors for local recurrence.

Patients were followed-up as follows:

Physical examination every 3 months for 2 years, then every 6 months for 2 years, then annually thereafter.

Where RT was given: baseline mammography 6-8 weeks after treatment.

Biannual mammography on the treated side for 2 years then annually thereafter.

Annual mammography on the contralateral side.

### **Outcomes**

Recurrence-free survival

Risk factors for local recurrence

[NB Only the method of detection of local recurrence is cited]

### **Follow up**

Mean 95.9 months, median 99 months, range 1-160 months.

### **Results**

Local recurrence occurred in 12 of 88 cases (13.6%).

Method of detection of local recurrence included:

Mammography: 9 cases (75%)

Palpable mass or lymphadenopathy: 2 cases (16.7%)  
Incidental detection at time of cosmetic surgery: 1 case (8.3%).

**General comments**

Local recurrence defined as biopsy-proven tumour anywhere in the previously treated breast.

### **Health Economics Summary**

A joint literature review was performed to assess, on one hand, the cost-effectiveness of breast imaging modalities (i.e. mammography, ultrasound (US), magnetic resonance imaging (MRI), mammoscintigraphy and PET / CT) in the follow up of patients with invasive breast cancer, and on the other hand, to assess the cost-effectiveness of mammography, US and MRI in the follow up of patients with DCIS. From 347 references initially identified through the search, 333 were excluded on the grounds of the title and abstract, and 14 references were considered further. All the retrieved papers were finally excluded: 4 studies did not include an economic analysis (Emens et al 2003; Grilli 1995; Khandekar 1996; Sakorafas et al 2000), 1 did not consider the relevant PICO question (Mould 2004), 3 did not consider the relevant PICO interventions (Coleman et al 1990; Mapelli et al 1995; Schapira et al 1991), 1 did not consider the relevant PICO comparator (Mandelblatt et al 2006) and 1 was written in a foreign language (Lamy 2005). Therefore, no evidence was found to assess the cost-effectiveness of breast imaging modalities in the follow up of invasive breast cancer patients and in patients with DCIS so no further economic modelling was undertaken.

## **9.2 What is the role of follow-up in patients who have been treated for breast cancer?**

### **Short Summary**

There is a reasonable volume of evidence available that is related to follow-up of patients with breast cancer. A systematic review of mixed study design (Collins *et al.* 2004) found that most patients expressed a preference for attending regular follow-up sessions, even when asymptomatic. Although patients reported that the anticipation of attending these routine sessions was provoked anxiety, reduced fear of recurrence and less physical and psychological distress was experienced after attending their routine visit. A report on follow-up of a UK breast cancer charity focus group (Breakthrough 2007) concluded that patients should be given the information and support they need if they want to consider opting out of follow-up care.

With respect to optimal frequency of follow-up, one systematic review of RCTs concluded that the available trials are unable to indicate an ideal frequency of follow-up (Montgomery *et al.* 2007). However the review cited trials that suggest that detection of recurrence is not affected by 3 monthly versus 6 monthly follow up, nor by scheduled follow-up versus that available to patients on demand.

A Cochrane review (Rojas *et al.* 2000) found no statistically significant difference in 5 year overall survival arising from routine follow-up versus intensive (increased frequency and testing) follow up regimens.

With respect to evidence about where should follow-up should take place and who should perform follow-up, one systematic reviews of RCTs concluded that traditional routine clinic visits are an inefficient method of safeguarding against recurrent disease; with no difference in either total recurrences detected in hospital, versus by the GP was reported, or in serious clinical events, or total number of deaths (Montgomery *et al.* 2007). There was also no evidence for a difference in either the total number of recurrences detected, or overall survival, when follow-up is performed by a doctor, compared to a breast care nurse specialist (Montgomery *et al.* 2007). RCT evidence indicated that patient satisfaction is higher in patients followed up by nurses than in those followed up by doctors, but that quality of life is similar.

Evidence from qualitative studies also provided insight into the topic of effective follow up care for patients who had been treated for breast cancer. These studies broadly described that checking for recurrence; offering reassurance and providing information were key elements required in follow up care (Adewuyi-Dalton *et al.* 1998; Beaver *et al.* 2005; Jiwa *et al.* 2006; Kelly *et al.* 2006; Renton *et al.* 2002; Vanhuyse *et al.* 2007).

This PICO table was used to generate the search strategy used to search the literature for this question, see Appendix A

### Evidence Summary

There is a reasonable volume of evidence available that is related to follow-up of patients with breast cancer, including two systematic reviews of RCTs, one update to an RCT and two observational studies.

A framework was developed to select studies that provide information to answer the following broadly-defined questions:

- Should follow-up be performed?
- Is there an optimal frequency of follow-up?
- Where should follow-up take place?
- Who should perform follow-up?
- What should be the aims of follow-up?

Inconsistency exists between the comparisons made in the primary studies (Table 1). However there is generally no conflict of results; the randomised trials found no difference for most outcomes arising from different follow-up strategies. Some differences, arising in the original RCTs, are highlighted by papers, but these differences were lost when pooled or when examined with longer study follow-up.

Health economic data were excluded; randomised studies exist of health economic outcomes arising from different follow-up strategies.

A systematic review of mixed study design (Collins *et al.* 2004) found that most patients expressed a preference for attending regular follow-up sessions, even when asymptomatic.

One systematic review of RCTs concluded that the available trials are unable to indicate an ideal frequency of follow-up

Table 1: follow-up strategies evaluated

<b>Study</b>	<b>Design</b>	<b>Comparison</b>	<b>Follow-up schedule</b>
Grunfeld 1996*	RCT	Follow-up in general practice vs. hospital.	3 monthly clinical exam and history during the first year, 6 monthly for 4 years, then annual in one hospital, with three monthly first year, 4 monthly second year, 6 monthly for 5 years and then annual in the other. General practice group as per hospital of diagnosis. One to two yearly mammograms.
Gulliford 1997*	RCT	Frequent follow-up vs. annual follow-up.	3 monthly clinical exam and history during the first year, 4 monthly second year, 6 monthly for 5 years and then annual. One to two yearly mammogram, depending on whether BCT or mastectomy in the control group, annual clinical exam, history and mammogram in the trial group.
Brown 2002*	RCT	Traditional clinic follow-up vs. patient-initiated follow-up.	4-6 monthly clinical exam and history for the first 5 years then annual in control group vs. on request only in the study group. Annual mammograms in both.
Koinberg 2004*	RCT	Traditional clinic follow-up vs. on demand follow-up coordinated by a breast care nurse.	3 monthly clinical exam and history for 2 years, 6 monthly for three years then annual for 5 years and annual mammogram in the traditional follow-up group, with appointments on demand only and annual mammograms in the nurse led follow up group.
Baildam 2004*	RCT	Standard follow-up by hospital doctors vs. specially trained nurses.	Not given, but identical for both arms.
Kokko 2005*	RCT	3 monthly vs. 6 monthly follow up (and of intensive vs. as required investigations).	3 monthly vs. 6 monthly clinical examination and history.
Grunfeld 2006*	RCT	Follow-up by hospital Dr vs. follow-up by GP.	3-6 monthly for 3 years, 6 monthly for 2 years then annual, with annual mammogram.
Koinberg 2006	Prospective study	Multidisciplinary education programme vs. traditional follow-up	4 educational sessions in 4 weeks between 2-6 months following surgery, then on demand access vs. clinical exam twice a year for two years then annually until the fifth year.

Breakthrough Breast cancer 2007	Focus group report	None, specifically	None
---------------------------------	--------------------	--------------------	------

Note: \* denotes data reproduced from Montgomery *et al.* 2007.

### Should follow-up be performed?

No RCTs were identified of patients who received no follow-up of any sort.

A systematic review of mixed study design (Collins *et al.* 2004) found that most patients expressed a preference for attending regular follow-up sessions, even when asymptomatic. Although patients reported that the anticipation of attending these routine sessions was anxiety provoking, reduced fear of recurrence and less physical and psychological distress was experienced after attending their routine visit.

A report on follow-up of a UK breast cancer charity focus group (Breakthrough 2007) concluded that Patients should be given the information and support they need if they want to consider opting out of follow-up care.

### Is there an optimal frequency of follow-up?

One systematic review of RCTs concluded that the available trials are unable to indicate an ideal frequency of follow-up (Montgomery *et al.* 2007). However the review cited trials that suggest that detection of recurrence is not affected by 3-monthly versus 6-monthly follow up, nor by scheduled follow-up versus that available to patients on demand. There was also no difference in patient satisfaction and quality of life arising from scheduled versus 'on demand' follow-up (Montgomery *et al.* 2007).

The earlier Cochrane review of RCTs (Rojas *et al.* ) found no statistically significant difference in 5-year overall survival arising from routine follow-up versus intensive (increased frequency and testing) follow up regimens. This was based on pooled data from two RCTs<sup>u</sup> and there was also no statistically significant difference arising from the two follow-up strategies in subgroup analyses for patient age, tumour stage and nodal status (Rojas *et al.* ).

A later update to one RCT included in the Cochrane review reported no difference in estimated 10-year mortality between patient groups who received either intensive follow-up (increased frequency and testing) or standard clinical follow-up (physical examination and mammography) (Palli *et al.* 1999).

A systematic review of mixed study design found that there is little, and conflicting evidence for an ideal frequency of follow-up (Collins *et al.* 2004). Some included sources suggested that the frequency and length of the follow-up service should be tailored to meet the needs of individual patients. On the other hand, one study found evidence that patients had twice as many follow-up visits than as recommended in UK guidelines.

---

<sup>u</sup> GIVIO trial, and Rosselli Del Turco trial.

### **Where should follow-up take place? Who should perform follow-up?**

One systematic reviews of RCTs concluded that traditional routine clinic visits are an inefficient method of safeguarding against recurrent disease; with no difference in either total recurrences detected in hospital, versus by the GP, or in serious clinical events, or total number of deaths (Montgomery *et al.* 2007). There was also no evidence for a difference in either the total number of recurrences detected, or overall survival, when follow-up is performed by a doctor, compared to a breast care nurse (Montgomery *et al.* 2007). RCT evidence indicated that patient satisfaction is higher in patients followed up by nurses than in those followed up by doctors, but that quality of life is similar.

The earlier systematic review of RCTs (Rojas *et al.* ) also cited a secondary paper for one trial<sup>v</sup>, using published data only; this paper was not included by Montgomery *et al.* (2007), although a different publication for the trial was used. Rojas *et al.* report that questionnaire data from Grunfeld *et al.* (1999) indicated that patients were more satisfied with service delivery, consultation and the continuity of care provided by their GP than by a specialist.

A non-randomised prospective study (Koinberg *et al.* 2006) compared quality of life in patients who received follow up consisting of regular physician examinations, compared to patients who received a multidisciplinary education programme of 4 sessions over 4 weeks, between 2-6 months from surgery; thereafter patients could access their specialist by telephoning a nurse. The multidisciplinary educational programme was associated with similar quality of life outcomes as traditional follow-up, as measured on three scales for well-being, self-care and coping ability. The authors concluded that the programme could be an alternative to traditional follow-up.

### **What should be the aims of follow-up?**

A systematic review of mixed study design (12 predominantly non-randomised studies studies; 5045 patients) provided a pooled (weighted) estimate of the proportion of isolated locoregional recurrences diagnosed in asymptomatic patients by routine follow-up (de Bock *et al.* 2004). This proportion was 40% (95% CI 35%-40%).

A report on follow-up of a UK breast cancer charity focus group (Breakthrough 2007) stated the aims of follow-up as:

- Surveillance of ongoing treatment;
- Access to new treatments;
- Surveillance and management of chronic/long term side effects (which can emerge after 5-10 years after initial diagnosis);
- Surveillance and management of short-term side effects of treatment;
- Psychosocial welfare;
- Reassurance;
- Feeling that patient can easily access care when needed;

---

<sup>v</sup> Grunfeld *et al.* (1999) Comparison of breast cancer patient satisfaction with follow-up in primary care vs specialist care: results from a randomised controlled trial. *British Journal of Clinical Practice* 1999; 49:705-710.

- Long term, wider assessment including the needs of other family members;
- Monitoring of general health and being asked about well being;
- Access to breast reconstruction;
- Prosthesis fitting and advice;
- Fast track to an oncologist if anything is wrong.

**Evidence from qualitative studies:**

Beaver *et al.* (2005) examined the nature and content of interactions between patients attending hospital outpatients departments for routine follow-up following completed breast cancer treatment and health care professionals. Through qualitative methods, the study reported that follow-up visits appeared to consist of three primary components: checking for recurrence, offering reassurance and providing information. All consultations involved a clinical examination of the breast and surrounding areas and the extent of examination varied depending on who was conducting the exam. Patients did not have much concern on reducing visits from 3 to 6 months, however changing from 6 to 12 months and/or discharge was a considered a bigger step and created anxieties for some who seemed to depend on follow-up visits to detect recurrent disease. Clinic nurses were active in clarifying information despite having limited time available to meet the information needs of patients. Health care professionals indicated that the primary function of follow-up was to detect recurrent disease however were of the opinion that clinical examination at follow-up was highly unlikely to detect recurrent disease in asymptomatic women. Health care professionals did perceive that patients were reassured by the clinical examinations, despite the low rate of detection of recurrence. Health care professionals felt that the provision of information was an important part of follow-up, however admitted that they found it difficult to provide information to the patients in the time available. Doctors said that patients would have to be proactive and assertive in requesting information as they did not always encourage patients to ask questions.

Jiwa *et al.* (2006) conducted focus groups with patients attending a medical oncology follow-up and surgical follow-up clinics. The study aimed to identify the elements of a follow-up protocol for treated breast cancer patients in primary care, with reference to key stakeholders by determining the type of problem commonly documented during the follow-up of breast cancer patients and identification of the type of resources used. The study reported that the most frequent problems to arise related to anxiety and unrelated medical problems such as joint pain and menopausal symptoms. The main themes to emerge from the focus groups related to patient, disease, doctor and/or process. Results from the nominal discussion outlined the essential elements of a model of primary care follow-up as identified by the majority of the group. The discussions suggested that a formal 'handover' of patients from secondary care following a 'discharge' visit where the specialist would outline the case for withdrawing specialist involvement. The patient, if agreeable, would be discharged to the care of her GP who would receive a detailed summary of the patient's progress to date. A clear indication of when and how access to specialist care could be obtained in the event of future concerns

about a possible recurrence would be provided. The patient would have access to the breast care nurse and breast cancer support group and the breast care nurse would be able to refer patients to a surgeon or oncologist directly. The data suggest that the psychosocial needs of patients need to be taken into account when offering follow-up treatment and suggest that the needs of patients and their families, regarding the fear of recurrence, are not being met

Kelly *et al.* (2006) conducted focus groups to identify the priority issues of follow-up from the patient perspective. The primary reason given by patients for attending follow-up was for reassurance that the cancer had not returned. Participants also wanted information on new treatments and further tests. Key themes to emerge from the focus group interview were: the need for reassurance; continuity of care; privacy and dignity; information and detection of new symptoms and opportunities to discuss feelings and worries.

Renton *et al.* (2002) conducted study that used questionnaires to define patients' views on follow-up and to develop optimal breast cancer follow-up arrangements which meet the needs of women and make efficient use of available resources. The study reported that in general women appeared to be satisfied with current follow-up however they were open to changes to the current set-up. Women reported a number of factors that they felt were important to discuss during follow-up such as risk of recurrence or risk to daughters, the follow-up visits appear to be effective in alleviating the concerns and worries of the majority of women. Women appeared to have more confidence in specialist nurses compared to their own GP suggesting that a nurse-led model of follow-up may be a way forward. Continuity of care was a factor which was deemed to be important.

Vanhuyse *et al* (2007) reported the feasibility of patients transferring care back to the family physician for follow-up. This study used questionnaires and showed that it may be feasible to transfer follow-up care to the family physicians/GP's however there were many factors which remain to be addressed before this could happen including cost effectiveness, willingness and ability of family physicians/GP's to take on these patients, provision of resources, optimal timing for transfer and patient considerations.

Adewuyi-Dalton *et al.*(1998), identified views of women who took part in a randomised clinical trial comparing GP follow-up with out-patient follow-up were invited to take part if they were in the out-patient arm of the trial. The study reported that Continuity of Care; Access to Specialist Care; Quality of Consultation were main areas that women were affected by most significantly.

## Evidence Tables

### Systematic review of RCTs

Montgomery, Krupa & Cooke . Alternative methods of follow up in breast cancer: a systematic review of the literature. *Br.J.Cancer* 96[11], 1625-1632. 2007.

#### Design

Design: Systematic review of RCTs (other), evidence level: 1+  
Country: Various, setting: Other

#### Inclusion criteria

Applied to studies as follows:

- i) included patients treated for primary operable breast cancer; free of distant metastases at the time of initial treatment;
- ii) RCT comparing routine clinical mammographic follow-up (NICE 2002 guideline cited) versus alternative; or comparing different frequencies or durations of clinical follow-up.

Blinding was not considered necessary for inclusion.

#### Exclusion criteria

Defined by inclusion criteria

#### Population

-

#### Interventions

Aim: to review RCT evidence for different follow-up strategies, and to examine whether RCTs are suggestive of an ideal length or schedule of follow-up.

Comparisons in primary RCTs were as follows:

- i) Follow-up in hospital clinics versus that performed by GP (2 RCTs);
- ii) Traditional follow-up versus follow-up 'on demand' i.e. by contacting a breast care nurse (2 RCTs);
- iii) Routine follow-up by doctors versus routine follow-up by breast care nurses

(1 RCT);

iv) Different follow-up frequencies within a traditional follow-up framework (2 RCTs).

### **Outcomes**

Detection of recurrence

Adverse clinical events

Survival

Patient satisfaction

Quality of life, assessed using using validated tools as follows:

Hospital anxiety and depression scale (HADS); 5 RCTs;

EORTC QLQ-C30 and BR23 scale; 2 RCTs;

Medical outcomes short form SF-36 survey; 2 RCTs.

Economic analysis/workload concerns

### **Follow up**

Grunfeld 1996: 18 months

Gulliford 1997: 16 months

Brown 2002: 12 months

Koinberg 2004: 5 years

Baildam 2004: not reported

Kokko 2005: 4.2 years

Grunfeld 2006: 4.5 years

### **Results**

#### **DETECTION OF RECURRENCE**

The number of total recurrences detected did not vary by frequency of traditional follow-up: 3-monthly vs. 6 monthly (Kokko et al. 2005).

The number of total recurrences detected did not vary according to whether follow-up was performed by doctor vs. a breast care nurse (Baildam et al. 2004).

There was no statistically significant difference in the number of recurrences detected by nurses by 'on demand' follow-up vs. by routine visits (Koinberg et al. 2004). There was also no difference in time to event for locoregional recurrence, distant metastasis or death (Koinberg et al. 2004).

There was no statistically significant difference in the number of recurrences detected in hospital follow-up (13) vs. GP follow-up (6); difference 4.7% (95% CI -0.8% to 10.3%; Grunfeld et al. 1996). A latter trial conducted by the same team again found no statistically significant difference in the number of recurrences detected by hospital follow-up (13.2%) vs. GP follow-up (11.2%);

difference 2.02%, (95% CI -2.13 to 6.16%; Grunfeld et al. 2006).

#### ADVERSE CLINICAL EVENTS

There was no statistically significant difference in the rate of serious clinical events related to recurrence (e.g. spinal cord compression) between hospital-based and GP-performed follow-up: 3.7% vs. 3.5% respectively; difference 0.19% (95% CI -2.26% to 2.65%; Grunfeld et al. 2006).

#### SURVIVAL

There was no difference either in the absolute number of deaths, or in estimated overall survival in patients followed up by doctors vs. patients followed up by breast care nurses (Koinberg et al. 2004).

One RCT by Grunfeld et al. (2006) studied 968 patients and found little difference in the absolute number of deaths in patients who received hospital follow-up (30) vs. those who received GP follow up (29).

#### PATIENT SATISFACTION

The proportion of patients who were willing to enter 5 of the 7 RCTs reporting this outcome had mean 68.5%, median 66.5% and range 50%-93%.

Two RCTs found no difference in patient satisfaction associated with traditional follow-up versus follow-up 'on demand' i.e. by contacting a breast care nurse. Both trials reported high levels of patient satisfaction in both randomised groups (Brown et al. 2002; Koinberg et al. 2004). In the RCT by Brown et al. (2002) more women in the routine follow up group described the routine visits as reassuring ( $p < 0.0001$ ) whereas more women in the on-demand follow-up group reported this method as convenient ( $p < 0.0001$ ).

1 RCT found that follow-up frequency may be reduced from standard frequency without loss of patient satisfaction. In the same trial equal numbers of patients in the higher and lower frequency follow-up groups expressed a desire for less-frequent or more frequent visits, respectively (Gulliford et al. 1997).

1 RCT found that patient satisfaction, when measured using the Fallowfield Satisfaction with Consultation Questionnaire, was statistically significantly higher in patients followed up by nurses than in those followed up by doctors, with  $p < 0.001$  (Baildam et al. 2004).

#### QUALITY OF LIFE

5 RCTs examined quality of life. No trial found any difference in quality of life arising from randomised comparisons as follows:

Routine follow-up by doctors versus routine follow-up by breast care nurses;  
Traditional follow-up versus follow-up 'on demand' i.e. by contacting a breast care nurse;

Follow-up in hospital clinics versus that performed by GP.

#### AUTHORS' CONCLUSIONS

No RCT was identified with sufficient power to recommend an ideal frequency or duration of follow-up; No RCT to date can confirm the safety of alternative follow-up methods.

Traditional routine clinic visits are an inefficient method of safeguarding against recurrent disease; there is doubt as to whether they are the ideal setting in which to provide patients with psychological support.

#### **General comments**

In this systematic review, conducted in the UK, 'traditional follow' up is applicable to the UK; based upon NICE (2002) guidelines, and consisting of mammography, history taking and clinical examination.

Methods are well-described. Literature search performed on MEDLINE, EMBASE, EBM reviews, Cancerlit and Web of Science databases. Three literature search strategies included.

Literature reviewed to May 2006.

Study selection, data extraction and quality assessment performed independently by two reviewers, with subsequent resolution.

Assessment of study quality well-reported: 13 point checklist completed for each study which considered reporting of patient population; primary therapy; power calculation and sample size; differences between participants and non-participants; duration of follow-up (>5 years considered as important); loss to follow-up; description of interventions (follow-up schedule); use of objective, validated outcome measures; prospective assessment of outcome; publication in a peer-reviewed journal.

Cited information/data are as reported in the review; numbers, statistics, confidence intervals and p values were not always cited in the review.

#### **METHODOLOGICAL QUALITY OF THE RCTs**

Methodological quality of the 7 RCTs was generally high. Of a possible highest score of 13 on the quality checklist the mean score was 8.7. Excluding one study presented in abstract only (Baildam et al. 2004) the mean quality score was 10.7. The main drawback with the RCTs was inadequate size and follow-up duration. For this reason this well-conducted systematic review is graded as 1+.

Rojas, Telaro, Russo, Moschetti, Coe, Fossati, Palli, Roselli del & Liberati .  
Follow-up strategies for women treated for early breast cancer. Cochrane  
Database of Systematic Reviews: Reviews. 2000.;(4): [4], .

### **Design**

Design: Systematic review of RCTs (other), evidence level: 1+  
Country: Cochrane Review, setting: Other

### **Inclusion criteria**

All randomised controlled trials comparing different approaches to follow-up after completion of primary treatment. Additional information was extracted and reviewed from prospective non-randomised studies but was not used for quantitative pooling.

Primary study participants: women who have had primary surgical treatment for breast cancer (clinical stage I, II or III), with no evidence of recurrence.

Four studies met the inclusion criteria. All of them are multicentre randomised controlled trials comparing different types of follow-up in breast cancer patients. Overall, these studies included 3055 women (the number of patients ranged from 196-1320).

### **Exclusion criteria**

Defined by inclusion criteria.

### **Population**

number of patients = 3055.

### **Interventions**

Aim: to assess the effectiveness of different policies of routine follow-up testing on morbidity, mortality and quality of life in breast cancer patients after primary treatment.

Three comparisons were specified:

1. Follow-up based on routine clinical visits plus yearly mammogram compared to a more intensive surveillance including radiological and laboratory tests.
2. Centralised versus decentralised follow-up (i.e. surveillance offered by a specialist at a multidisciplinary breast clinic compared to that delivered by a general practitioner).
3. Regular follow-up compared to surveillance on demand.

### **Outcomes**

Disease free survival (expression of the time to detect a recurrence). It is used in this context to compare the power of different follow-up strategies to detect recurrence earlier, possibly in

an asymptomatic stage;

Overall survival;

Occurrence of metastases detected in an asymptomatic state;

Health related quality of life.

### **Follow up**

Median follow-up varied across trials with range 16-120 months.

### **Results**

1. Follow-up based on routine clinical visits plus yearly mammogram intensive group) compared to a more intensive surveillance including radiological and laboratory tests.

Pooled data from 2 RCTs:

There was no statistically significant advantage for 5-year overall survival arising from intensive surveillance: HR intensive group: control group 0.96 [95% CI 0.80-1.15].

There was no statistically significant advantage for 5-year disease-free survival arising from intensive surveillance: HR intensive group: control group 0.84 [95% CI 0.71-1.00]. This pooled result did not confirm a statistically significant result of the Roselli Del Turco trial in favour of intensive follow-up strategy.

There were no statistically significant differences in overall survival between the follow-up strategies in the subgroup analyses for age, tumour size and nodal status:

Overall survival; HR (intensive: control):

Age ≤ 40 years HR 1.08 [95% CI 0.65-1.80]

Age > 40 years HR 0.95 [95% CI 0.78-1.16]

T1 tumour HR 0.8 [95% CI 0.55-1.17]

T2 tumour HR 0.92 [95% CI 0.73-1.17]

T3 tumour HR 1.44 [95% CI 0.91-2.30]

N0 nodes HR 1.35 [95% CI 0.94-1.94]

N1+ nodes HR 0.84 [95% CI 0.68-1.04]

There were no statistically significant differences in disease-free survival between the follow-up strategies in the subgroup analyses for age, tumour size and nodal status:

Disease-free survival; HR (intensive: control):

Age ≤ 40 years HR 0.94 [95% CI 0.59-1.47]

Age > 40 years HR 0.84 [95% CI 0.70-1.01]

T1 tumour HR 0.72 [95% CI 0.52-1.00]

T2 tumour HR 0.83 [95% CI 0.67-1.04]

T3 tumour HR 1.35 [95% CI 0.82-2.21]

N0 nodes HR 0.84 [95% CI 0.62-1.14]  
N1+ nodes HR 0.83 [95% CI 0.68-1.02]

Asymptomatic detection of metastases:

GIVIO trial only: 31% of cases of metastases in the intensive group and 21% in the clinical group were detected in an asymptomatic phase. This is consistent with results of several prospective non-randomised studies (Hannisdal 1993, Logarar 1990, Rutgers 1989, Vestergaard 1989, Mahoney 1986, Hietanen 1986, Wick-erhan 1986, Pandya 1983).

Quality of life:

GIVIO trial only: Questionnaires were administered 4 times between 6 and 60 months with an average response rate of 73.5%; overall no significant difference was found between the two follow-up strategies.

2. Centralised versus decentralised follow-up (i.e. surveillance offered by a specialist at a multidisciplinary breast clinic compared to that delivered by a general practitioner).

Time to detection of recurrence

The Grunfeld trial, comparing follow-up offered by a hospital based specialist with follow-up offered by a general practitioner, shows no differences in time to detection of recurrence between the groups. In the hospital group, the median time from first symptoms suggesting recurrence to confirmation by a hospital

specialist was 21 days, in the general practice group it was 22 days. The median difference was 1.5 days.

The number of recurrences was different in the two groups (10/148 general practice group, 16/148 hospital group,  $p=NS$ ) probably because of the short time of follow-up for the trial.

Quality of life

Quality of life shows an expected small deterioration for both groups during the trial. The hospital group has a statistically significant increase in symptom scores for fatigue, dyspnoea and appetite loss. There is no difference in overall health, social and emotional functioning and levels of anxiety and depression. This study also collected data on the patients who were asked about the trial but did not participate (149/445, 33.5%). These women were older than participants and had a lower education level but there were no important differences in clinical characteristics or in baseline quality of life scores.

The Grunfeld data were used in a new publication that analysed patient satisfaction with care by general practitioners versus hospital specialists over an 18-month period (see Grunfeld secondary reference). Questionnaires completed by 93% of patients indicated that they were more satisfied with service delivery, consultation and the continuity of care provided by their general practitioner than by a specialist.

### 3. Regular follow-up compared to surveillance on demand.

The Gulliford trial comparing conventionally scheduled follow-up and less frequent follow-up (restricted to the time of mammography) shows that 7% of eligible patients refused to enter the study. The characteristics of these patients may suggest that younger women with more aggressive primary disease are not willing to reduce the frequency of follow-up visits. Unfortunately, no assessment is available of these patients in relation to their quality of life.

No significant differences have been found between the groups in regard to the use of telephone and visits to general practitioners during the trial. Approximately one-third of the patients in both groups expressed a preference for a less frequent schedule of follow-up visits, but only 56 women answered this question on the questionnaire.

#### Authors conclusions

In light of the evidence presented here, less intensive follow-up strategies based on periodical clinical exam and annual mammography seem as effective as more intense surveillance schemes. Further laboratory and radiological examinations may add useful information where women are symptomatic or the clinical visit suggests the need for further investigations. A general practitioner's participation in the delivery of follow-up care appears feasible and appropriate as long as the care is organised in such a way that access to hospital care is easy when required.

#### **General comments**

Four RCTs were included:

1. GIVIO trial
2. Rosselli Del Turco trial
3. Grunfeld trial
4. Gulliford trial

The pooled data come from 2 RCTs: GIVIO trial and the Rosselli Del Turco trial).

Literature search was performed on the Cochrane Controlled Trial Register, EMBASE and MEDLINE databases; search date 14th May 2004. Two search strategies reported in full. References within included studies were reportedly checked for further sources. Each potentially eligible study was independently assessed by two reviewers for inclusion in the review and for quality. Aspects of study quality assessment are reported; blinding was not considered to be necessary.

## Systematic review of combined study designs

Collins, Bekker & Dodwell . Follow-up care of patients treated for breast cancer: a structured review. [Review] [59 refs]. Cancer Treat.Rev. 30[1], 19-35. 2004.

### **Design**

Design: Systematic review of combined study designs (other), evidence level: 2 +

Country: Various, setting: Other

### **Inclusion criteria**

Studies providing data according to the specific research questions on follow-up of patients treated for breast cancer (see 'interventions'), and published in English between the years 1989-2001.

### **Exclusion criteria**

Case reports;  
Views/experiences of health professionals;  
Studies of health technologies/prognostic factors.

### **Population**

-

### **Interventions**

Aim: to identify and integrate primary empirical evidence on the effectiveness of follow-up strategies for patients treated for breast cancer.

Specific research questions:

1. What is the optimal intensity of routine follow-up investigations?
2. Which type of health professional should provide follow-up care?
3. What are the optimal frequency and length of follow-up services?
4. What is the impact of routine follow-up care on patient morbidity?
5. What interventions have been found to be effective in reducing patient morbidity?
6. What level of involvement do patients have in choices about their follow-up care?

### **Outcomes**

Authors provide narrative summary answers to their 6 research questions, based upon tabulated data for every included study.

### **Follow up**

NA

### **Results**

1. What is the optimal intensity of routine follow-up investigations?

Authors conclude: a minimal approach is as effective as intensive interventions for routine breast cancer follow-up in terms of survival, timeliness of recurrence detection and quality of life. In addition, the data suggest that routine follow-up may be more beneficial in terms of survival for the detection of contralateral disease than recurrent disease.

2. Which type of health professional should provide follow-up care?

Little empirical evidence is available (NB literature search cut-off date: 2001). Prior reviews suggest GP-led care is as effective as specialist care and DH guidance (1996) recommends GPs be involved in the organisation of local arrangements for patients whose follow-up is being scaled down. Few studies have employed a design and set of outcome measures that would elicit data to address satisfactorily the question of which health professional should provide follow-up care.

3. What are the optimal frequency and length of follow-up services?

Little empirical evidence is available. Available evidence is conflicting. On the one hand, guidelines and data suggest the frequency and length of the follow-up service should be tailored to meet the needs of individual patients. On the other hand, one study found evidence that patients had twice as many follow-up visits as recommended, i.e., there is a standard of follow-up care that can be exceeded.

4. What is the impact of routine follow-up on patient morbidity?

Little empirical evidence is available. In studies that assessed this outcome, most patients expressed a preference for attending regular follow-up sessions, even when asymptomatic. Although patients reported that the anticipation of attending these routine sessions was anxiety provoking, reduced fear of recurrence and less physical and psychological distress was experienced after attending their routine visit.

5. What interventions have been found to be effective in reducing patient morbidity?

No published empirical evidence was identified to suggest factors that are associated with reduced morbidity.

6. What level of involvement do patients have in choices about their follow-up care?

Within the context of follow-up care for patients treated for breast cancer, there is no published empirical evidence describing patients' preference for involvement in decision making about treatment choices or need for (further) information. However, one study investigated the effect of patient decision-making in follow-up care and found that patients who reported more involvement in decision making reported better quality of life. Within other

health contexts, the provision of good information and the making of informed decisions are associated with better outcomes.

### **General comments**

Literature search: performed on the following databases MEDLINE, EMBASE, CINAHL, British Nursing Index, RCN Journals Database, PsycINFO, National Research Register (NRR), Health Management Information Consortium (HMIC), Cochrane Database of Systematic Reviews (CDSR) and the NHS Centre for Reviews and Dissemination databases.

From these searches, it was evident that studies before 1989 would not add to the evidence base to meet this review's aims. Therefore, this review focussed on empirical evidence published between 1989 and 2001. In-depth searches of MESH headings, references of identified articles and hand searching of the Annals of Oncology journal were carried out for the years 1989-2001.

Data extraction: A data extraction form was developed to elicit the following data systematically from each article: study details such as aim, psychological theories informing interventions and/or measures, design, methodology, sample; aspect of service assessed; description of intervention; measures of effectiveness; results and authors conclusions.

Assesment of study quality: the research quality of the study was assessed by evaluating the following: adequacy of sample size, stratified/random sample, representativeness of study population, attrition rate, definition of intervention, blinding of assessors, randomisation procedure, similarity of study/control groups at baseline, intention to treat analysis, validation of measures, timing of measures, consistency of measures with aims, consistency of conclusions with results and analysis concerns such as confounders, interpretation and generalisability.

One researcher selected the studies, although 10% of decisions were reviewed by two other researchers.

Of 4418 articles identified by the literature search, 38 were included in the final review (including 5 randomised studies that have been reported in systematic reviews by Rojas et al. 2000 and Montgomery et al. 2007.

Cited results are based upon authors' narrative summary of the studies that scored highest for quality assessment.

de Bock, Bonnema, van der, Kievit & van d . Effectiveness of routine visits and routine tests in detecting isolated locoregional recurrences after treatment for early-stage invasive breast cancer: a meta-analysis and systematic review (DARE provisional record). J.Clin.Oncol. 22, 4010-4018. 2004.

### **Design**

Design: Systematic review of combined study designs (other), evidence level: 2 +  
Country: Various, setting: Other

### **Inclusion criteria**

Studies in any language published between 1966 and 2002 according to three criteria:

1. patients treated for primary operable breast cancer i.e. without known distant metastases outside the breast and the axilla at the time of treatment of the first breast tumor;
2. local-regional recurrence defined as a recurrence of breast cancer in the same breast or chest wall or regional lymph node area, including supraclavicular lymph node involvement, but excluding retrosternal lymph node involvement;
3. Rate of isolated locoregional recurrences may be compared in asymptomatic patients versus symptomatic patients.

The included studies were 1 RCT (Grunfeld et al. 1996), 1 prospective study and 10 retrospective studies.

### **Exclusion criteria**

Defined by inclusion criteria.

### **Population**

number of patients = 5045.

### **Interventions**

Aim: To review the effectiveness of routine visits and routine tests in detecting isolated locoregional recurrences in asymptomatic patients after treatment for early-stage invasive breast cancer.

In 4 studies primary treatment was mastectomy. In 5 studies primary treatment was breast conserving surgery. In 1 study there was a mix of these treatments and in 2 studies primary treatment was not reported.

### **Outcomes**

Proportion of isolated locoregional recurrences diagnosed in asymptomatic patients by routine visits/tests.

Factors that are predictive of the proportion of locoregional recurrences that

were detected whilst asymptomatic by routine visits/tests. Factors examined were: treatment of first tumor (mastectomy vs. breast-conserving therapy), year of publication (before 1995 vs. 1995 and later), number of patients in the study (less than 500 vs. more), design of the study (nonrandomised, noncontrolled, retrospective, vs. other), number of planned mammograms (up to five in 5 years vs. five in 5 years), and the quality score (above the median quality score vs. at or under the median quality score).

### **Follow up**

Variable in primary studies.

### **Results**

In total in 12 studies there were 378 locoregional recurrences in 5045 patients:

Detected at routine visits:

Without symptoms: 152 (40% of all recurrences)

With symptoms: 69 (18%)

Detected outside of routine visits: 155 (41%)

Unknown: 2 (1%)

Pooled estimate of the proportion of isolated locoregional recurrences diagnosed in asymptomatic patients by routine visits/tests (12 studies; 5045 patients): 40% (95% CI 35%-40%)

The proportion of locoregional recurrences that were detected whilst asymptomatic by routine visits/tests was statistically significantly higher in univariate analysis for the following variables: mastectomy, study publication prior to 1995, <500 patients in the study and  $\leq 5$  planned mammograms in a 5 year period. There was no significant difference for RCT study design and study quality score.

In multivariate analysis mastectomy was associated with a significantly higher rate of isolated locoregional recurrences diagnosed in asymptomatic patients (OR 1.7; 95% CI 1.1-2.8) whereas larger studies whether or not more than 5 mammographies were planned per year, were associated with a smaller number of isolated locoregional recurrences diagnosed in asymptomatic patients (OR 0.4; 95% CI 0.2-0.6) as were smaller studies with with more than five planned mammograms (OR 0.4, 95% CI 0.2-0.7).

### **General comments**

Literature search performed on MEDLINE, CancerLit, Cochrane, Web of Sciences, Embase, and Current Contents databases. MESH search terms and free text terms described.

Data were extracted independently by two investigators by means of a predefined form. Topics in this form were: number of patients, years of patient inclusion, age at time of first diagnosis of breast cancer, distribution of stage

and treatment of this primary breast cancer, adjuvant treatment, design of the study, number of planned visits and mammograms during the first 5 years of follow-up, and median or mean time of follow-up per study.

Methodological quality of studies was assessed independently by two authors according to a predefined checklist that considered patient populations; trial participation; reporting of disease-related characteristics; primary treatment; extent of follow-up (5 years considered adequate); reporting of follow-up regimen; loss to follow-up; prospective assessment of outcomes. Of a possible maximum quality score of 9, the mean score in the 12 included studies was 4.8; median 4, range 3-8. There was no association between study size and effect size.

The pooled estimate reported is based on a meta-analysis, weighted for the sample size of each contributing study.

## Randomized controlled trial

Palli, Russo, Saieva, Ciatto, Del Turco, Distante & Pacini . Intensive vs clinical follow-up after treatment of primary breast cancer: 10-Year update of a randomized trial [2]. Journal of the American Medical Association. 281[17], 1586. 1999.

### Design

Design: Randomized controlled trial (other), evidence level: 1+  
Country: Italy, setting: Other

### Inclusion criteria

Patients surgically treated for unilateral invasive breast cancer with no evidence of metastases.

### Exclusion criteria

Not reported.

### Population

number of patients = 1243.

### Interventions

Intensive follow-up group (n=622): received physical examination 3 monthly in the first 2 years and 6 monthly thereafter; also annual mammography, biannual chest X-ray and bone scan;

Clinical follow-up group (n=621): received physical examination and mammography according to the same schedule as above, but with no other routine diagnostic tests.

### Outcomes

Estimated 10-year mortality

### Follow up

Outcome assessed at 10-year follow-up.

### Results

Estimated 10-year mortality were not different for the clinical (31.5%) and intensive (34.8%) follow-up groups; HR 1.05; 95% CI 0.87-1.26.

Authors conclusion: even though more local recurrences were detected in the intensive follow-up group when analysed at 5 years, this did not translate to an overall survival advantage at 10 years.

### General comments

Paper provides longer (10 year) follow up data to that cited in the Cochrane Review by Rojas et al. (2000). Consider result with that of the Cochrane

Review.

Paper is a brief research letter.

The main prognostic characteristics were similar between the two randomised groups.

10-year data were available for 99.2% of patients.

## Prospective comparative study

Koinberg, Langius-Eklof, Holmberg & Fridlund . The usefulness of a multidisciplinary educational programme after breast cancer surgery: a prospective and comparative study. *European Journal of Oncology Nursing*.;2006.Sep.; 10(4):273.-282. 2006 Sep; 10[4], 273-282.

### Design

Design: Prospective comparative study (other), evidence level: 3  
Country: Sweden, setting: Secondary care

### Inclusion criteria

Patients treated for breast cancer of TNM stage I or II.

### Exclusion criteria

9 patients declined to participate and received traditional follow-up outside of the study.

### Population

number of patients = 96, mean age = 61 years.

### Interventions

Aim: to evaluate a multidisciplinary educational programme as an alternative to standard physician-based follow-up, for patients treated for low risk breast cancer.

Two groups were defined and followed-up prospectively:

Multidisciplinary educational programme group (n=50); followed up as follows: 4 sessions in 4 weeks between 2-6 months following surgery. Sessions led by a specialist nurse with physiotherapist, social worker, physician and patient advocacy worker present. Content: recovery from surgery, prevention of lymphoedema, management of menopausal side effects, body image/sexual issues. At the close of the programme women could contact the specialist nurse by telephone for advice/referral to a physician.

Traditional group (n=46); examination by a physician twice a year for 2 years and annually for up until the 5th year

Both comparison groups were followed up with mammography; at 18-24 month intervals in the intervention group and annually in the traditional follow-up group.

### Outcomes

Functional Assessment of Cancer Therapy General Scale (FACT-G): 27 item scale with 4 subscales:  
Physical well-being; Functional well-being; Social/family well-being; Emotional well-being.

Self-care Aspects Questionnaire (SCA): 3 subscales: Coping ability; Participation in decision making; Knowledge about breast cancer.

Sense of Coherence Scale (SOC): based on the extent to which an individual sees the world as comprehensible; manageable; meaningful.

### **Follow up**

Assessment was made at baseline and 1 year following diagnosis.

### **Results**

#### **FACT-G**

At baseline there were no statistically significant differences between the groups except for physical well-being; women in the multidisciplinary educational programme had worse physical well-being than those in the traditional group. The women in the multidisciplinary educational programme increased in their physical well-being and functional well-being during the 1-year follow-up. The women in the traditional group increased in functional well-being and decreased in social well-being during the 1 year follow-up.

#### **SCA**

There were no statistically significant differences either between groups or within groups with regard to coping ability, participation in decision making and knowledge, either at baseline or at the 1-year follow up.

#### **SOC**

There were no statistically significant differences between the comparison groups at baseline or at the 1-year follow-up. There was a statistically significant difference ( $p < 0.001$ ) in SOC in the traditional group: baseline (74.4) and 1-year (67.7) i.e. a reduction by 8.4%; regarded as clinically important.

Authors conclude: the multidisciplinary educational programme was associated with similar outcomes as traditional follow-up in terms of well-being, aspects of self-care and coping ability and could be an alternative to traditional follow-up (see comment re: local recurrence).

### **General comments**

The two groups were defined by two different treatment centres, and were mostly similar in terms of demographic and treatment-associated variables. A smaller proportion of patients in the traditional follow-up group received breast conserving surgery (52%) than in the multidisciplinary programme group (88%);  $p < 0.001$ , Chi square. Authors state that this may explain the lower reported physical well-being at baseline in the multidisciplinary programme group.

Mammography surveillance varied between groups.

No specific patient-education is reported in the multidisciplinary programme for detection of locoregional recurrence; in this respect the two interventions appear to have non-identical aims, and detection of local recurrence was not evaluated as an outcome measure.

Power calculation performed to justify sample size.

## Qualitative Study

Breakthrough breast cancer . Follow-up care - what do breast cancer patients want? 2007.

### Design

Design: Qualitative Study (other), evidence level: 3  
Country: United Kingdom, setting: Community

### Inclusion criteria

10 members of the charity Breakthrough Breast Cancer's Campaigns & Advocacy Network (Breakthrough CAN).

### Exclusion criteria

Attendees were self selected following an invitation to all members of Breakthrough CAN. The authors report that therefore the attendees of the group are not representative of all breast cancer patients' views but provide a useful 'snapshot' of opinions on follow up care. The 10 attendees had varying experiences of follow-up: one member attended no follow-up and another did so for 27 years.

### Population

number of patients = 10.

### Interventions

Aim: to assess the views on follow-up held by breast cancer advocates at a focus group facilitated by Breakthrough Breast Cancer on 20 April 2007.

Specific questions discussed by the group were:

What do breast cancer patients understand by follow up care?  
What are the benefits and drawbacks of current follow up care arrangements?  
What should follow up care involve?  
Where should follow up care take place and who should carry it out?  
How long should follow up care be provided?

### Outcomes

Recommendations based upon the questions discussed.

### Follow up

NA

### Results

The group summed up the aims of follow-up as:

Surveillance of ongoing treatment;  
Access to new treatments;  
Surveillance and management of chronic/long term side effects (which can emerge after 5-10 years after initial diagnosis);

Surveillance and management of short-term side effects of treatment;  
Psychosocial welfare;  
Reassurance;  
Feeling that patient can easily access care when needed;  
Long term, wider assessment including the needs of other family members;  
Monitoring of general health and being asked about well being;  
Access to breast reconstruction;  
Prosthesis fitting and advice;  
Fast track to an oncologist if anything is wrong.

The group did not come to a consensus about where follow up care should take place, who should carry it out or how long it should be provided. However, there was agreement that a 'one size fits all' approach to follow up care is unlikely to meet the needs of breast cancer patients; follow up should be tailored to individuals, with full input from patients themselves.

The group also discussed the need for patients to have the option of opting out of follow up care but with rapid access back into the follow up care system if needed. However, other members of the group were not comfortable with the idea of patients having to self refer for follow up care.

#### Conclusions

1. Patients view follow up care as wider than just their clinical needs. Follow up care can help to meet psychosocial and other needs which patients consider just as important.
2. Follow up care should be tailored to the individual, with the patient fully involved at every decision making stage.
3. Patients should be given information about what to expect at their follow up care appointments.
4. Patients or breast cancer advocates could play a role in educating GPs about breast cancer. If GPs play a greater role in providing follow up care this could help ensure that they are informed about breast cancer issues.
5. Follow up care is essential as more newer targeted therapies are used (e.g. aromatase inhibitors). The longer term side effects of such treatments may not be as well known as other more established treatments.
6. Whatever follow up care arrangements are put in place, signposting to other services such as lymphoedema services, complementary therapies and further support is essential.
7. When measuring the financial costs of follow up care, patients felt that factors such as the psychological benefits of follow up should be taken into account.
8. Patients should be given the information and support they need if they want to consider opting out of follow up care.

#### Recommendations of the focus group:

1. Follow up should be individualised for each patient, with the patient fully involved at every decision making stage.
2. All breast cancer patients should be given information about what to expect

- at their follow up care appointments. The amount and level of information should be tailored to each patient.
3. Breast cancer patients should be signposted to lymphoedema services, complementary therapy services and other support services at their follow up care appointments.
  4. All patients discharged from follow up care should be provided with high quality, patient-focused information about how to get back into the system quickly.
  5. If GPs are to play a greater role in providing follow up care, further training should be available to support them.

**General comments**

Small qualitative study based upon the views of 10 breast cancer advocates i.e. individuals with a role nominated by a large UK charity, to represent patients with breast cancer.

Beaver, K., Luker, K. (2005) Follow-up in breast cancer clinics: reassuring for patients rather than detecting recurrence *Psycho-Oncology* 14:94-101

**Design:** Mixed Methods

**Evidence Level:** 3

**Country:** UK

**Aim:** To explore the nature and content of interactions between patients attending hospital outpatients departments for routine follow-up following completed breast cancer treatment and health care professionals.

Beaver *et al.* (2005) examined the nature and content of interactions between patients attending hospital outpatients departments for routine follow-up following completed breast cancer treatment and health care professionals. Through qualitative methods, the study reported that follow-up visits appeared to consist of three primary components: checking for recurrence, offering reassurance and providing information. All consultations involved a clinical examination of the breast and surrounding areas and the extent of examination varied depending on who was conducting the exam. Patients did not have much concern on reducing visits from 3 to 6 months, however changing from 6 to 12 months and/or discharge was a considered a bigger step and created anxieties for some who seemed to depend on follow-up visits to detect recurrent disease. Clinic nurses were active in clarifying information despite having limited time available to meet the information needs of patients. Health care professionals indicated that the primary function of follow-up was to detect recurrent disease however were of the opinion that clinical examination at follow-up was highly unlikely to detect recurrent disease in asymptomatic women. Health care professionals did perceive that patients were reassured by the clinical examinations, despite the low rate of detection of recurrence. Health care professionals felt that the provision of information was an important part of follow-up, however admitted that they found it difficult to provide information to the patients in the time available. Doctors said that patients would have to be proactive and assertive in requesting information as they did not always encourage patients to ask questions.

**Inclusion criteria:**

Patients who had successfully completed active breast cancer treatment and who had no current clinical problems and were returning for routine follow-up visits.

Health care professionals who conducted patient consultations (e.g. medical staff, breast care practitioner) and who had a supporting role (e.g. clinic nurses).

**Exclusion criteria:**

None given

**Population:**

Eligible for participation = 141

16 consented but consultations were not observed due to two women available for observation at the same time.

9 women refused to participate

10 women did not attend their appointments

2 women were not considered to be routine follow-up cases.

N=104

**Interventions:** Qualitative methods including: observation, audio-recording consultations and interviews with health care professionals.

**Outcomes:****Results:**

No recurrences were detected by clinical examination in asymptomatic women.

Mean consultation duration was 6.2 minutes, with breast care nurse practitioners taking longer over consultations than medical colleagues.

Follow-up visits appeared to consist of three primary components: checking for recurrence, offering reassurance and providing information.

All consultations involved a clinical examination of the breast and surrounding areas and the extent of examination varied depending on who was conducting the exam.

Patients did not have much concern on reducing visits from 3 to 6 months, however changing from 6 to 12 months and/or discharge was a considered a bigger step and created anxieties for some who seemed to depend on follow-up visits to detect recurrent disease.

Clinic nurses were active in clarifying information despite having limited time available to meet the information needs of patients.

Health care professionals indicated that the primary function of follow-up was to detect recurrent disease however were of the opinion that clinical examination at follow-up was highly unlikely to detect recurrent disease in asymptomatic women. Health care professionals did perceive that patients were reassured by the clinical examinations, despite the low rate of detection of recurrence. Health care professionals felt that the provision of information was an important part of follow-up, however admitted that they found it difficult to provide information to the patients in the time available. Doctors said that patients would have to be proactive and assertive in requesting information as they did not always encourage patients to ask questions.

There was an 86.8% response rate to the patient questionnaire (N=92)  
60.9% of women indicated a degree of concern associated with attendance at follow-up visits, particularly related to the possibilities of recurrence.  
The mean duration of consultations was perceived to be 11.5 minutes as compared to the recorded time of 6.2 minutes. 54% of patients over-estimated their consultation time, 42% were correct to within 5 minutes and 4% under estimated duration.

77.8% of patients reported that they asked questions during consultation, though this did not appear to be the case on observation.  
86.1% of those that perceived they had posed questions reported to be satisfied with the response.

### **General comments**

The results of this study appear to support the fact that recurrent disease is unlikely to be picked up during follow-up visits. HCP's did not expect to detect recurrence yet continued to check for it.

Although women reported that they asked questions during follow-up, observation of consultation did not back this up. Perhaps women were less inclined to ask questions during an observed consultation?

Women appeared reassured by follow-up visits and the powerful nature of this reassurance should not be underestimated when considering alternative options.

Routine follow-up visits could be moved from hospital outpatients to local clinics where the need for reassurance could be met with specialist nurses taking a more prominent role in providing follow-up care.

**Authors Conclusion:** Continuing to ask women to attend hospital outpatients for brief consultation visits may create a cycle of dependency and give an incomplete message on how recurrent disease is detected. Any new policy initiatives will need to take into consideration patient expectations on what constitutes follow-up service provision.

Jiwa, M., Thompson, J., Coleman, R., Reed, M. (2006) Breast cancer follow-up: could primary care be the right venue? *Current Medical Research and Opinions* 22;4:625-630

**Design:** Retrospective Data Analysis

**Evidence Level:** 3

**Country:** UK

**Aim:** to identify the elements of a follow-up protocol for treated breast cancer patients in primary care, with reference to key stakeholders by determining the type of problem commonly documented during the follow-up of breast cancer patients and identification of the type of resources used.

Jiwa *et al.* (2006) conducted focus groups with patients attending a medical oncology follow-up and surgical follow-up clinics. The study aimed to identify the elements of a follow-up protocol for treated breast cancer patients in primary care, with reference to key

stakeholders by determining the type of problem commonly documented during the follow-up of breast cancer patients and identification of the type of resources used. The study reported that the most frequent problems to arise related to anxiety and unrelated medical problems such as joint pain and menopausal symptoms. The main themes to emerge from the focus groups related to patient, disease, doctor and/or process. Results from the nominal discussion outlined the essential elements of a model of primary care follow-up as identified by the majority of the group. The discussions suggested that a formal 'handover' of patients from secondary care following a 'discharge' visit where the specialist would outline the case for withdrawing specialist involvement. The patient, if agreeable, would be discharged to the care of her GP who would receive a detailed summary of the patient's progress to date. A clear indication of when and how access to specialist care could be obtained in the event of future concerns about a possible recurrence would be provided. The patient would have access to the breast care nurse and breast cancer support group and the breast care nurse would be able to refer patients to a surgeon or oncologist directly. The data suggest that the psychosocial needs of patients need to be taken into account when offering follow-up treatment and suggest that the needs of patients and their families, regarding the fear of recurrence, are not being met

**Inclusion criteria:** None Given

**Exclusion criteria:** None Given

**Population:** N=100; 51 patients attending a medical oncology follow-up clinic (tertiary care) and 49 attending a surgical follow-up clinic (secondary care).

**Interventions:** Stakeholder focus groups to identify a set of themes relating to follow-up care followed by a nominal group discussion with a representative from each of the stakeholder groups to devise a model for follow up in the primary care setting.

**Outcomes:** Barriers to follow-up in the primary care setting.

**Results:**

The evaluated records described 702 patient years of follow-up and reported that the most frequent problems to arise related to anxiety and unrelated medical problems such as joint pain and menopausal symptoms.

Anxiety and depression tended to present relatively soon after treatment and could feature for a number of years. Concomitant medical problems tended to present later in the follow-up period.

The main themes to emerge from the focus groups related to patient, disease, doctor and/or process.

Results from the nominal discussion outlined the essential elements of a model of primary care follow-up as identified by the majority of the group. The discussions suggested that a formal 'handover' of patients from secondary care following a 'discharge' visit where the specialist would outline the case for withdrawing specialist involvement. The patient, if agreeable, would be discharged to the care of her GP who would receive a detailed summary of the patient's progress to date.

A clear indication of when and how access to specialist care could be obtained in the event of future concerns about a possible recurrence would be provided.

The patient would have access to the breast care nurse and breast cancer support group

and the breast care nurse would be able to refer patients to a surgeon or oncologist directly.

**General comments**

Policy on follow-up varies world-wide and the advent of aromatase inhibitors may increase the length of time in specialist follow-up due to the need for expert medical surveillance, however there is debate as to whether there is a need for specialist follow-up to detect secondary lesions.

The authors acknowledge the potential risk of bias in the study in relation to the medical records examined, highlighting the fact that they may have included records of patients opposed to discharge from specialist care.

The data suggest that the psychosocial needs of patients need to be taken into account when offering follow-up treatment and suggest that the needs of patients and their families, regarding the fear of recurrence, are not being met.

There are some cases where there is a need for continued specialist care and therefore a follow-up care program may need to take account of local arrangements and the needs of the individual patient.

Kelly, L., Caldwell, K., Henshaw, L. (2006) Involving users in service planning: A focus group approach

**Design:** Focus Groups

**Country:** UK

**Aim:** To identify the priority issues of follow-up from the patient perspective.

Kelly *et al.* (2006) conducted focus groups to identify the priority issues of follow-up from the patient perspective. The primary reason given by patients for attending follow-up was for reassurance that the cancer had not returned. Participants also wanted information on new treatments and further tests. Key themes to emerge from the focus group interview were: the need for reassurance; continuity of care; privacy and dignity; information and detection of new symptoms and opportunities to discuss feelings and worries.

**Population:** N = 10 women, diagnosed with breast cancer who had completed treatment and were being followed up by the study site service or other local services within the cancer network.

**Interventions:**

**Outcomes**

**Results:**

The primary reason given by patients for attending follow-up was for reassurance that the cancer had not returned. Participants also wanted information on new treatments and further tests.

Key themes to emerge from the focus group interview were:

- The need for reassurance
- Continuity of care
- Privacy and dignity
- Information and detection of new symptoms
- Opportunities to discuss feelings and worries

A need for reassurance was described by women and they welcomed their regular checks at hospital, demonstrating the anxiety they experience and how this is an essential element which needs to be addressed in a follow-up program.

Continuity of care was an important feature of follow-up for the women who expressed a need to see the same person at each follow-up visit in order that they could build a patient-doctor relationship.

Concerns regarding privacy and dignity were linked to breast examination technique with some women describing instances where they felt vulnerable, frustrated and angry, although some patients did describe a positive experience. The women in this study were able to recognise consistency and experience in the examination techniques and inconsistencies appeared to raise concerns amongst the patients.

Participants in this study described their reliance on follow-up visits for obtaining new and accurate information and for detecting recurrence.

There was a need for patients to be able to discuss worries and feelings during follow-up visits.

**General comments**

**Author's Comment:** Using a qualitative approach provided a platform for patients to provide valuable information about local services while using a group of women who knew each other resulted in a positive group dynamic and interaction which appeared to enhance data collection due to the participants being able to discuss many sensitive and personal issues.

Renton, J., Twelves, C., Yuille, F. (2002) Follow-up in women with breast cancer: the patients' perspective *The Breast* 11;257-261

**Design:** Cross Sectional Survey

**Evidence Level:** 3

**Country:** UK

**Aim:** To define patients' views on follow-up and to develop optimal breast cancer follow-up arrangements which meet the needs of women and make efficient use of available resources.

Renton *et al.* (2002) conducted study that used questionnaires to define patients' views on follow-up and to develop optimal breast cancer follow-up arrangements which meet the needs of women and make efficient use of available resources. The study reported that in general women appeared to be satisfied with current follow-up however they were open to changes to the current set-up. Women reported a number of factors that they felt were important to discuss during follow-up such as risk of recurrence or risk to daughters, the follow-up visits appear to be effective in alleviating the concerns and worries of the majority of women. Women appeared to have more confidence in specialist nurses compared to their own GP suggesting that a nurse-led model of follow-up may be a way forward. Continuity of care was a factor which was deemed to be important.

**Inclusion criteria:** Women attending the outpatient breast cancer follow-up clinic at the Victoria Infirmary in Glasgow over a five week period between March and April 2000.

**Exclusion criteria**

**Population:** N=134

**Interventions**

A questionnaire consisting of both open and closed questions was developed in conjunction with breast cancer patients and staff and piloted on 23 women to check feasibility before being administered to the study population.

**Outcomes:**

Previous experience of the clinic (where relevant)  
Attitudes to the current clinic arrangements  
Patients needs and perceptions

**Results**

### Current Clinic

88% of those surveyed were satisfied with the current duration and frequency of follow-up visits.

46% reported feeling anxious, worried or frightened before a visit and 96% of those surveyed reported feeling relaxed, happy and okay following the visit.

### Importance and Satisfaction

87% of women surveyed considered follow-up visits to be important and 92% of all women surveyed expressed their satisfaction with current arrangements.

70% of women considered the risk of recurrence and 61% considered the effects of treatment to be important topics to be discussed at follow-up.

65% of patients deemed it important to see the same member of staff at each follow-up visit and 58% of women felt that waiting times of more than 30 minutes was unsatisfactory.

Other factors which appeared to cause concern included the risk of breast cancer affecting their daughters, alternative treatments, mood and body image.

### Specific Alternative Arrangements

Similar proportions of women preferred to talk to a consultant (39%) and a specialist nurse (44%) regarding breast cancer.

77% of women were confident in the consultant while only 33% expressed confidence in the specialist nurse. Despite this, 67% of women indicated that they would be happy for a specialist nurse to take responsibility for follow-up care.

Only 16% of women expressed confidence in their GP although 39% indicated that they would be happy with their GP being responsible for follow-up.

### **General comments**

In general women appeared to be satisfied with current follow-up however they were open to changes to the current set-up.

Women reported a number of factors that they felt were important to discuss during follow-up such as risk of recurrence or risk to daughters, the follow-up visits appear to be effective in alleviating the concerns and worries of the majority of women.

Women appeared to have more confidence in specialist nurses compared to their own GP suggesting that a nurse-led model of follow-up may be a way forward.

Continuity of care was a factor which was deemed to be important.

Vanhuyse, M., Bedard, P., Sheiner, J., Fitzgerald, B., Clemons, M. (2007) Transfer of follow-up care to family physicians for early stage breast cancer *Clinical Oncology* 19:172-176

**Design:** Prospective Study

**Country:** Canada

**Aim:** To determine the number of patients for whom transfer back to the family physician for follow-up was feasible.

Vanhuyse *et al* (2007) reported the feasibility of patients transferring care back to the family physician for follow-up. This study used questionnaires and showed that it may be feasible to transfer follow-up care to the family physicians/GP's however there were many factors which remain to be addressed before this could happen including cost effectiveness, willingness and ability of family physicians/GP's to take on these patients, provision of resources, optimal timing for transfer and patient considerations.

**Inclusion criteria:**

Patients were deemed eligible to transfer back to the family physician if there was a pre-existing relationship with the physician; the patient agreed to the transfer; the patient was clinically free of local or distant recurrent disease; not require follow-up as specified by clinical trial inclusion and; have completed adjuvant chemo/radiotherapy or commenced adjuvant endocrine therapy.

**Exclusion criteria**

**Population:** N=193

**Interventions:** Assessed for suitability for transfer of follow-up back to the family physician

**Outcomes:** Follow-up transferred to family physician or continuing with follow-up in a cancer care centre according to usual practice.

**Results:**

A total of 83 patients (43%) were deemed suitable for transfer back to family physician for continued follow-up. Reasons for not transferring patients included: clinical trial enrolment (50.9%), ongoing endocrine treatment (31.8%), new symptoms (6.3%) or recurrent disease (0.9%).

One patient refused transfer to family physician.

All patients that transferred back to family physician had a pre-existing relationship with their physician whereas 8.2% of those not transferred did not have a family physician. 57.9% of transferred patients were also being followed by other oncologists compared with 65.5% of patients not transferred (p=0.05).

Significantly more patients in the non-transferred group were being considered for switching from Tamoxifen to aromatase inhibitor therapy (p=0.005).

**General comments**

Transfer of patients to their family physician/GP for follow-up after completion of primary treatment could free up time for oncologists to spend with other patients.

57.9% for transferred patients were being also followed up by a radiation or surgical

oncologist which suggests duplication of resources.

This study shows that it may be feasible to transfer follow-up care to the family physicians/GP's however there are many factors which remain to be addressed before this could happen including cost effectiveness, willingness and ability of family physicians/GP's to take on these patients, provision of resources, optimal timing for transfer and patient considerations.

Adewuyi-Dalton, R., Ziebland, S., Grunfeld, E., Hall, A., (1998) Patients views of routine hospital follow-up: a qualitative study of women with breast cancer in remission *Psycho-Oncology* 7:436-439

**Design:** Qualitative Methods

**Evidence Level:** 3

**Country:** UK

**Aim:** To identify views about continuity of care, access to specialist services and quality of the consultation and relate these to the length of time since treatment.

Adewuyi-Dalton *et al.* 1998, identified views of women who took part in a randomised clinical trial comparing GP follow-up with out-patient follow-up were invited to take part if they were in the out-patient arm of the trial. The study reported that Continuity of Care; Access to Specialist Care; Quality of Consultation were main areas that women were affected by most significantly.

**Inclusion criteria:** Women who took part in a randomised clinical trial comparing GP follow-up with out-patient follow-up were invited to take part if they were in the out-patient arm of the trial.

**Exclusion criteria**

**Population:** N=109 transcripts available for analysis

**Interventions**

**Outcomes:**

Continuity of Care

Access to Specialist Care

Quality of Consultation

**Results:**

Continuity of Care

The chance to build a personal relationship with the doctor was highly valued by women, yet they rarely saw the same doctor when attending for follow-up. Other reasons for a desire for continuity included uncertainty about the expertise of different staff, apparent lack of knowledge of case history or co-morbidity, difficulties asking questions and the prospect of being given bad news by a stranger.

Access to Specialist Care

The availability of cancer expertise within the clinic environment and quick access to diagnostic tests were seen as benefits of out-patient follow-up.

There was concern that GP's are overworked and could not be expected to have specialist knowledge.

Quality of the Consultation

The limited time available for consultation appeared to be a primary theme, with the lack of time with a specialist contributing to levels of dissatisfaction regarding information about treatment, diagnosis and side effects.

**General comments**

Continuity of care and access to specialist care are again primary themes emerging from patient questionnaires, particularly in the early stages of follow-up.

From this presented it appears that the need for unrushed consultations persists throughout the follow-up period and perhaps is even more important in the later stages of follow-up when visits are annual.

## 3. Any further comments

The following report was used as a basis: *Fischbacher, C. Immediate versus delayed breast reconstruction Steer 2002; 2(17)*. Used their original search (lines 30-82 of search strategy above), limited from 2002 onwards as original search executed early that year. Systematic Reviews, RCTs and Observational filters used as appropriate. SIGN Health Economics filter & SCHARR Quality of Life filter applied to basic search for the health economics review.

## 4. Update Search

For the update search, only the RCT & Systematic Review filter was used in light of the evidence required for the initial evidence review for this topic, date limit 2006-2008 and English language research chosen only.

**3. Any further comments**

Same literature search strategy used as for the original TA report, an exclusions filter only applied to basic search for the clinical review. SIGN Health Economics filter applied to basic search for the health economics review. Both searches executed from 2005 onwards as TA109 included both clinical and cost-effectiveness issues.

#### 4. Update Search

For the update search, an RCT & Systematic Review filter was used, date limit 2007-2008 and English language research chosen only.

## 2. Any further comments

This search constituted an update of two guideline/systematic review documents which were developed at about the same time, in 2004. They were:

1. Cancer Care Ontario Practice Guideline **Use of Bisphosphonates in Women with Breast Cancer** (Breast Cancer Disease Site Group) 2003. Last searched for evidence in February 2004.
2. Cochrane Review **Bisphosphonates for breast cancer (Pavlakis et al)** 2005. Last searched for evidence in December 2004.

Therefore, this search was undertaken from 2003 onwards. No filters were placed on the results (only a basic exclusions filter), but only trials and good quality reviews were included.

## 3. Update Search

For the update search, the same search criteria/filters were applied as initial search, date limit 2007-2008 and English language research chosen only.

## 3. Any further comments

Systematic Reviews (2002+) and RCT filters placed on search. Search executed from 1999 onwards as based on Cochrane Review: Radiotherapy for Early Breast Cancer. Health Economics and Quality of Life filters added to the above search, no date limit set as review did not cover cost effectiveness.

#### 4. Update Search

For the update search, the same search criteria/filters were applied as initial search, date limit 2006-2008 and English language research chosen only.

#### Topic 17: Follow-up of Breast Cancer Patients

- WHETHER to follow-up patients treated for early breast cancer i.e. Does follow-up benefit patients? Is there an optimum frequency of follow-up?
- WHERE to perform follow-up i.e. is a hospital-based model, primary-care based model or another model (e.g. integrated) of provision superior to alternatives?
- WHO should perform follow-up? Consider: different medical specialties, allied health professionals, patients.
- What should be the AIMS of follow-up? Consider: detection of recurrence, manage ongoing medication, monitor long-term side effects e.g. menopausal changes, bone loss

## **APPENDIX B - Economic Plan**

This document identifies the priorities for economic analysis and the proposed methods for addressing these questions as described in section 8.1.3.1 of the Guidelines Manual (2006).

### **Guideline**

Title of guideline: Breast cancer (early): diagnosis and treatment

### **Process for agreement**

The economic plan was prepared by the guideline economist in consultation with the rest of the NCC technical team and GDG. It was discussed and agreed on 3<sup>rd</sup> September 2007 by the following people <sup>w</sup>:

#### **For the NCC and GDG:**

NCC economist: Raquel Aguiar-Ibáñez

NCC representative(s) <sup>x</sup>: Andrew Champion

Victoria Titshall

Angela Bennett

GDG representative(s) <sup>y</sup>: Jim Smallwood (GDG Chair)

Adrian Harnett (GDG Lead Clinician)

#### **For NICE:**

CCP lead <sup>z</sup>: Tim Stokes

Commissioning manager: Nicole Elliott

Economic lead <sup>aa</sup>: Francis Ruiz

Costing lead: Mark Minchin

Proposals for any substantive changes will be circulated by email to this group. If revisions are agreed, they will be listed as addenda to this document (section 5 below).

---

<sup>w</sup> This may be done by face-to-face meeting, teleconference, or email as convenient.

<sup>x</sup> May be the project manager, a systematic reviewer or research fellow and/or the centre director or manager, as appropriate for the NCC and guideline.

<sup>y</sup> May be GDG chair, clinical lead and/or other members as appropriate.

<sup>z</sup> CCP Director or Associate Director who is taking the lead for the guideline.

<sup>aa</sup> One of the CCP health economic Technical Advisors.

**Proposed economic plan**

**Complete one row for each clinical question in the guideline:**

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis?</i> <sup>bb</sup>	<i>Comment and explanation</i>
<p>Topic 1:</p> <p>1 What is the optimal time interval from completion of definitive surgery to commencement of adjuvant therapy?</p>	<p>5. Low priority for a</p>	<p>The number of patients involved within this topic is large since it would affect all early breast cancer patients undergoing surgery.</p> <p>There may be some improvement in terms of longer survival and lower relapse rates for patients with earlier starting of adjuvant therapy after surgery (Colleoni et al 2000; Lorisich et al 2006; Mikeljevic t al 2004). However, evidence is not conclusive (Cold et al 2005; Froud et al 2000; Nixon et al 1994; Shannon et al 2000; Vujovic et al 2006). Moreover, there is no real consensus regarding the definition of delay.</p> <p>Costs of adjuvant therapy are not likely to change. However, if delayed treatment effectively has an impact on relapse, there may be some long-term costs of treating those patients that relapse due to delay treatment.</p>

<sup>bb</sup>

- 1 'Not relevant': questions where economic analysis is not appropriate (e.g. about definitions, prognosis or information needs for patient);
- 2 'In literature': questions where high-quality, recent and relevant economic evaluations are already available;
- 3 'High priority for analysis': questions where an economic analysis is planned (important implications and analysis is thought to be feasible);
- 4 'Medium priority for analysis' questions where an economic analysis may be done (less important implications or questions over feasibility);
- 5 'Low priority for analysis': questions where economic analysis could be done, but the expected impact on outcomes and NHS resources is low.

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>Therefore, there is uncertainty for both health benefits and cost implications. If treatment delay does not cause an impact on health, the topic will not have implications in terms of health economics and therefore an economic analysis will not be required. However, if there is conclusive evidence that time of starting treatment will have an impact on health outcomes, there may be some cost implications and a further analysis may help assess the cost-effectiveness of early start of adjuvant therapy.</p>
<p>Topic 2:</p> <p>What is the optimal tumour-free tissue margin to achieve in patients who undergo wide local excision (WLE) for ductal carcinoma in situ (DCIS)?</p> <p>2</p>	<p>5. Low priority for a</p>	<p>DCIS patients represent a small proportion over the total number of patients with breast cancer (approximately 20% of all breast cancers diagnosed through mammography; Erbas et al 2006).</p> <p>If clear (tumour-free) margins in excised tissue are not obtained, even after surgical revision of the original excision, mastectomy may be required. Additionally, the risk of local recurrence increases if positive margins are found after lumpectomy and breast irradiation; this applies also to patients with DCIS (Scarath et al 2002). If margins remain positive after excision, the tumour-involved margins should be either re-excised or mastectomy should be undertaken.</p> <p>There is a lack of evidence regarding how expensive it would be to identify and achieve optimal margins of</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis?</i> <sup>bb</sup>	<i>Comment and explanation</i>
		<p>excision. However, there may be a reduction in additional re-excisions and mastectomies as a consequence of correctly identifying excision margins. The cost implications are expected to be a balance of additional breast surgery (for those with “inadequate” margins) versus a reduction in risk of local recurrence. It is unlikely that the optimum margin for excision will be identified from the available evidence. Therefore, it may not be possible to conduct an economic analysis under these circumstances. The total impact on costs is not expected to be high due to the low number of patients affected.</p>
<p>3</p> <p>Topic 4:  When should patients with DCIS who have undergone complete excision (CE) or WLE be given RT?</p>	<p>5. Low priority for a</p>	<p>Approximately 20% of the tumours diagnosed through mammographic screening programmes are DCIS (Erbas et al 2006). RT after breast conserving surgery may decrease recurrence and increase quality of life, although the impact on survival seems negligible (Suh et al 2005). The purpose of the question here posed is to identify if there is a group of patients that may benefit from RT after having undergone either CE or WLE.</p> <p>RT is an expensive intervention, although its costs may be compensated by the savings in salvage therapy related to the reduced risk of recurrence. In some low-risk patients, these costs may not outweigh the benefits (Silverstein 2003).</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>There is uncertainty regarding the final impact of RT since effectiveness and cost-effectiveness evidence are limited. A further economic evaluation may decrease the uncertainty related to the topic and may help assessing the cost-effectiveness implications of the topic within the guidelines. However, given the lower number of patients involved and the likelihood that problems in conducting the economic evaluation will arise due to lack of data, the topic seems to be a medium/low priority in terms of further economic analysis.</p>
<p>4</p> <p>Topic 5:  Is there an indication for the use of tamoxifen after excision of pure DCIS?</p>	<p>5. Low priority for a</p>	<p>Tamoxifen may reduce local recurrence and the number of breast cancer events in patients with DCIS, although an improvement in survival has not been observed, while patients may experience relevant adverse effects (Fisher et al 1998; Fisher et al 1999).</p> <p>Tamoxifen is not expensive treatment, and the overall relevance of this topic, in terms of the number of patients affected, is low (since DCIS patients represent a relatively low percentage of breast cancer patients and, moreover, it is not clear for how many of them the treatment would be indicated, reducing therefore the overall relevance even further).</p> <p>Given the lack of conclusive evidence regarding the</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		beneficial use of tamoxifen on DCIS patients' health and the unlikely relevant impact on costs, further analysis could only be relevant if tamoxifen is found to be beneficial for DCIS patients, or for a subgroup of them. Moreover, the number of patients that would be affected for any recommendation related to this topic would be low. Therefore, the topic is considered to be a low priority for further economic analysis.
<p>Topic 6:</p> <p>6.a. In patients with invasive breast cancer when is SLNB justified as a staging procedure?</p> <p>6.b. In patients with DCIS when is SLNB justified as a staging procedure?</p> <p>5</p>	2. In literature	<p>The routine use of axillary lymph node dissection (ALND) does not benefit about 70% of patients (i.e. those with negative nodes) and it is an expensive procedure (Bombardieri et al 1998). The use of sentinel lymph node biopsy (SLNB) can reduce costs and morbidity (e.g. hospitalisations and lymphoedema) by avoiding ALND in early breast cancer patients with negative nodes, and by conducting selective ALND on those with positive nodes (Bembenek et al 2001; Borgstein et al 1998).</p> <p>Evidence regarding this topic seems to be promising but limited as to support recommendations regarding the use of SLNB alone (McCready et al 2005). However, some economic analyses considering SLNB appear to be available (Brancato et al 2004; Burak et al 2002; Fortunato et al 2004; Gemignani et al 2000; Perrier et al 2004; Roka et al 2004), which could be useful to assess the cost-effectiveness of SLNB</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>without the need to conduct further economic analyses. It should be taken into account that these analyses may not be representative of the UK clinical setting. In such a case, a further economic analysis would be required to estimate the cost-effectiveness of SLNB within the UK setting, and therefore the topic would become a high priority in terms of requiring further economic analysis.</p>
<p>6</p> <p>Topic 7:</p> <p>What is the role of pre-treatment ultrasound (US) assessment in staging the axilla?</p>	<p>3. High priority for :</p>	<p>Staging of the ipsilateral axilla is crucial to decide what local and systematic treatments are required for patients with early invasive breast cancer. Relevant information for staging can be obtained through alternative methods, such as axillary dissection, which was traditionally used although it is currently associated with increased morbidity (Damera et al 2003). There are less invasive methods for the preoperative assessment of the axilla, such as SLNB and axillary node sampling. In addition, other non-surgical techniques have been used, such as US, which may or may not be combined with Fine Needle Aspiration Cytology (FNAC) or core biopsy.</p> <p>Pre-treatment US may help offering definitive surgery for patients with lymph node metastatic disease and avoid having inappropriate surgical procedures (Brancato et al 2004), although the number of false</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>positives and false negatives with this procedure is high, and therefore further tests may be required, with the consequent implications on resource utilisation and additional costs.</p> <p>A positive recommendation regarding the use of pre-treatment US in the staging of the axila could affect all patients with early invasive breast cancer, therefore the impact in terms of the number of patients affected would be high.</p> <p>The financial consequences are considerably relevant (in terms of future savings in procedures avoided). The impact on health benefits and long-term prognosis for patients with and without US of the axila may be less relevant if the use of US does not have an impact in survival/quality of life in the long term.</p> <p>Therefore, the relevance of the topic in terms of further economic analysis seems high.</p>
<p>7 Topic 8: In patients with breast cancer which strategies are effective in preventing arm lymphoedema?</p>	<p>5. Low priority for a</p>	<p>Around 12% of women undergoing breast surgery and lymph node dissection will develop lymphodema (Forchuk, Baruth et al. 2004). In UK, one in four breast cancer patients is affected by lymphodema (Morgan, Franks et al. 2005).</p> <p>Different strategies are available that can be used with the aim of preventing lymphoedema, such as:</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>education, exercise, compression garments, skin care, simple lymph drainage massage, advice on interventions to avoid (for example, venepuncture), pharmaceuticals (e.g. diuretics), physiotherapy and psychological support.</p> <p>Literature regarding the effectiveness of interventions used to prevent lymphodema is scarce (Forchuk, Baruth et al. 2004). The systematic review of the clinical evidence for this topic found some benefit derived from preventing lymphoedema by means of generalised or aerobic exercise, although this was not consistent all across the studies, which showed high degree of heterogeneity. Additionally, no consistent evidence was found related to the benefit obtained by exercise/physiotherapy to the shoulder/arm. No economic evaluations have been found from the economic search that have considered this topic.</p> <p>The annual costs related to lymphoedema treatment are relevant. Although an estimation for the annual cost per patient treated for lymphoedema was not found for a UK setting, a study (Le et al 1993) found that the annual cost per patient in France was FF 1,655 (or approximately £1,500 as for 2006 prices). A study conducted in Spain (Gonzalez-Viejo et al 2001) found that the average annual number of sessions of manual lymphatic drainage per breast cancer patient</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>with lymphoedema following mastectomy was 28 (range: 15-50), being the health care costs associated to these sessions equal to an equivalent of £712 (range: £316, £984 for 2006 prices). Approximately between 35,000 and 37,000 new cases of breast cancer are diagnosed every year (data from 2003, <a href="http://www.cancerhelp.org.uk">www.cancerhelp.org.uk</a>; and considering that between 80 and 85% of all breast cancer patients diagnosed are EBC; National Horizon Scanning Centre 2006). Assuming that 25% of those will experience lymphoedema (Morgan, Franks et al. 2005), i.e. between 8,800 and 9,200 patients) there is scope for improvement of the allocation of health care resources if effective treatments are available to prevent lymphoedema. However, the costs of prevention should be compared with the benefits achieved to see if lymphoedema prevention is a cost-effective intervention.</p> <p>Although there are important financial implications (in terms of the annual cost per patient treated for lymphoedema), the topic has been identified as a low priority given the relatively low number of patients affected, when compared to other topics, and the lack of consistent evidence showing that prevention of lymphoedema is an effective intervention.</p>
8 Topic 9:	5. Low priority for a	Oestrogen receptor alpha (ER) is a powerful predictor

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
<p>Does progesterone receptor (PR) status add further, useful information to that of oestrogen receptor (ER) status in patients with invasive breast cancer?</p>		<p>of tumour response to therapy. ER(+) is associated with good results using hormone therapy alone, with approximately 80% of invasive early breast cancer patients being ER(+). However, ER assessment may lack accuracy and some patients with ER(+) will not respond to hormone therapy.</p> <p>PR may add relevant information regarding prediction of tumour response to treatment when deciding the type of treatment a patient with invasive early breast cancer should receive.</p> <p>The cost per PR test is approximately between £20 and £60 (Personal Communication), although there may be potential savings by conducting the test if more accurate treatment is given as first line. Testing for ER and PR simultaneously will be cheaper and quicker than doing the tests sequentially. Since approximately 60-70% of patients are ER(+), it may be cost-effective to test all the patients (although this hypothesis should be tested).</p> <p>However, recent evidence concluded that testing for PR status added limited relevant information in any comparison and, consequently, PR should only be used as a research tool at present (Petto et al 2007, personal communication).</p> <p>There is uncertainty regarding the final impact in terms of both health benefits and costs, and recent evidence</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis?<sup>bb</sup></i>	<i>Comment and explanation</i>
		highlights the difficulties of conducting an economic analysis on the topic. Therefore, at the moment, due to lack of appropriate data, this topic is a low priority in terms of further economic analysis since an economic evaluation will not be possible to be performed.
<p>Topic 11:</p> <p>What is the prognostic significance of small metastatic deposits in sentinel nodes?</p> <p>9</p>	5. Low priority for a	<p>Initially, it seems that recommendations regarding this topic will not change clinical practice considerably, although it may add more laboratory work time, additional tests (i.e. immunohistochemistry) and some additional treatment and surgery if micro-metastasis are found to be of prognostic relevance.</p> <p>There is not conclusive information about these issues and it is not clear whether the development of an economic model would solve this uncertainty since there may not be sufficient clinical data to conduct the analysis. Therefore, this topic has been considered low priority for further economic analysis.</p>
<p>Topic 12:</p> <p>a) What is the role of breast MRI in the preoperative staging of patients with biopsy proven invasive breast cancer?</p> <p>10</p> <p>b) What is the role of breast MRI in pre-operative staging of patients with DCIS?</p>	5. Low priority for a	After breast conservation, 60% of patients will require re-excision, with some of them requiring several surgeries before mastectomy (Esserman et al 1999). The use of MRI as a staging tool before surgery may reduce multiple re-excisions and anxiety for the patient. This may have a financial impact on the total costs, derived from the lower number of repeated surgeries required once an appropriate intervention has been identified and conducted.

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>Women with stage I or II breast cancer have been shown to have similar survival independently of whether mastectomy or breast conservation is undergone (Esserman 1999). However, in terms of quality of life, a reduction in the number of surgeries undergone may reduce the anxiety for the patient and therefore may influence the gain in QALYs. MRI may be specifically useful for patients with mammographically dense breasts.</p> <p>Given the potential savings that MRI may produce, it may be relevant to conduct a modelling exercise to assess the cost-effectiveness of this intervention in a UK setting. However, there is limited evidence that would make it difficult to conduct such analysis which has led to identify the topic as low priority.</p>
<p>Topic 14:</p> <p>14.a. What treatments are effective and safe for use to treat patients with menopausal symptoms and invasive breast cancer</p> <p>1</p> <p>14.b. What treatments are effective and safe for use to treat patients with menopausal symptoms and DCIS ?</p>	<p>5. Low priority for a</p>	<p>Up to 40% of women experience menopausal symptoms because of breast cancer or its treatments (<a href="http://www.plwc.org/portal/site/PLWC">http://www.plwc.org/portal/site/PLWC</a>). Some treatments seem to improve menopausal symptoms such as hot flushes (Nelson et al 2005). However, management of menopausal symptoms does not seem to have any impact on survival.</p> <p>There are differences in costs in terms of the different hormone treatments for the management of</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>menopausal symptoms (with the monthly cost ranging from between £3.71 and £8.66 for generic estradiol to between £29.70 and £55.07 for prometrium-progesterone; 2005 UK prices, adjusted from <a href="http://www.crbestbuydrugs.org/PDFs/HormonesFINAL.pdf">http://www.crbestbuydrugs.org/PDFs/HormonesFINAL.pdf</a> using OECD Purchasing Power Parities: <a href="http://www.oecd.org/dataoecd/61/56/1876133.xls">http://www.oecd.org/dataoecd/61/56/1876133.xls</a>).</p> <p>Therefore, it is likely that there will be cost differences when broader interventions are compared (e.g. group therapy, antidepressants or psychological support).</p> <p>No economic evidence in the form of an economic evaluation seems to be available in relation to this topic. If one or several treatments/strategies are shown to be effective for the management of menopausal symptoms, an economic analysis could help identify which is the most cost-effective intervention. However, limitations are likely to be found when conducting the economic analysis due to lack of data on clinical effectiveness. Therefore, the topic is considered to be medium/low priority in terms of the requirements for further economic analysis.</p>
<p>Topic 16:</p> <p>1 2 16.a. What is the role of breast imaging modalities in the follow-up of patients with invasive breast cancer?</p>	<p>4. Medium priority 1</p>	<p>For an imaging test to be effective and cost-effective in the follow-up of patients with either invasive breast cancer or DCIS, the detection of early recurrence and consequent therapy should lead to an improvement in survival and quality of life at a reasonable/acceptable</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
16.b. What is the role of breast imaging modalities in the follow-up of patients with DCIS?		<p>cost. Some studies have shown that most recurrences are not asymptomatic and can be detected by history and physical examination, and moreover, the impact on survival is unknown (Khandekar et al 1996). These facts would undermine the usefulness of imaging techniques to follow up breast cancer patients. For the subgroup of patients undergoing breast conserving surgery followed by RT the number of false positives with mammography are considerably high. Moreover, mammography seems to be of little use for ipsilateral local recurrence since its sensitivity and specificity are low.</p> <p>Routine long-term follow up was already recognised not to be necessary when the previous NICE Guidance on Breast Cancer Services were developed (i.e. Improving Outcomes in Breast Cancer. Manual Update 2002; <a href="http://guidance.nice.org.uk/csgbc/guidance/pdf/English">http://guidance.nice.org.uk/csgbc/guidance/pdf/English</a>); however, this is still an ongoing practice. Due to lack of evidence about the benefits for patients derived from follow-up with imaging techniques, this topic has been categorised as a medium priority for further economic evaluation. A cost analysis could be useful to highlight the savings that could be achieved by avoiding this ineffective practice.</p>
1 Topic 17:	5. Low priority for a	The purpose of following up women with breast cancer

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
<p>3 What is the best setting for clinical follow up of patients treated for breast cancer?</p>		<p>after they have received primary treatment is to identify any recurrence or contralateral new primary breast cancer as soon as possible, since it is believed that earlier identification will increase the likelihood of keeping the disease under control. However, the use of different settings/schedules for the follow-up of patients with breast cancer does not seem to have a relevant impact on the identification of recurrences or contralateral new primary breast cancer (Rojas et al 2000; Grunfeld et al 2006), while it seems to have disadvantages, such as increase in the anxiety for patients when being followed up (Grunfeld et al 1996; Grunfeld et al 1999). Furthermore, follow-up does not seem to have an impact on post-operative survival (Grogan, Rangan et al. 2002; Rojas et al 2000). However, it is believed that the health benefits could be higher than stated (as derived from GDG member's opinion).</p> <p>There are some financial implications related to the follow-up setting chosen, although the literature available is not conclusive. According to some studies, primary care-based follow-up or less intensive follow-up is less expensive than hospital-based follow-up (Grunfeld et al 1999) or more intensive follow-up (Mapelli et al 1995). However, following discussion with the GDG members, studies seem to be available showing the opposite results (i.e. primary care-based</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>follow up more expensive than hospital-based follow up).</p> <p>The topic has been identified as a low priority topic based on the fact that the setting of follow-up does not seem to have a relevant impact on the health benefits obtained by patients or on the financial implications. What has been highlighted is the importance of setting a national guideline that identify what to do, who should do it and where, and when it should be done, since at the moment, different things are done at different places.</p>
<p>Topic 19:</p> <p>What are the indications for completion axillary clearance when the axilla has been found by biopsy to contain metastasis?</p> <p>1 4</p>	<p>4. Medium priority 1</p>	<p>Approximately 40% of breast cancer patients present with metastatic disease in the axilla (Liang, Sickle-Santanello et al. 2001). There is uncertainty regarding the status of non-sentinel nodes when a positive sentinel node is found (Chu, Turner et al. 1999) and the current clinical practice for these patients is to continue with completion axillary dissection once a positive sentinel node has been identified, even if the sentinel node is the only focus of axillary metastasis in 67% of patients (Liang, Sickle-Santanello et al. 2001).</p> <p>Patients with micrometastasis in the sentinel node and T1/T2 lesions and those with macrometastasis and T1 lesions may benefit from not undergoing completion axillary clearance in terms of avoidance of physical and</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>psychological distress (Karamlou et al 2003). The impact of this on survival has not been clearly stated.</p> <p>There may be savings by avoiding completion axillary clearance procedures in a subgroup of breast cancer patients with positive nodes. However, achieving accurate identification of node status to appropriately select those patients that should avoid completion axillary clearance may add some further costs.</p> <p>The literature regarding this topic is limited, especially in terms of identifying the (small) group who potentially do not need axillary dissection following SLN (there is some research under way but the results of the trial have not been published yet), and in terms of economic evaluations.</p> <p>This topic appears to be highly related to topic 6 (i.e. In patients with: a) invasive breast cancer; b) with DCIS, when is SLNB justified as a staging procedure?). Therefore, if both topics are finally considered to be high priority, there may be the possibility of combining them in one economic analysis.</p>
1 Topic 22: 5	4. Medium priority 1	The choice of undergoing immediate versus delayed breast reconstruction depends on many factors, such

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
<p>When is it appropriate to perform immediate breast reconstructive surgery?</p>		<p>as medical, financial and emotional factors (Cheng, Lin et al. 2006).</p> <p>Immediate breast conserving surgery appears to achieve better aesthetic results after mastectomy and seems to benefit patients from a psychological viewpoint (Neyt et al 2005). However, there is not an impact in local recurrence and there is no evidence about whether survival is increased.</p> <p>Relevant savings can be realised by conducting immediate breast reconstruction in those women for whom it is possible (Khoo et al 1998; Neyt et al 2005), although the option of delayed reconstruction, which is more expensive, appeared to be required for breast cancer patients undergoing postoperative radiotherapy (Neyt et al 2005).</p> <p>Although the number of patients that would be affected by any recommendation related to this topic is high, the associated health benefits and costs of immediate versus delayed reconstructive surgery seem to be moderate. Therefore, the topic has been identified as a medium priority in terms of further economic analysis.</p> <p>There is some economic evidence available, especially in the form of cost studies, assessing the differences in costs between immediate and delayed breast</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		conserving surgery. A systematic review of the economic literature may provide relevant information to assess the cost-effectiveness of immediate breast conserving surgery and the impact of this intervention within the clinical guideline.
<p>Topic 23:</p> <p>23.a. What are the indications for RT after breast conserving surgery?</p> <p>23.b. What are the indications for an external beam RT boost to the site of local excision after breast conserving surgery?</p> <p>1 6</p>	4. Medium priority 1	<p>It is expected that about two thirds of localised breast cancer patients would be suitable for breast conservation, some of whom will opt for mastectomy rather than breast conservation (Sainsbury, Anderson et al. 2000).</p> <p>Nowadays radiation therapy (RT) after breast conserving surgery (BCS) seems to be a widely accepted standard practice, even if its impact on survival is uncertain. Post-BCS RT benefits patients by reducing the risk of local recurrence, and it may additionally improve the patient's quality of life by reducing the fear of potential recurrences and by conserving the breast (Hayman et al 2000).</p> <p>The additional use of a boost after completing RT has been suggested to reduce local recurrence for patients with positive margins after BCS, although its benefit is less evident for patients with negative margins (Hayman et al 2000). The issue of whether all patients should receive a boost after completing RT is controversial and it has important financial implications</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>due to the high costs of the RT boost.</p> <p>RT is routinely used for a high number of patients and it is a considerably expensive intervention, while the health benefits seem to be moderate. There could be relevant financial implications (in terms of cost savings) if RT is found to be not effective for some subgroups of BC patients. However, the costs of RT are not as high as some of the chemotherapy drugs administered to BC patients and compared, as well, to the use of aromatase inhibitors (AIs), that are prescribed for years (Personal Communication) Therefore, the topic has been identified as a medium priority.</p> <p>Some economic evidence is available that supports the use of RT following BCS (Hayman et al 1998), although it does not support the use of an electron-beam boost, in addition to post-BCS RT, for the treatment of breast cancer patients with negative margins after BCS (Hayman et al 2000).</p> <p>A systematic review of the literature may provide some insight into whether RT/ RT boost are cost-effective interventions. However, it is important to consider that the available evidence may not be applicable to the UK setting and/or to a specific subgroups of patients.</p>
1 Topic 24:	4. Medium priority	There may be a benefit, in terms of survival, for

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
<p>7</p> <p>Which groups of patients should receive chest wall radiotherapy after mastectomy?</p>		<p>postmastectomy patients receiving RT. However, the costs of RT are high, and it is necessary to show evidence that the health benefits obtained by incurring such costs are worth the money.</p> <p>There is some available cost-effectiveness evidence (Lee, Glick et al 2002; Marks, Hardenbergh et al 1999; Dunscombe, Samant et al 2000), although specific studies for a UK setting may not be available. Overall, these studies show a very low increase in the LYG and QALYs, at a higher cost than no-RT, for specific groups of patients. A greater use of postmastectomy RT, even limited to the subgroup of patients with axillary nodal involvement, would result in substantial financial costs (Hayman and Hillner 1999).</p> <p>No economic analysis seems to have been performed with the aim of identifying the type of patients that should receive postmastectomy RT, therefore there may be a need to develop a specific decision analytic model considering different types of patients that may benefit from this intervention. However, it is expected that there will be limitations if an economic analysis is to be performed.</p> <p>Although the financial implications of this topic are high, the topic has been identified as medium/low priority since the benefits derived from chest wall RT</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		after mastectomy seem to be limited to a sub-group of breast cancer patients, and because of the feasibility issues that would be expected to arise if an economic evaluation was to be developed.
<p>1 8</p> <p>Topic 25: What are the indications for RT to the supraclavicular fossa, internal mammary chain and axilla?</p>	5. Low priority for a	The evidence regarding the health benefits obtained by patients receiving RT to the supraclavicular fossa, the internal mammary chain and axilla in addition to chest wall RT after surgery is scarce and conflicting (Lievens, Kesteloot et al, 2005; Liljegren et al, 1997; Malin et al 2002). Consequently, it seems that there is not sufficient evidence to support the routine use of RT in this way. Therefore, the topic has been identified as low priority in terms of further economic analysis.
<p>1 9</p> <p>Topic 26: What is the role of primary medical (including neoadjuvant) treatment in patients with early, invasive breast cancer?</p>	5. Low priority for a	<p>By starting with adjuvant chemotherapy/neoadjuvant therapy, 90% of patients can expect a clinical response and 60% can achieve sufficient reduction as to enable lumpectomy without adversely affecting their clinical outcomes (Esserman et al 1999).</p> <p>There may be some impact on patients' health since some of them will undergo less invasive surgery. Additionally, there may be some financial implications related to the fact that breast conserving surgery is usually less expensive than mastectomy.</p> <p>Given the relatively low number of patients involved within this topic and the moderate impact on health</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis?<sup>bb</sup></i>	<i>Comment and explanation</i>
		benefits and costs, the topic has been considered as medium/low priority.
<p>Topic 28:</p> <p>For patients with inflammatory or locally advanced breast cancer who are treated with primary cytotoxic chemotherapy, what is the role of surgery and/or radiotherapy?</p> <p>2 0</p>	5. Low priority for a	<p>The percentage of patients with locally advanced breast cancer (including those with inflammatory breast cancer) seems to be no higher than 25% (<a href="http://www.cancer.gov/cancertopics/factsheet/Sites-Types/IBC">http://www.cancer.gov/cancertopics/factsheet/Sites-Types/IBC</a>; Favret and Carlston 2001), and it is around 5% in UK clinical practice. Most patients have poor outcomes which may be due to micrometastatic disease (Favret and Carlson 2001).</p> <p>Primary or neoadjuvant cytotoxic chemotherapy can convert inoperable locally advanced breast cancers in operable by reducing the extent of the disease, and it can allow breast conserving surgery (BCS) rather than mastectomy in some patients by decreasing the tumour size (<a href="http://www.bcbs.com/betterknowledge/tec/vols/19/19_07.html">http://www.bcbs.com/betterknowledge/tec/vols/19/19_07.html</a>). There is limited evidence showing that primary cytotoxic chemotherapy may avoid surgery in a small group of patients (Favret and Carlson 2001); however, surgery seems to be necessary in most of the patients. On the other hand, RT seems to increase local response in some patients (Rodger, Leonard et al. 1994). For patients undergoing BCS rather than mastectomy (after response to primary chemotherapy), there may be an increase in the risk of ipsilateral</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>breast tumour recurrence (Technology Evaluation Centre 2004). The impact on survival of undergoing surgery and/or RT after chemotherapy is not clear from the available evidence.</p> <p>Surgery costs may be reduced if breast conserving surgery, rather than mastectomy, is undergone by most of the patients after treatment with primary chemotherapy. Further savings could be achieved if breast surgery is shown not to be necessary for all patients with inflammatory or locally advanced breast cancer after receiving primary cytotoxic chemotherapy. On the other hand, if RT is considered to be an effective intervention, this will have relevant financial implications given the fact that RT is comparatively expensive.</p> <p>If surgery and/or RT are found to be beneficial for patients with inflammatory or locally advanced breast cancer, a further economic evaluation could help identify whether the interventions (i.e. surgery and/or RT) are cost-effective, since no economic evaluation seems to be currently available. However, given that the number of patients affected is considerably low, the topic seems to be a medium/low priority for further economic analysis.</p>
2 Topic 29c:	4. Medium priority	Adjuvant treatment with aromatase inhibitors (AIs) for

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
<p>1</p> <p>What is the best timing/ sequencing of aromatase inhibitors and the duration of treatment as adjuvant therapy in post menopausal women with hormone receptor positive breast cancer?</p>		<p>postmenopausal women with hormone-receptor-positive (HR(+)) cancer have been shown to achieve lower recurrence rates compared to tamoxifen. These patients represent a large subgroup group within the overall population of breast cancer patients.</p> <p>On the other hand, there is no available data to identify the optimal duration of treatment with an AI or the optimal sequencing of treatment (Cuzick, Sasieni et al. 2006). The health benefits derived from using different timings, sequencings and durations for AIs are not clear due to the limited information available regarding this issue.</p> <p>There may be relevant financial implications related to the different times/sequencing and durations of AIs treatment, not only for the differences in costs associated with each of the timing/sequencing treatment options, but additionally because they may lead to different levels of prevention of recurrences. The effect on drug cancer spending will be considerably high since not only are AIs more expensive than tamoxifen (NICE Technology Appraisal Guidance 112, 2006) but many patients will be treated with AIs instead; additionally, duration of treatment is being lengthened, with a consequent increase of costs.</p> <p>Economic evidence in the form of economic</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>evaluations seems to be very limited (Hillner 2004). Although the NHS is spending a considerable amount of money on AIs, lack of data on the different timings and sequencing on the use of AIs will limit the development of any further economic evaluation. Due to these feasibility issues, the topic has been identified as medium to low priority.</p>
<p>2 Topic 29d2: 2 In premenopausal breast cancer patients, what are the benefits of adjuvant ovarian suppression/ablation in addition to other treatments?</p>	<p>4. Medium priority 1</p>	<p>Ovarian ablation has been shown to reduce significantly the number of recurrences and improve survival among women under 50 if they do not receive chemotherapy, although the results were more uncertain when chemotherapy was administered (Early Breast Cancer Trialists' Collaborative Group 2000). Patients seem to benefit more in terms of recurrence-free survival and overall survival if they are oestrogen receptor positive.</p> <p>Although an improvement in survival has been observed after ovarian ablation, the topic seems to be medium to low priority since the number of patients benefiting from this intervention is limited to those that do not achieve ovarian suppression by chemotherapy. Moreover, the additional costs associated with ovarian ablation are expected to be low (e.g. the cost of one year's supply of tamoxifen has been shown to be equivalent to the overall cost of surgical oophorectomy;</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>Kwon, Yamada et al. 1997).</p> <p>Available economic evidence seems to be limited and not sufficient to identify if ovarian suppression/ablation is a cost-effective intervention. Further economic analysis may be required to definitely assess the cost-effectiveness of this topic and its implications within the guideline.</p>
<p>2 Topic 29e: 3 Which subgroups of post menopausal breast cancer patients should receive AIs as adjuvant therapy?</p>	<p>4. Medium priority †</p>	<p>Breast cancer patients that are postmenopausal comprise a large subgroup of early breast cancer patients (Hillner 2004). Therefore the number of patients that could be potentially affected by the decisions taken regarding topic 29e seems high.</p> <p>The use of AIs (e.g. anastrozole) seems to reduce recurrences and it possibly improves patient's quality of life (Hillner 2004), but no impact on survival has been observed. There may be some relevant adverse events that need to be taken into account when assessing the overall health benefit.</p> <p>AIs appear to be more expensive than tamoxifen, although the higher costs may be compensated in part by lower costs in the treatment of recurrences (Hillner 2004; Rocchi and Verma 2006).</p> <p>Although the financial implications of this topic are high</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>(since a considerable amount of cancer budget is spent on AIs), the topic has been identified as medium to low priority because of the limited available evidence, which will lead to feasibility problems when conducting any further economic evaluation. Some economic evaluations are already available that may help identify whether the use of AIs is cost-effective; however, they seem to be limited to the assessment of anastrozole (Hillner 2004; Rocchi and Verma 2006), which would limit cost-effectiveness comparisons across different AIs.</p>
<p>2 Topic 30: 4 What are the indications for the measurement of bone mineral density in patients with invasive breast cancer who are on adjuvant hormonal therapy?</p>	<p>3. High priority for :</p>	<p>Use of bone mineral density measurements may help detecting breast cancer patients with relevant bone loss and therefore target treatment, which may reduce the number of fractures experienced by these patients. Additionally, different levels of accuracy in detecting bone loss are achieved depending on the technique used. It is not clear if measuring bone mineral density will have an impact on survival.</p> <p>There may be differences in costs between the different techniques used to measure bone mineral density. Moreover, if measurement of bone density reduces the number of fractures, there will be a reduction in the use of health care resources which may compensate the costs incurred in using the</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>technique.</p> <p>This topic has been identified as a high priority in terms of conducting further economic analysis given that the use of AIs (which have been associated with bone loss) is likely to become routine practice for the treatment of postmenopausal patients. However, it should be considered that the available clinical evidence is limited and therefore some feasibility problems may arise when undertaking such analysis.</p>
<p>2 Topic 31: 5 Is adjuvant online a clinically effective tool to assist with clinical decisions about adjuvant therapy in patients with EBC?</p>	<p>5. Low priority for a</p>	<p>The primary purpose of this topic is to summarise and critique what is known about Adjuvant! (www.adjuvantonline.com), its validity and usefulness as a tool for supporting clinical decisions about adjuvant chemotherapy in NHS patients with early invasive breast cancer. Given the difficulties of identifying how this tool could change the behaviour of clinicians when making choices about the adjuvant chemotherapy treatment to give to the patients, and how this change in behaviours would impact patients' outcomes, the topic has been considered not relevant for further economic analysis. Adjuvant! is based exclusively on effectiveness and it does not consider the cost-effectiveness and the quality of life of the recommended treatments.</p> <p>In relation to the use of adjuvant chemotherapies in</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>UK, three technology appraisals have been recently published which assess the use of three adjuvant chemotherapies for EBC patients: trastuzumab for early-stage human epidermal growth factor receptor-2 (HER2) positive breast cancer patients (TA107), paclitaxel for early node-positive breast cancer patients (TA108) and docetaxel for early node-positive breast cancer patients (TA109). It is initially expected that the recommendations from these technology appraisals will be incorporated verbatim into the EBC clinical guideline. However, these technology appraisals may be updated in the following period and therefore, the resulting recommendations may change. In any case, the latest/most up-to-date recommendations should be the ones to be considered for this guideline.</p>
<p>2 Topic 35: 6 What are the indications (if any) for the use of bisphosphonates in patients with early breast cancer?</p>	<p>5. Low priority for a</p>	<p>Bisphosphonates do not seem to improve survival but may reduce pain and skeletal problems in women who have had bone metastases. Current evidence is insufficient to support the use of bisphosphonates as adjuvant therapy to prevent skeletal related events or improve survival in women with early breast cancer.</p> <p>Even if the widespread use of bisphosphonates would have a major financial impact, the topic has been identified as low priority because this widespread use is not likely to occur given the lack of clinical evidence supporting its use.</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>Since bisphosphonates seem to have no relevant impact in terms of the health benefits achieved and, consequently, they are unlikely to be recommended for patients with early breast cancer, further economic analysis seems not to be required.</p>
<p>2 7</p> <p>Topic 37:</p> <p>37.a. What are the effective strategies to prevent psychological distress in patients with early stage breast cancer?</p> <p>37.b. What are the effective strategies to manage psychological distress in patients with early stage breast cancer?</p>	<p>5. Low priority for a</p>	<p>The first months following the diagnosis of breast cancer are critical for patients. Some interventions, such as the use of advanced practice nurses (APN), nursing support or cognitive behavioural therapy, can reduce patients' anxiety and improve their knowledge of the disease and the control of symptoms with specialised care, and improve additionally their quality of life, although improvement in survival has not been shown (Ritz, Nissen et al. 2000; Whatley et al 2000; Zabalegui et al 2005; Tatrow and Montgomery 2006).</p> <p>There are approximately 25% of patients affected by distress and no clear guidelines about what should be done, when, how often and by whom. The biggest issue seems to be related to prevention of distress, rather than treatment (since prevention would be applied to all women while only 25% of breast cancer patients would require treatment for psychological distress, or even less if preventative measures work).</p> <p>Antidepressants are currently used to treat</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis?</i> <sup>bb</sup>	<i>Comment and explanation</i>
		<p>psychological distress and have been shown to benefit patients. Given that they are very expensive treatments, the financial implications associated with this topic are high.</p> <p>It is expected that lack of data in terms of the size of treatment and the number of people benefiting from some of the available treatments (Whatley 2000) will make the development of an economic evaluation difficult. Therefore, the topic has been identified as a low priority for further economic analysis.</p>
<p>2 Topic 39: 8 What strategies are effective in reducing arm and shoulder mobility problems after breast cancer surgery??</p>	<p>4. Medium priority 1</p>	<p>Arm and shoulder mobility problems are the two most frequent impairments observed among breast cancer patients. They seem to be related to axillary lymph node dissection and axillary radiation therapy (RT), especially if RT is combined with surgery (McNeely, Campbell et al. 2005). Many patients are affected by decreased shoulder range of motion (ROM) and by the impact it has on quality of life.</p> <p>Some interventions (such as physical exercise and nursing support) have been shown to be effective in improving physical functioning and quality of life of patients (Markes, Brockow et al. 2006; McNeely, Campbell et al. 2006; Knols, Aaronson et al. 2005; ). However, no impact in survival has been shown (Zabalegui, Sanchez et al. 2005).</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>There is uncertainty in terms of the content, frequency, intensity and duration of the optimal strategy (Karki, Simonen et al. 2001; Shamley, Barker et al. 2005). Moreover, the economic evidence in relation to this topic is very limited (Gordon, Scuffham et al. 2005). There may be relevant differences in costs depending on the type of intervention undergone; the main economic factor is expected to be manpower since not all hospitals have physiotherapy cover.</p> <p>This topic seems to be a medium priority topic. It may be related to topic 8. Further economic analyses may help identify the most cost-effective intervention for improvement of arm and shoulder mobility at the same time as there may be a possibility of linking this topic with topic 8? However, there may be some limitations in data availability that may hinder the development of such analysis.</p>
<p>2 9 Topic 40:  What is the role of mastectomy in patients with localised Paget's disease of the nipple?</p>	<p>5. Low priority for a</p>	<p>Between 0.5 and 4.3 out of every 100 women with breast cancer have Paget's disease (Sutton, Singh et al. 1999; Marcus 2004; <a href="http://www.cancerbackup.org.uk/Cancertype/Breast/Typesofbreastcancer/Pagetsdisease">http://www.cancerbackup.org.uk/Cancertype/Breast/Typesofbreastcancer/Pagetsdisease</a>) and the optimal surgical management for these patients is yet to be defined, with modified radical mastectomy being the standard care (Sutton, Singh et</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>al. 1999; Kawase, Dimaio et al. 2005).</p> <p>Patients with Paget's disease of the breast that undergo mastectomy may benefit by experiencing lower recurrence rates, although a subgroup of patients (i.e. those without palpable masses or mammographic abnormalities) may benefit in the same way by undergoing wide local excision instead. Survival does not appear to be influenced by the type of surgical procedure undergone (Kawase et al 2005; Marcus et al 2004; Marshall et al 2003).</p> <p>If a subgroup of patients is identified as benefiting from wide local excision rather than mastectomy, there may be a reduction in costs derived from shorter hospital stay and lower costs for less invasive surgery.</p> <p>There is uncertainty regarding both health benefits and cost implications since the evidence is quite limited, especially regarding economic studies. An economic analysis could help shed light on the identification of the cost-effective surgical management for patients with Paget's disease of the breast. However, given the small number of patients affected and the relatively low impact of the interventions on the health benefits experienced by patients, the overall impact of this analysis on the whole clinical guideline is expected to be minor and therefore the topic has been identified as</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		low priority for further economic analysis.
<p>3 Topic 41: 0 What is the most effective RT dose fractionation regimen for patients undergoing external beam RT after surgical excision of breast cancer?</p>	4. Medium priority 1	<p>In 2004 there were 44,659 new cases of breast cancer diagnosed in the UK, 44,335 (99%) of them in women (<a href="http://info.cancerresearchuk.org/cancerstats/types/breast/incidence/">http://info.cancerresearchuk.org/cancerstats/types/breast/incidence/</a>). Between 70 and 80% of these patients will present with early invasive ductal BC, and 10% with invasive lobular BC, while the percentage of patients with either inflammatory BC or Paget's disease are between 1 and 2% for each category. Surgery (either breast conserving surgery or mastectomy) is a usual treatment for early invasive BC patients (with some exceptions such as not being fit for the operation), while RT appears to be a widely accepted standard practice after surgery. According to a recent report, 71.7% of BC patients will require RT (<a href="http://www.cancer.nhs.uk/documents/nrag_files/Scenario%20Sub%20Group%20report%20-%20Jan%202007%20-%20fin.pdf">http://www.cancer.nhs.uk/documents/nrag_files/Scenario%20Sub%20Group%20report%20-%20Jan%202007%20-%20fin.pdf</a>). Therefore, the number of patients that can be potentially affected by any recommendation regarding the appropriate RT fractionation rate is high.</p> <p>Around 10-20% of BC patients with large primary tumours and extensive lymph node involvement experience local relapse despite receiving postoperative RT (Koukourakis 2003). Late side effects may be more likely for fraction sizes over 2 Gy (Rodger</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis?</i> <sup>bb</sup>	<i>Comment and explanation</i>
		<p>1998). Moreover, the clinical practice regarding the use of RT in UK BC patients has been shown to vary in terms of the dose, fractionation and areas irradiated (Goy and Dobbs 1998).</p> <p>In 2003 a 1-week audit was conducted across all UK RT centres to document RT fractionation practice. In the case of post-operative management of BC, it was concluded that the uniform use of 15 fractions would reduce the overall RT workload by 4%, while the use of 25 fractions would increase it by 7% (Williams et al 2006).</p> <p>The most relevant costs to consider in relation to the administration of different fractionation regimes comprises the cost per fraction and the number of fractions administered. According to the results of a study that assessed the potential changes in the net costs of focal RT at differing doses per fraction and interfraction intervals, higher costs of treatment are related to the administration of smaller doses and to higher number of fractions administered (Jones et al. 1998). In addition, the authors of this study suggested that in the estimation of the RT costs, the additional costs related to treatment failure (i.e. administration of subsequent chemotherapy, surgery, palliative and terminal care) should be included as well. Therefore, differences in the cost per fractionation, in the number</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis? <sup>bb</sup></i>	<i>Comment and explanation</i>
		<p>of sessions given and in the failure rates associated with each of the alternative fractionation regimes will be crucial and may derive in relevant financial implications.</p> <p>The only randomised control trial (RCT) that has been conducted considering different RT fractionation regimes among UK EBC patients aims to find alternative radiotherapy regimens using fraction sizes larger than 2 Gy that could be as effective but less costly than the standard regimen (i.e. 2 Gy in 25 fractions; Policy Research Programme, Department of Health:  <a href="http://www.info.doh.gov.uk/doh/rd2policy.nsf/vwwebheadings/1D56F5060B262DA680256BB5005621F6?opendocument">http://www.info.doh.gov.uk/doh/rd2policy.nsf/vwwebheadings/1D56F5060B262DA680256BB5005621F6?opendocument</a>). Alongside the START trial an economic evaluation is being conducted. It seems that the results of this RCT will be available in the near future. What it is not so clear is that the results of the economic evaluation will be available at the same time.</p> <p>Given that this trial is UK-based, the results of the associated economic evaluation are likely to be applicable to the EBC clinical guideline. A further economic analysis may not be required if the results of the economic evaluation are available on time; in this case, the economic evaluation could be critically appraised in terms of its methodological quality and</p>

<i>Clinical Question (in PICO format if possible)</i>	<i>Requires analysis?<sup>bb</sup></i>	<i>Comment and explanation</i>
		applicability for the UK setting to determine if the recommendations for this topic can be based on these cost-effectiveness results. However, in case the cost-effectiveness results are not available on time, it may be necessary to conduct an economic evaluation based on the clinical results of the RCT.

**For each question where economic analysis is proposed:**

Question number(s) <sup>cc</sup>	Outline proposed method of analysis <sup>dd</sup>
Topic 7	<p><u>Aim:</u> The role of pre-treatment US in the staging of the axilla is to offer definitive surgery for patients with lymph node involvement and avoid having unnecessary second procedures. A cost-effectiveness analysis will be developed to assess the cost-effectiveness of pre-treatment US to stage the axilla in patients with early invasive breast cancer from the NHS perspective.</p> <p><u>Intervention:</u> The types of pre-treatment US ultrasound that will be considered at analysis are:</p> <ul style="list-style-type: none"> <li>• US with concurrent FNAC</li> <li>• US with concurrent core biopsy</li> </ul> <p>US alone will not be included for not being considered to be good clinical practice since the management of the axilla is largely dependent on histological findings in support of imaging and clinical examination.</p> <p><u>Comparator:</u> The comparators with which pre-treatment US will be compared do not involve pre-treatment US assessment, and will be:</p> <ul style="list-style-type: none"> <li>• SLNB, with ANC conducted only on those patients with evidence of lymph node involvement based on SLNB results.</li> <li>• 4 node sampling, with ANC conducted only on those patients with evidence of lymph node involvement based on 4 node sampling results.</li> <li>• For completeness, the other alternative included in the economic analysis will be axillary node clearance without the initial use of either pre-treatment US, SLNB or 4 node sampling. The inclusion of this comparator is justified on the fact that it represents traditional practice and a recent survey conducted in UK has reported that 27% of surgeons still perform ANC as initial management, without previous consideration of the nodal status (Mansfield et al 2007).</li> </ul>

<sup>cc</sup> Two or more questions may be addressed by a single analysis if appropriate.

<sup>dd</sup> Give a brief description of the type of analysis that is proposed, as far as is known at this stage. Consider the type of economic evaluation (CEA, CUA, CCA,...); how outcomes will be measured (QALYs, LYS,...); the type of modelling (decision tree, Markov, simulation...); proposed comparators and population subgroups to be considered; potential sources of information and assumptions; and whether analysis could be based on an existing model. Follow methods advised in the Guidelines Manual whenever possible. Note that this is not expected to be a full project protocol, and that the methods of analysis may change.

(Note that, following recommendations of the GDG contacts, palpation alone as the basis of axillary staging, will not be considered as an alternative comparator for this analysis for not being a recommended clinical practice).

Methods:

Decision analysis will be used to model the clinical pathway and to estimate the cost-effectiveness of the strategies to stage the axilla that will be included in this economic evaluation.

The clinical data used to populate the model will be mainly derived from the systematic reviews conducted to identify clinical and cost-effectiveness evidence for the topic. In addition, data related to other EBC topics may be included in this model. For example, it may be of interest to consider data from topics 6 and 19 (in terms of whether recurrences and survival differ for patients undergoing SLNB, axillary node sampling or axillary clearance). This type of data will allow to estimate a more accurate lifetime horizon for patients undergoing pre-treatment US versus the comparators. Additional searches will be conducted to identify data on the prognosis, quality of life (QoL) and health care resource utilisation of patients according to each treatment group. Unit costs will be derived, whenever possible, from national sources (e.g. NHS Reference Costs).

If sufficient data are available to populate the model, a total of 4 groups of patients will be considered, according to whether they undergo US, either with core biopsy or with FNAC, or no pre-treatment US (either SLNB, 4-node sampling or initial axillary dissection).

In general terms, patients without evidence of lymph node involvement undergo SLNB or 4 node sampling (avoiding axillary clearance, which is a more invasive procedure, with higher levels of associated morbidity) while those with evidence of lymph node involvement undergo axillary clearance (avoiding unnecessary SLNB or 4 node sampling).

For the group of patients undergoing pre-treatment US, a positive result would mean that the patient will undergo definitive axillary surgery if abnormal axillary lymph nodes are detected (avoiding additional surgical procedures, i.e. SLNB or 4 node sampling). If the results are negative, surgical staging of the axilla will be conducted by either SLNB or 4 node sampling to identify further patients with node involvement. By using pre-treatment US a more accurate, definitive surgery is supposed to be offered to patients, avoiding having additional, unnecessary axillary surgery.

For the groups of patients undergoing SLNB or 4 node sampling, axillary dissection would be conducted on the basis of their results:

no further axillary surgery would be recommended for those with negative axilla, while those with positive axilla should undergo axillary clearance.

The last strategy considered is the use of axillary clearance for all patients as the initial management procedure to stage the axilla, without any previous axillary assessment by either pre-treatment US, SLNB or 4 node sampling. This strategy is expected to derive in higher number of complications and morbidity among patients.

The NHS perspective will be adopted, which means that the health benefits and costs to be considered in the analysis will be those relevant to the NHS:

- In terms of costs, those to be included will be the costs borne by the NHS, including personal social services (PSS) if applicable.
- In terms of health benefits, the ideal outcome to consider will be the number of quality adjusted life years (QALYs) gained. However, there may be some data limitations when identifying whether recurrences, survival and QoL differ for patients having pre-treatment US compared to those patients who do not have pre-treatment US. An alternative outcome that can be estimated through the model is the number of unnecessary procedures (axillary clearances and/or SLNB or 4 node sampling) avoided by using pre-treatment US.

Following the methodological recommendations presented in the Guide to the Methods of Technology Appraisal ([www.nice.org.uk](http://www.nice.org.uk); reference N0515), a lifetime horizon is to be adopted, and discounting will be conducted using a discount rate of 3.5% for both health outcomes and costs.

An incremental cost-effectiveness analysis will be conducted after ranking the alternative strategies from the most to the least cost-effective and excluding, if necessary, the dominated strategies (i.e. those strategies achieving lower effectiveness and incurring higher costs when compared to any other). The results of the incremental analysis will be reported as the incremental cost per additional unit of benefit obtained with the most effective and most expensive strategy when compared to the next most effective and most expensive one.

A Markov process will be used to include recurrences and mortality in the model. one-way and multi-way deterministic sensitivity analyses will be conducted to identify those variables contributing the more to uncertainty. In addition, whenever possible probability distributions will be assigned to different clinical and cost parameters so that a probabilistic sensitivity analysis can be carried out to assess the overall uncertainty of the model and the

	<p>robustness of the results.</p> <p><u>Feasibility issues:</u>  Lack of data may limit the time horizon of this model. The sensitivity and specificity of US may vary depending on specific subgroups of patients, such as those with non-palpable axillary nodes, or those for whom US allows to obtain biopsy material. However, it is not likely that specific prognostic data will be found for each patient subgroup depending on whether they have undertaken US as staging procedure of the axilla. In such a situation, GDG members will be consulted to identify, if possible, appropriate assumptions to allow the estimation of final outcomes (i.e. life years gained and QALYs). If this is not possible, intermediate outcomes, such as the number of unnecessary procedures avoided, may be considered for the estimation of the cost-effectiveness ratios.</p> <p>In addition, data about the accuracy of pre-treatment US conducted concurrently with core biopsy or with FNAB are scarce, which has led to the GDG contacts of this topic to suggest that both interventions should be considered in combination, although it is likely that US combined with FNAB will be considered in the base case analysis, while if data are available for that, the consideration of US with core biopsy will be done through sensitivity analyses.</p>
Topic 30	<p><u>Aim:</u>  Adjuvant hormonal therapy may cause relevant bone loss in breast cancer patients. The use of BMD measurements may help detecting breast cancer patients with relevant bone loss and therefore target treatment to reduce the number of fractures and increase their quality of life. An economic evaluation may be conducted to assess the cost-effectiveness of undergoing measurements of BMD in patients with early invasive breast cancer who are receiving adjuvant hormonal therapy from an NHS perspective. However, at the moment this analysis is pending on the availability of clinical data, which will be derived either from the Osteoporosis guideline or from a systematic review of the clinical evidence carried out by the NCC-C.</p> <p><u>Intervention:</u>  The intervention to be considered at analysis would be the measurement of BMD by means of Peripheral dual energy X-ray Absorptiometry (P-DEXA). Further clarification would be required from the GDG contact members to identify whether any other method to measure BMD will be considered at analysis.</p> <p><u>Comparator:</u>  The comparators that would be considered are:</p> <ul style="list-style-type: none"> <li>• Do nothing</li> <li>• Lifestyle advice</li> <li>• Bisphosphonate therapy</li> </ul>

- Calcium and vitamin D supplements
- NTX CTX measurements
- Any other alternative to BMD measurement identified from the systematic review of the literature (?)

It will be necessary to discuss with the GDG members on what grounds these comparators (e.g. lifestyle advice, bisphosphonate therapy and calcium and vitamin D supplements) would be administered for all patients or for a selected group of patients in whom bone loss has been identified, perhaps based on post-BMD measurement.

Methods:

Decision analysis is the proposed method to model the clinical pathway and to estimate the cost-effectiveness of measuring BMD compared to the other alternative strategies considered for this economic evaluation. A decision tree could be used and it is likely that Markov processes would be embedded in the decision tree in order to estimate fractures and recurrent fractures, as well as cancer recurrence.

The clinical data used to populate the model will be mainly derived from the systematic reviews conducted to identify clinical and cost-effectiveness evidence for the topic. If data from the NICE Guidelines for Osteoporosis are available on time, they are likely to be used as well to populate the model. In addition, data related to topic 35 (i.e. indications for the use of bisphosphonates in early breast cancer patients) may be used, based on the recommendations formulated for this topic.

The number of patient groups will depend on the number of alternative interventions to that of the measurement of BMD identified by the systematic review.

The aim of measuring BMD is to identify patients with bone loss and therefore commence treatment earlier, so that the number (and severity?) of bone fractures can be reduced, and the patient's quality of life increased. The NHS perspective will be adopted, which means that the health benefits and costs to be considered in the analysis will be those relevant to the NHS:

- In terms of costs, those to be included will be the costs borne by the NHS, including personal social services (PSS) if applicable.
- In terms of health outcomes, the model will estimate the number of fractures avoided and the improvements in quality of life (i.e. QALYs gained) according to the alternative strategies.

Following the methodological recommendations presented in the Guide to the Methods of Technology Appraisal ([www.nice.org.uk](http://www.nice.org.uk);

	<p>reference N0515), a lifetime horizon is to be adopted, and discounting will be conducted using a discount rate of 3.5% for both health outcomes and costs.</p> <p>An incremental cost-effectiveness analysis will be conducted after ranking the alternative strategies from the most to the least cost-effective and excluding, if necessary, the dominated strategies (i.e. those strategies achieving lower effectiveness and incurring higher costs when compared to any other). The results of the incremental analysis will be reported as the incremental cost per additional unit of benefit obtained with the most effective and most expensive strategy when compared to the next most effective and most expensive one.</p> <p>Whenever possible, probability distributions will be assigned to different clinical and cost parameters within the model so that a probabilistic sensitivity analysis can be carried out to assess the overall uncertainty of the model and the robustness of the results. In addition, one-way and multi-way deterministic sensitivity analyses will be conducted to identify those variables contributing the more to uncertainty.</p> <p><u>Feasibility issues:</u> It is not clear at this point that the available literature is sufficient to populate this model for all the comparators previously mentioned. The available evidence seems to be limited and this may lead to relevant feasibility problems when developing and populating the model.</p>
Topic 6	<p>While developing this economic plan, some evidence in the form of economic evaluations was identified in relation to topic 6. Therefore, a systematic review of the economic literature related to this topic will be conducted. This will serve to assess the cost-effectiveness of the use of SLNB as staging procedure in patients with invasive breast cancer (Topic 6.a) and in patients with DCIS (Topic 6.b). It is expected that the economic literature available will be related exclusively to topic 6.a and, therefore, assessment of the cost-effectiveness of SLNB as staging procedure for DCIS patients may not be possible from the systematic review.</p> <p>The results of the systematic review will be presented to the GDG for further discussion of the limitations, consistency and applicability/directness of the results for the NHS.</p>

Topic 41	<p>The issue of what type of fractionation should be administered for RT seems to be a relevant one, although it was not initially considered in the guideline since the results of the only RCT assessing the issue (the START trial) were not to be available on time to meet the deadline for this guideline.</p> <p>Once the timeline was extended, it was recognised that the results of the RCT will be available on time to be included here and therefore the issue of fractionation became a relevant one and needed to be included in the guideline.</p> <p>The GDG contacts have decided that this new topic 41 has a higher priority than topic 23 for economic analysis; therefore topic 23 has been removed from the list of high priority topics within the Economic Plan. Given that a RCT is on its way for publication and may include an economic evaluation of the different fractionation regimes considered in the trial, a further economic analysis may not be required for this topic.</p> <p>The GDG has suggested that, in case the economic evaluation is not available on time, and in case time permits, a cost-minimisation analysis could be conducted under the expectation that there will not be relevant differences in terms of the effectiveness of different fractionation regimes. Before any economic analysis is conducted, we need to be able to identify the most appropriate way to go forward with this topic. For this, before conducting a cost-minimisation analysis it needs to be confirmed that effectiveness does not differ across different fractionation regimes. In case adverse events differ depending on the fractionation regimen administered, a cost-minimisation analysis would not be appropriate.</p>
